THE MEASUREMENT OF LIQUID RESISTANCES.*

BY J. SWINBURNE.

The great difficulties in measuring liquid resistances arise from polarisation at the electrodes. Various methods of eliminating the errors arising from polarisation, and from variations of surface resistance due to bubbles, have come into use; the most usual being to employ an alternating current and a telephone.

The following are some methods of avoiding polarisation errors in a manner analogous to that employed by Sir William Thomson, Mr. Heaviside, and others, in measuring low resistances. In measuring low resistances, the resistances of the contacts are high in comparison, and have to be eliminated. Fig. 1 shows the vessel employed. It consists of a glass tube, with cups, A and B, at the ends, for the main electrodes. Near the ends are feeler cups, C, D, and it is the difference of potential of these feeler cups that is measured. They are connected by means of parchmented siphon tubes, such as those used in Raoult's cell, with vessels containing electrodes in a suitable electrolyte. For instance, suppose the resistance of sulphuric

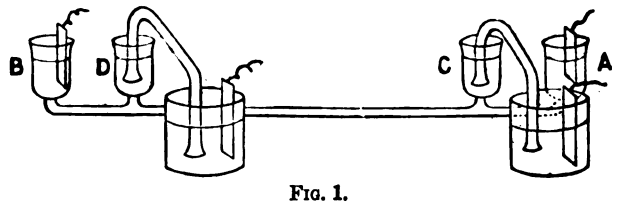

FIG. 1.

acid is to be measured. The main electrodes are platinum or lead. The siphon tubes are filled with acid and connected to vessels filled with sulphate of zinc. The electrodes in these are zinc amalgam. The apparatus may be arranged either so that there is no current from C to D, or so that there is a current which may polarise the amalgams a little. In this case the polarisation can be observed. Fig. 2 shows a method with no current. The main circuit from the battery, E, is through a resistance, R, which is fairly large, so that variations of resistance or back pressure elsewhere in the circuit do not affect the current much. Then it passes through a standard resistance, S, to the main electrode, then through the tube back to the battery. The fall of pressure between the feelers, C and D, is compared with that over the standard resistance, S, by means of the potentiometer arrangement shown diagrammatically. For accurate work a resistance box is used; the wire is only shown for clearness. In this case there is no current in the feeler circuit, and, therefore, no polarisation. A deflection can be taken on each side of zero, if desired, so as actually to reverse the current. Polarisation of the feeler electrodes can also be detected instantly by breaking both the cell circuits. There should then be no deflection. The drawback to this method is that successive readings have to be taken, and if bubbles are coming off the main electrodes, the main current can never be quite constant. Fig. 3 shows another

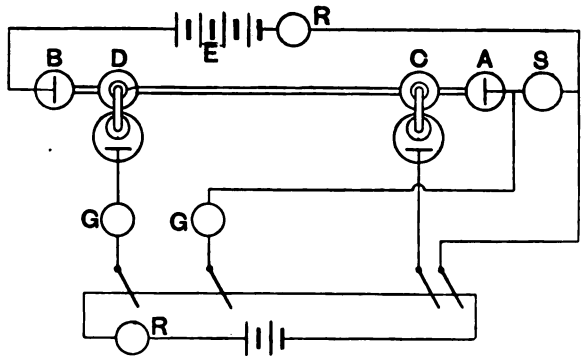

FIG. 2.

disposition with a differential galvanometer, whose coils are lettered G G. In this case there is a current in the feeler circuit. To make sure that it produces no error the direction of the main current is commuted quickly at K. Any polarisation then gives a double deflection. The apparatus may also be coupled up as a Thomson low-resistance bridge. By varying the number of cells, Ohm's law can be checked. As Prof. Stroud has pointed out to me, the resistances of the siphon tubes must be taken into account. They can, however, be made inappreciable in comparison with that of the galvanometer circuits.

Amalgamated zinc does polarise slightly, or some other action takes place which produces an equivalent result. Unless the

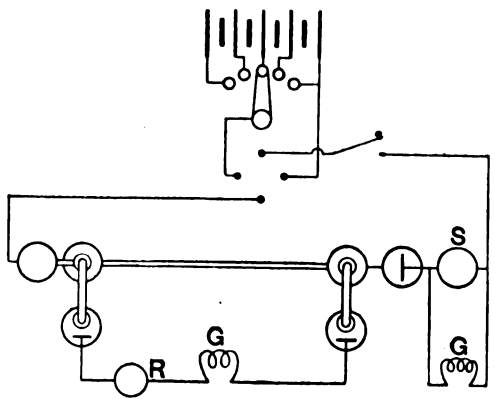

FIG. 3.

time of contact is long, however, it does not give rise to trouble. Polarisation shows at once by the deflection on lifting the main key.

The main tube is calibrated by filling it with mercury. Mine is straight, but it would be better to coil it up to go into a water bath easily. If one siphon tube is not enough a second intermediate tube with a vessel can be used. I think one is generally enough, however. For instance, for measuring caustic sulphate of soda would be used in the siphon tubes, and so on. I have not experimented on various electrodes yet. Amalgams of silver or copper in suitable solutions, or mercury in mercurous nitrate, may be better than zinc amalgam in zinc sulphate.

ELECTROLYTIC PROBLEMS.*

BY ROBERT L. MOND.

The study of Clerk Maxwell's theory of the propagation of electric energy through the dielectric along conductors, having, through the magnificent experimental work of Hertz, emerged from the purely mathematical stage, it may be of interest to apply it to the elucidation of the phenomena occurring on the propagation of electric energy through that class of conductors known as electrolytes.

The propagation of electric energy along metallic conductors is invariably found to produce the following four phenomena: —I.—The electric energy is propagated with the velocity of light. II.—An electro-magnetic field is produced. III.—Induced currents are produced in neighbouring conductors. IV. —Heat is produced in the conductor uniformly along its length proportional to the strength of the current and the resistance of the conductor.

These four phenomena are also produced during electrolysis; they are, however, accompanied by a fifth phenomenon, namely, chemical decomposition at the electrodes, and this chemical decomposition is strictly proportional to the strength of the current, but not to its intensity. Hence, by infinitely increasing the potential and diminishing the strength of the current, we can make the absorption of electrical energy due to chemical action as small as we please; and thus we can establish so complete an analogy between propagation of electric energy along metallic conductors and along electrolytes that any views brought forward to explain the phenomena in the one case must perforce apply to the other.

The theory of the propagation of electric energy along metals has been thus concisely defined by Prof. J. J. Thomson:— "The velocity of transmission of an electric impulse along a wire is, according to Maxwell's theory, equal to the velocity with which light passes through the dielectric in which the energy resides, and the function of the wire seems merely to be that of guiding the discharge which travels at a rate fixed by the dielectric." Prof. H. Hertz has recently shown that when an electric oscillation travels along a wire the electric force produces a mechanical effect at right angles to the wire, whilst the magnetic force which accompanies it tends to repel a ring brought into its vicinity; thus there are two vibrations perpendicular to each other, the nodes of the one coinciding with the antinodes of the other, passing along the wires, whence he concludes that "from the above experiments with conductors of very simple form it is evident that a conductor of any form, when placed in the path of electro-magnetic waves, is subject to forces of a very complex character."

Since a guiding conductor surrounded by dielectric is required (according to the above theory) for the propagation of electric energy in definite directions, the question arises, "How can an electrolyte act as such a guiding conductor?" For this there are two possible explanations. Either (1) the bulk of the electrolyte might be considered the conductor, and the surrounding medium the dielectric, such as glass or air; or (2) in the electrolyte itself a rearrangement of molecules is produced, some (*i.e.*, the best conducting) forming the guiding conductors along the lines of force between the electrodes, others dielectric tubes surrounding the same. The first proposition is untenable, for, although it explains how an electro-magnetic field may be produced outside the electrolyte, it utterly fails to explain how a fairly uniform field is produced inside it. Molecular chains have formed the basis of every theory of electrolysis since they were first proposed by Grotthuss, although the mode of action of the molecules has been explained in a great number of different ways. The molecular arrangement required for the second proposition, *i.e.*, molecular chains surrounded by dielectric tubes, was first proposed by Prof. G. Wiedemann, who brings weighty proofs in its favour, but who also, like his predecessors, assumes that the current passes through the molecular chain. He has, however, provided the requisite mechanism for the application of Clerk Maxwell's theory to electrolysis.

The electric energy in being propagated through these dielectric tubes along the chain of conducting molecules produces these magnetic and electric effects which act chemically on the dielectric, decomposing the molecules into atoms, or weakening their affinity along the zones of intense electric action surrounding each molecular chain. A similar view was already suggested by Faraday, when he considers the electric current to be "an axis of power having contrary forces exactly equal in amount in opposite directions," modifying the chemical affinity of the electrolyte in directions parallel to the axis, and providing the conditions for the transfer of electro-positive and negative ions in their respective directions. That there is a tendency for a strong electric field to produce molecular decomposition is evident from the action of the silent discharge and the electric arc, and also from such observations as those made by Bouty of electrolytic action on the surface of condenser plates.

The view proposed, which considers metallic and electrolytic conduction as identical, finds strong support in the following investigations. Prof. J. J. Thomson finds, as the result of experiments, "that the velocity of propagation of a rapidly alternating current along an electrolyte surrounded by air cannot differ much from the rate along a wire;" and in examining the resistance of electrolytic alternating currents, "the results obtained agree sufficiently well to enable us to say that the relative resistance of electrolytes is the same when a current is alternating a hundred million times a second, as for a steady current." Prof. Mengarini, of Rome, in a very exhaustive Paper on electrolysis by alternating currents, formulates the following law:—(4) "A limiting value to the rapidity of alternations exists, beyond which decomposition does not take place;" which he proves both theoretically and experimentally; and he finds that at the limit "the voltameter only becomes heated by the passage of the current like an ordinary metallic conductor." He also states in his conclusions (6): "A voltameter traversed by an alternating current behaves like a metallic conductor possessing self-induction." A Committee appointed by the British Association has also investigated a series of solid compounds, such as sulphides and selenides, some of which conduct purely metallically, others purely electrolytically, and others in both ways at the same time, and declared themselves unable to draw any marked line of distinction between these bodies.

To resume. The number of the molecular chains formed will depend on the strength of the electric field and on the concentration of the electrolyte, whilst the cross-sectional area of each zone of decomposition will depend on the strength of the current and number of chains, and the current density will be measured by the number of such chains in the cross-section of the electrolyte.

The existence of these zones explains:—

I.—How the atoms can travel along molecular chains towards their respective electrodes without recombination.

II.—Why the atoms are given off as molecules at the electrodes only, because there the electric field being weakest, and atoms of one kind preponderating, they combine and are given off.

By artificially weakening the electric field by introducing a metallic plate into the path of the molecular chains, such plate acts similar to an electrode. Mr. A. Tribe, by interposing silver plates in a copper sulphate cell, obtained one end coated with copper, the other with protoxide of silver, and found the boundary line of the zone of deposition to be at right angles to the line of flow of the current. This enabled him to observe the refraction of this line of flow by interposing a porous vessel with water, whose parallel sides were inclined at an angle of 45deg. to the sides of the rectangular electrolytic trough, a most important verification of the directive tendency of the current in an electrolyte.

Prof. J. J. Thomson has also shown that an electric field is weakened in the presence of a solid dielectric, because the surface tension is increased. Hence, if a solid dielectric is intruded into a zone of intense electric action, by sending the current through a porous diaphragm or a cracked glass plate, the fields will be weakened and atoms liberated, as abundantly proved by the experiments of Grotthuss, F. Braun, Ostwald, Tamman, Overbeck, and others.

* Paper read before the British Association, in Section A, at Cardiff, August, 1891.

III.—Why the atoms cannot escape through out of the liquid is explained by the directive force preventing the atoms escaping laterally out of the decomposing zones

It is obvious that only an exceedingly small electromotive force would be required to produce the minimum zone of decomposition necessary for electrolysis along a single or few molecular chains; and, since a weak electric field could only have a few lines of force, there would only be a few such rows, and this gives us an explanation for the electrolysis produced by the infinitesimal currents observed by Helmholtz, M. Depretz, and others. Also, if two bad conductors of slightly varying conductivity be mixed, such as alcohol and water, the conditions are provided for electrolytic action, the better conducting forming the guiding conductors, the other dielectric tubes, whence a greatly increased conducting power is produced and observed; as witness the experiments of Gladstone and Tribe, Overbeck, Pouillet, Ayrton and Perry, and others. This also explains the action of exceedingly minute quantities of impurities on influencing the conductivity of electrolytes.

The assumption that the solvent is primarily decomposed suffices to explain all the chemical phenomena observed in electrolytic cells, and was fully accepted by the older electricians, being specially worked out by Berzelius and his school. The electrolysis of solutions by strong currents gives strong support to this view; for when constituents of the solvents are more rapidly generated than they can be absorbed by secondary chemical action, they are given off in the free state. I have shown this to be the case for copper sulphate solutions, from which I have obtained oxygen and hydrogen by sufficlently increasing the strength of the current. Kohlrausch also states that in very dilute solutions water is discomposed.

The complicated phenomena classed under polarisation are mainly due to voltaic currents arising from chemical changes taking place at the electrodes and their physical effects.

The phenomenon known as wandering of the Ions has been shown by Professors Wiedemann and Quincke to be due to three causes. I. The free charges on the surface of the molecular chains, producing motion in opposite directions of the salt and the solvent molecules. II. The same effect being also produced by the free charges on the electrodes; and III. By the electrification of the vessel containing the electrolyte, which latter they also consider to explain the phenomena known as electrical endosmose.

It is obvious that these explanations may also be adopted in connection with the above expressed views.

In order to corroborate the theory of molecular chains, I have carried out a series of experiments with different apparatus to study whether the displacement of the molecular conductors would influence the conductivity. I found that the resistance of a jet of electrolyte, which was caused to flow at varying speeds between the electrodes rose proportional to the velocity of the electrolyte up to a maximum of about 10 per cent. of the total deflection. In order to ensure the result being solely due to the velocity of the jet and not to diminution of the area of the conductor, the electrodes carefully insulated except at places where the jets (one to each electrode) impinged, were kept immersed in separate cells connected with a tube and provided with overflow tubes, the jet playing beneath the surface of the electrolyte; the result was in complete accordance with those previously obtained.

Faraday has shown that an interrupted current flowing through an electro-magnet is able to induce a current in a secondary coil made of an india-rubber tube filled with an electrolyte wound round the keeper. Considering it to be of interest to have both a primary and secondary coil of electrolytic conductor, I constructed two flat spirals of india-rubber tubing, filled with acidulated copper sulphate, and provided with copper electrodes; for the primary, a continuous current of 90 volts was employed, which was simply interrupted by means of an electric bell worked from an independent battery. The secondary coil was connected with a Sir Wm. Thomson 60 ohm reflecting galvanometer; a thermo current giving 10 divisions was observed, but the effect of the induced alternating current was to produce intermittently deflections of over 50 divisions on each side of the zero, thus removing all doubt of the success of the experiment.

The complete analogy between an electrolyte and a high-resistance wire led me to suspect that if such a wire were inserted between the electrodes electrolysis would be observed at the ends. On referring to the literature, I found that Jacobi had obtained the desired result with a German silver wire in a copper sulphate solution, but did not obtain the result with platinum. Having some thin platinoid wire at hand, I determined to repeat the experiment, coiling the wire to increase its resistance. Copper was deposited along about one-half of it, beginning slowly at the negative electrode, whilst the other half turned black by oxydation, and was gradually destroyed at the end nearest the positive electrode.

I know that the view I have ventured to bring before you leaves many facts connected with electrolysis as yet unexplained, but the same must be admitted for all other theories on the subject hitherto propounded, over which this view has, I believe, the advantage that it brings the propagation of electric energy along electrolytes into harmony with the now generally accepted theory of Clerk Maxwell of the propagation along metallic conductors, and that it offers an explanation of the electrical as well of the chemical phenomena observed.

DR. OLIVER LODGE'S PRESIDENTIAL ADDRESS TO SECTION A.

(ABSTRACT.)

During the past year three or four events call for special mention in an annual deliverance of this kind by a physicist. One is the Faraday centenary, which was kept in a happy and simple manner by a cosmopolitan gathering in the place so long associated with his work, and by discourses calling attention to the modern development of discoveries made by him. Another is the decease of the veteran Wilhelm Weber, one of the originators of that absolute system of measurement which, though still ungrasped in its simplicity and completeness by the majority of men engaged in practice, nor even, I fear, wholly understood by some of those engaged in University teaching, has yet done so much, and is destined to do still more, for the unification of physical science, and for a thorough comprehension of its range and its limitations. A third event of importance during the year is the discovery in America of a binary system of stars, revolving round each other with grotesque haste, and with a proximity to each other such as to render their ordinary optical separation quite impossible. The change in the refrangibility of light by reason of the motion of its source, though commonplace enough now, was at first regarded as too small to be observed, and one or two attempts directed to detecting the effect of this principle on the spectra of the stars, or sometimes on sunlight reflected by a 45deg. mirror into the line of the earth's motion (which is not a possible method), wholly failed. I take pleasure in remembering that this effect was clearly observed for the first time by the gentleman we this year honour as our President; and that it is by this very means that the latest sensational discovery in astronomy of the rapidly revolving twin star, β-Aurigæ, by Prof. Pickering and the staff connected with the Draper Memorial, was made. The fourth event to which it behoves me to refer is the practical discovery of a physical method for colour photography. The first suggestion of the method, so far as I know, was made by Lord Rayleigh in the course of a mathematical paper on the reflection of light, and with reference to some results of Becquerel obtained on a totally different plan. He said in a note that if by normal reflection waves of light were converted into stationary waves, they could shake out silver in strata half a wave-length apart, and that such strata would give selective reflection and show iridescence. Independently of all this, Herr Otto Wiener, imitating Hertz's experiments with ordinary light, in 1889, reflected a beam directly back on itself, and, by interposing a very thin collodion film at extraordinarily oblique incidence, succeeded in the difficult experiment of so magnifying, by the cosine of inclination, the half wave-length, as to get the silver deposited in strata of visible width, and thus to photograph the interference nodes themselves at the places where they were cut by the plane of the film. Then M. Lippmann, using a thicker film, not put obliquely but normal to the light, obtained the strata within the thickness of the film itself—hundreds of layers; and so, employing incident light of definite wave-length, was able to produce a stratified deposit, which reflected back at appropriate incidences the same wave-length as produced it; thus reproducing, of course, the definite colour.

I now leave the retrospect of what has been done, although many other topics might usefully detain us, and I proceed to glance forward at the progress ahead and at the means we have for effectively grappling with our due share of it. There is a subject which has

Digitized by Google

long been in my mind, and which I determined to bring forward whenever I had a cathedral opportunity of doing so; and, now, if ever, is a suitable occasion. It is to call attention to the fact that the further progress of physical science in the somewhat haphazard and amateur fashion in which it has been hitherto pursued in this country is becoming increasingly difficult, and that the quantitative portion especially should be undertaken in a permanent and publicly-supported physical laboratory on a large scale. If such an establishment were to weaken the sinews of private enterprise and individual research it should be strenuously opposed; but, in my opinion, it would have the opposite effect, by relieving the private worker of much which he can only with great difficulty, sacrifice, and expense, undertake. To illustrate more precisely what I mean, it is sufficient to recall the case of astronomy. The amateur astronomer has much work lying ready to his hand, and he grapples with it manfully. To him is left the striking out of new lines and the guerilla warfare of science. Skirmishing and brilliant cavalry evolutions are his natural field; he should not be called upon to take part in the general infantry advance. It is wasting his energies, and he could not do it in the long run well. What, for instance, would have been the state of astronometry—the nautical almanack department of astronomy—without the consecutive and systematic work of the National Observatory at Greenwich? It may be that some enthusiastic amateurs would have devoted their lives to this routine kind of work; and here at one time, and there at another, a series of accurate observations would have been kept for several years. Pursued in that way, however, not only would the effort be spasmodic and temporary, but the energy and enthusiam of those amateurs would have been diverted from the pioneering more suited to them, and have been cramped in the groove of routine, eminently adapted to a permanent official staff, but not wholesome for an individual. Long-continued consecutive observations may be made by a leader of science, as functions may be tabulated by an eminent mathematician; but if the work can be done almost equally well (some would say better) by a professional observer or computator, how great an economy results.

Now all this applies equally to physics. The ohm has been determined with 4-figure, perhaps with 5-figure accuracy; but think of the list of eminent men to whose severe personal labour we owe this result, and ask if the spoil is worth the cost. Perhaps, in this case, it is, as a specimen of well-conducted determination. We must have a few specimens, and our leaders must show us the way to do things. But let us not continue to use them for such purposes much longer. The quest of the fifth or sixth decimal is a very legitimate, and may become a very absorbing, quest, but there are plenty of the rank and file who can undertake it if properly generalled and led: not as isolated individuals, but as workers in a National Laboratory under a competent head and a governing committee. By this means work far greater in quantity, and, in the long-run, more exact in quality, can be turned out, by patient and conscientious labour without much genius, by the gradual improvement of instrumental means, by the skill acquired by practice, and by the steady drudgery of routine. Paris has long had one form of such an institution, in the Conservatoire des Arts et Métiers, and has been able to impose the metric system on the civilised world in consequence. It can also point to the classical determinations of Regnault as the fruits of just such a system. Berlin is now starting a similar or a more ambitious scheme for a permanent national physical institute. Is it not time that England, who in physical science, I venture to think, may in some sort claim a leading place, should be thinking of starting the same movement?

The Meteorological and Magnetic Observatory at Kew (in the inauguration of which this Association took so large a part) is a step, and much useful quantitative work is done there. The new Electric Standardising Laboratory of the Board of Trade is another and, in some respects perhaps, a still closer approximation to the kind of thing I advocate. But what I want to see is a much larger establishment, erected on the most suitable site, limited by no speciality of aim nor by the demands of the commercial world, furnished with all appropriate appliances, to be amended and added to as time goes on and experience grows, and invested with all the dignity and permanence of a national institution; a Physical Observatory, in fact, precisely comparable to the Greenwich Observatory, and aiming at the very highest quantitative work in all departments of physical science. That the arts would be benefited may be assumed without proof. It is largely the necessity of engineers that has inspired the amount of accuracy in electrical matters already attained. The work and appliances of the mechanical engineer eclipse the present achievements of the physicist in point of accuracy, and it is by the aid of the mechanician and optician that precision even in astronomy has reached so high a stage. There is no reason why physical determinations should be conducted in an amateur fashion, with comparatively imperfect instruments, as at present they mostly are. Discoveries lie along the path of extreme accuracy, and they will turn up in the most unexpected way. The aberration of light would not have been discovered had not Bradley been able to measure to less than 1 part in 10,000; and what a brilliant and momentous discovery it was! He was aiming at the detection of stellar parallax, but the finite velocity of light was a bigger discovery of light than any parallax. This is the type of result which sometimes lurks in the fifth decimal, and which confers upon it an importance beside which the demands of men who wish to serve the taste and the pocket of the British public sink into insignificance.

In a National Observatory accuracy should be the one great end: the utmost accuracy in every determination that is decided on and made. Only one thing should be more thought of than the fifth significant figure, and that is the sixth. The consequences flowing from the results may safely be left; such as are not obvious at once will distil themselves out in time. And the great army of outside physicists, assured of the good work being done at headquarters, will (to speak again in astronomical parable) cease from peddling with taking transits or altitudes, and will be free to discover comets, to invent the spectroscope, to watch solar phenomena, to chemically analyse the stars, to devise celestial photography, and to elaborate still more celestial theories, all of which novelties in their maturity may be handed over to the National Observatory, to be henceforth incorporated with, and made part of, its routine life, leaving the advance guard and skirmishers free to explore fresh territory, secure in the knowledge that what they have acquired will be properly surveyed, mapped, and utilised, without further attention from them. As to the practical applications, they may in any case be left to take care of themselves. The instinct of humanity in this direction, and the so-called solid gains associated with practical achievements, will always secure a sufficient number of acute and energetic workers to turn the new territory into arable land and pasture adapted to the demands of the average man. The labour of the agriculturist in rendering soil fertile is, of course, beyond praise; but it is not the work of the pioneer. As Mr. Huxley eloquently put it, when contrasting the application of science with the advance of science itself, speaking of the things of commercial value which the physical philosopher sometimes discovers:—"Great is the rejoicing of those who are benefited thereby, and, for the moment, science is the Diana of all the craftsmen. But even while the cries of jubilation resound, and this flotsam and jetsam of the tide of investigation is being turned into the wages of workmen and the wealth of capitalists, the crest of the wave of scientific investigation is far away on its course over the illimitable ocean of the unknown."

I have spoken of the work of the National Laboratory as devoted to accuracy. It is hardly necessary to say that it will be also the natural custodian of our standards, in a state fit for use and for comparison with copies sent to be certified. Else, perhaps, some day our standard ohm may be buried in a brick wall at Westminster, and no one living may be able to recall precisely where it is.

But, in addition to these main functions, there is another, equally important with them, to which I must briefly refer. There are many experiments which cannot possibly be conducted by an individual, because 40 and 50 years is not long enough for them. Secular experiments on the properties of materials—the elasticity of metals, for instance; the effect of time on molecular arrangement; the influence of long exposure to light, or to heat, or to mechanical vibration, or to other physical agents. Does the permeability of soft iron decay with age, by reason of its Ampèrian currents? Do gases cool themselves when adiabatically preserved, by reason of imperfect elasticity or too many degrees of freedom of their molecules? Unlikely, but not impossible. Do thermoelectric properties alter with time? And a multitude of other experiments which appear specially applicable to substanees in the solid state—a state whieh is more complicated, and has been less investigated, than either the liquid or the gaseous; a state in which time and past history play an important part.

Whichever of these long researches requires to be entered on, a national laboratory, with permanent traditions and a continuous life, is undoubtedly the only appropriate place. At such a place as Glasgow the exceptional magnitude of a present occupant may, indeed, inspire sufficient piety in a successor to secure the continuance of what has been there begun; but in most college laboratories, under conditions of migration, interregnum, and a new *régime*, continuity of investigation is hopeless.

I have, at any rate, said enough to indicate the kind of work for which the establishment of a well-furnished laboratory with fully-equipped staff is desirable, and I do not think that we, as a nation, shall be taking our proper share of the highest scientific work of the world until such an institution is started on its career. There is only one evil which, so far as I can see, is to be feared from it: if ever it were allowed to impose on outside workers as a central authority, from which infallible dicta were issued, it would be an evil so great that no amount of good work carried on by it could be pleaded as sufficient mitigation. If ever by evil chance such an attitude were attempted, it must rest with the workers of the future to see that they permit no such shackles; for if they are not competent to be independent, and to contemn the voice of authority speaking as mere authority, if their only safeguard lies in the

Digitized by Google

absence of necessity for struggle and effort, they cannot long hope to escape from the futility which surely awaits them in other directions.

I am thus led to take a wider range, and, leaving temporary and special considerations, to speak of a topic which is as yet beyond the pale of scientific orthodoxy, and which I might, more wisely, leave lying by the roadside.

Our ancestors fought hard and suffered much for the privilege of free and open inquiry, for the right of conducting investigation untrammelled by prejudice and foregone conclusions, and they were ready to examine into any phenomenon which presented itself. This attitude of mind is, perhaps, necessarily less prominent now, but it would be a great pity if a too absorbed attention to what has already been acquired, and to the fringe of territory lying immediately adjacent thereto, were to end in our losing the power of raising our eyes and receiving evidence of a totally fresh kind, of perceiving the existence of regions into which the same processes of inquiry as had proved so fruitful might be extended, with results at present incalculable and perhaps wholly unexpected. I myself think that the ordinary processes of observation and experiment are establishing the existence of such a region ; that, in fact, they have already established the truth of some phenomena not at present contemplated by science, and to which the orthodox man shuts his ears.

Everybody is by no means bound to investigate everything ; though, indeed, it is customary in most fields of knowledge for those who have kept aloof from a particular inquiry to defer in moderation to those who have conducted it, without feeling themselves called upon to express an opinion. Some there are, no doubt, who consider that they have given sufficient time and attention to the subject with only negative results. Their evidence is, of course, important ; but, plainly, negative evidence should be of immense bulk and weight before it can outweigh even a moderate amount of positive evidence. However, it is not of the action of individuals that I wish to speak, it is of the attitude to be adopted by scientific bodies in their corporate capacity ; and for a corporate body of men of science, inheritors of the hard-won tradition of free and fearless inquiry into the facts of Nature untrammelled by prejudice, for any such body to decline to receive evidence laboriously attained and discreetly and inoffensively presented by observers of accepted competency in other branches, would be, if ever actually done and persisted in, a terrible throwing away of their prerogative, and an imitation of the errors of a school of thought against which the struggle was at one time severe.

Now let me be more definite, and try to state what this field is, the exploration of which is regarded as so dangerous. I might call it the borderland of physics and psychology. I might call it the connection between life and energy ; or the connection between mind and matter. It is an intermediate region, bounded on the north by psychology, on the south by physics, on the east by physiology, and on the west by pathology and medicine. An occasional psychologist has groped down into it and become a metaphysician. An occasional physicist has wandered up into it and lost his base, to the horror of his quondam brethren. Biologists mostly look at it askance, or deny its existence. A few medical practitioners, after long maintenance of a similar attitude, have begun to annex a portion of its western frontier. The whole region seems to be inhabited mainly by savages, many of them, so far as we can judge from a distance, given to gross superstition. It may, for all I know, have been hastily traversed and rudely surveyed by a few clear-eyed travellers ; but their legends concerning it are not very credible, certainly are not believed. Why not leave it to the metaphysicians ? I say it has been left to them long enough. They have explored it with insufficient equipment. The physical knowledge of the great philosophers has been necessarily scanty. Men of genius they were, and their writings may, when interpreted, mean much. But to us, as physicists, they are unsatisfactory ; their methods are not our methods. They may be said to have floated a balloon over the region with a looking-glass attached, in which they have caught queer and fragmentary glimpses. They may have seen more than we give them credit for, but they appear to have guessed far more than they saw. Our method is different. We prefer to creep slowly from our base of physical knowledge, to engineer carefully as we go, establishing forts, making roads, and thoroughly exploring the country ; making a progress very slow, but very lasting. The psychologists from their side may meet us. I hope they will ; but one or other of us ought to begin.

A vulnerable spot on our side seems to be the connection between life and energy. The conservation of energy has been so long established as to have become a commonplace. The relation of life to energy is not understood. Life is not energy, and the death of an animal affects the amount of energy no whit ; yet a live animal exerts control over energy which a dead one cannot. Life is a guiding or directing principle, disturbing to the physical world, but not yet given a place in the scheme of physics. The transfer of energy is accounted for by the performance of work ; the guidance of energy needs no work, but demands force only. What is force ? and how can living beings exert it in the way they do ? By what means is force exerted, and what, definitely, is force ? I can hardly put the question here and now so as to be intelligible, except to those who have approached and thought over the same difficulties ; but I venture to say that there is here something not provided for in the orthodox scheme of physics ; that modern physics is not complete, and that a line of possible advance lies in this direction. But the whole region is unexplored territory, and it is conceivable that matter may react on mind in a way we can at present only dimly imagine. In fact, the barrier between the two may gradually melt away, as so many other barriers have done, and we may end in a wider perception of the unity of nature, such as philosophers have already dreamt of. I care not what the end may be. I do care that the inquiry shall be conducted by us, and that we shall be free from the disgrace of jogging along accustomed roads, leaving to outsiders the work, the ridicule, and the gratification, of unfolding a new region to unwilling eyes.

It may be held that such investigations are not physical and do not concern us. We cannot tell without trying. In that I trust my instinct. I believe there is something in this region which does concern us as physicists. It may concern other sciences too. It must, one would suppose, some day concern biology ; but with that I have nothing to do. Biologists have their region, we have ours, and there is no need for us to hang back from an investigation because they do. Our own science, of Physics or Natural Philosophy in its widest sense, is the King of the Sciences, and it is for us to lead, not to follow. Now I say that the doctrine of ultimate intelligibility should be pressed into other departments also. At present we hang back from whole regions of inquiry and say they are not for us. A few we are beginning to grapple with. The nature of disease is yielding to scrutiny with fruitful result ; the mental aberrations and abnormalities of hypnotism, duplex personality, and allied phenomena, are now at last being taken under the wing of science, after long ridicule and contempt. The phenomenon of crime, the scientific meaning and justification of altruism, and other matters relating to life and conduct, are beginning, or perhaps are barely yet beginning, to show a vulnerable front over which the forces of science may pour. What we know is as nothing to that which remains to be known. This is sometimes said as a truism ; sometimes it is half doubted. To me it seems the most literal truth, and that if we narrow our view to already half-conquered territory only, we shall be false to the men who won our freedom, and treasonable to the highest claims of science.

I must now return to the work of this section, from which I have apparently wandered rather far afield, further than is customary—perhaps further than is desirable. But I hold that occasionally a wide outlook is wholesome, and that without such occasional survey, the rigid attention to detail and minute scrutiny of every little fact, which are so entirely admirable and are so rightly here fostered, are apt to become unhealthy, dull, and monotonous. Our life-work is connected with the rigid framework of facts, the skeleton or outline map of the universe ; and, though it is well for us occasionally to remember that the texture and colour and beauty which we habitually ignore are not therefore in the slightest degree non-existent, yet it is safest speedily to return to our base and continue the slow and laborious march with which we are familiar and which experience has justified. It is because I imagine that such systematic advance is now beginning to be possible in a fresh and unexpected direction that I have attempted to direct your attention to a subject which, if my prognostications are correct, may turn out to be one of special and peculiar interest to humanity.

THE LONDON-PARIS TELEPHONE.*

BY W. H. PREECE, F.R.S.

1. I have already on two occasions, at Newcastle and at Leeds, brought this subject before Section G, and have given the details of the length and construction of the proposed circuit. I have now to report not only that the line has been constructed and opened to the public, but that its success, telephonic and commercial, has exceeded the most sanguine anticipations. Speech has been maintained with perfect clearness and accuracy. The line has proved to be much better than it ought to have been, and the purpose of this Paper is to show the reason why.

The lengths of the different sections of the circuit are as follows:—

London to St. Margaret's Bay	84·5	miles.
St. Margaret's Bay to Sangatte (cable)	23·	,,
Sangatte to Paris	199·	,,
Paris underground	4·8	,,
Total	311·3	,,

* Paper read before the British Association, in Section G, at Cardiff, August, 1891.

Digitized by Google

The resistances are as follows :—

Paris underground	70	ohms.
French line	294	„
Cable	143	„
English line	183	„
Total (R)	693	

The capacities are as follows :—

Paris underground	0·43	microfarads.
French line	3·33	„
Cable	5·52	„
English line	1·32	„
Total (K)	10·62	„

$693 \times 10{\cdot}62 = 7{,}359 = K\,R.$

A product which indicates that speeds should be very great.

2. *Trials of Apparatus.*—The preliminary trials were made during the month of March between the chief telegraph offices of the two capitals, and the following microphone transmitters were compared :—

Ader	Pencil form.
Berliner	Granular „ (Hunnings).
D'Arsonval	Pencil „
De Jongh	„ „
Gower-Bell	„ „
Post Office switch instrument	Granules and lamp filaments.
Roulez	Lamp filaments.
Turnbull	Pencil form.
Western Electric	Granular.

The receivers consisted of the latest form of double-pole Bell telephones with some Ader and D'Arsonval receivers for comparison. After repeated trials it was finally decided that the Ader, D'Arsonval, Gower-Bell (with double-pole receivers instead of tubes), Roulez and Western Electric were the best, and were approximately equal.

These instruments were, therefore, selected for the further experiments, which consisted of using local extensions in Paris and London. The wires were in the first instance extended at the Paris end to the Observatory through an exchange at the Avenue des Gobelines. The length of this local line is 7 kilometres. The wires are gutta-percha covered, placed underground, and not suitable for giving the best results.

The results were, however, fairly satisfactory. The wires were extended to the Treasury in London by means of the ordinary underground system. The distance is about two miles, and although the volume of sound and clearness of articulation were perceptibly reduced by these additions to the circuit, conversation was quite practicable.

Further trials were also made from the Avenue des Gobelines on underground wires of five kilometres long, and also with some renters in Paris with fairly satisfactory results. The selected telephones were equally efficient in all cases, which proves that to maintain easy conversation when the trunk wires are extended to local points it is only necessary that the local lines shall be of a standard not lower than that of the trunk line. The experiments also confirm the conclusion that long distance speaking is solely a question of the circuit and its environments, and not one of apparatus. The instruments finally selected for actual work were Gower-Bell for London and Roulez for Paris.

3. The results are certainly most satisfactory. There is no circuit in or out of London on which speech is more perfect than it is between London and Paris. In fact, it is better than I anticipated, and better than calculation led me to expect. Speech has been possible not only to Paris but through Paris to Bruxelles, and even, with difficulty, through Paris to Marseilles, a distance of over 900 miles. The wires between Paris and Marseilles are massive copper wires specially erected for telephone business between those important places.

4. *Business Done.*—The charge for a conversation between London and Paris is 8s. for three minutes' complete use of the wire. The demand for the wire is very considerable. The average number of talks per day, exclusive of Sunday, is 86. The maximum has been 108. We have had as many calls as 19 per hour—the average is 15 during the busy hours of the day. As an instance of what can be done, 150 words per minute have been dictated in Paris and transcribed in London by shorthand writing. Thus in three minutes 450 words were recorded, which at 8s. cost five words for a penny.

5. *Difficulties.*—The difficulties met with in long distance speaking are several, and they may be divided into (*a*) those due to external disturbances and (*b*) those due to internal opposition.

(*a.*) Every current rising and falling in the neighbourhood of a telephone line within a region, say, of 100 yards, whether the wire conveying it be underground or overground, induces in the telephone circuit another current, producing in the telephone a sound which disturbs speech, and if the neighbouring wires are numerous and busy, as they are on our roads and railways, these sounds become confusing, noisy, and ultimately entirely preventative of speech. This disturbance is, however, completely removed by forming the telephone circuit of two wires placed as near to each other as possible, and twisted around each other without touching, so as to maintain the mean average distance of each wire from surrounding conductors, the same everywhere. Thus similar currents are induced in each of the two wires, but being opposite in direction, as far as the circuit is concerned, they neutralise each other, and the circuit, therefore, becomes quite silent.

In England we make the two wires revolve completely round each other in every *four* poles, but in France it is done in every *six* poles. The reason for the change is the fact that in the English plan the actual crossing of the wires takes place in the span between the poles, while in the French plan it takes place at the poles. This is supposed to reduce the liability of the wires to be thrown into contact with each other by the wind, but, on the other hand, it diminishes the geometrical symmetry of the wires—so very essential to ensure silence. As a matter of fact, contacts do not occur on well-constructed lines, and I think our English wires, being more symmetrical, are freer from external disturbance than those in France.

(*b.*) The internal opposition arises from the resistance R, the capacity K, and the electro-magnetic inertia, L, of the circuit. A current of electricity takes time to rise to its maximum strength and time to fall back again to zero. Every circuit has what is called its *time constant*, *t* (Fig. 1), which regulates the number of current waves which can be transmitted through it per second. This is the time the current takes to rise from zero to its working maximum and the time it takes to fall from this maximum to zero again, shown by the shaded portions of the figure, the duration of the working current being immaterial and shown by the unshaded portion. The most rapid form of quick telegraphy requires about 150 currents per second, currents each of which must rise and fall in $\frac{1}{150}$th of a second, but for ordinary telephone speaking we must have about 1,500 currents per second, or the time which each current rises from zero to its maximum intensity must not exceed $\frac{1}{3000}$th part of a second. The time constant of a telephone circuit should, therefore, not be less than ·0003 second.

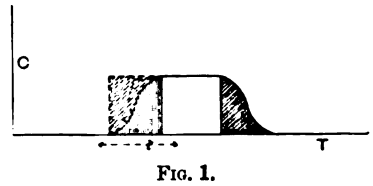

FIG. 1.

Resistance alone does not affect the time constant. It diminishes the intensity or strength of the currents only ; but resistance, combined with electro-magnetic inertia, and with capacity, has a serious retarding effect on the rate of rise and fall of the currents. They increase the time constant and introduce a slowness which may be called *retardance*, for they diminish the rate at which currents can be transmitted. Now, the retardance due to electro-magnetic inertia increases directly with the amount of electro-magnetic inertia present, but it diminishes with the amount of resistance of the conductor. It is expressed by the ratio L/R, while that due to capacity increases directly, both with the capacity and with the resistance, and it is expressed by the product K R. The whole retardance, and, therefore, the speed of working the circuit or the clearness of speech, is given by the equation

$$L/R + K\,R = t,$$

or

$$L + K\,R^2 = R\,t.$$

Now in telegraphy we are not able altogether to eliminate L, but we can counteract it, and if we can make $R\,t = 0$, then

$$L = -K\,R^2,$$

which is the principle of the shunted condenser that has been introduced with such signal success in our Post Office service, and has virtually doubled the carrying capacity of our wires.

If in the above equation we make $L = 0$,

$$K\,R = t.$$

This is done in telephony, and hence we obtain the law of retardance, or the law by which we can calculate the distance to which speech is possible. All my calculations for the London and Paris line were based on this law, and experience has shown it to be true.

How is electro-magnetic inertia practically eliminated? First by the use of two massive copper wires, and secondly by symmetrically revolving them around each other. Now L depends on the geometry of the circuit, that is, on the relative form and position

Digitized by Google

of the different parts of the circuit, which is invariable for the same circuit, and is represented by a coefficient, λ. It depends also on the magnetic qualities of the conductors employed and of the space embraced by the circuit. This specific magnetic capacity is a variable quantity, and is indicated by μ for the conductor, and by μ_0 for air. It depends also on the rate at which currents rise and fall, and this is indicated by the differential coefficient $d\,C/d\,t$. It depends finally on the number of lines of force due to its own current, which cut the conductor in the proper direction; this is indicated by β. Combining these together we can represent the electro magnetic inertia of a metallic telephone circuit as

$$L = \lambda\,(\mu+\mu_0)\,d\,C/d\,t\times\beta.$$

Now, $\lambda = 2\log d^2/a^2$. Hence the smaller we make the distance (d) between the wires, and the greater we make their diameter (a), the smaller becomes λ. It is customary to call the value of μ for

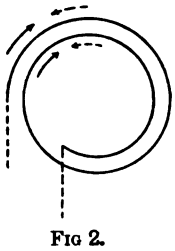

Fig 2.

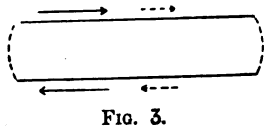

Fig. 3.

air and copper, 1, but this is purely artificial and certainly not true. It must be very much less than one in every medium, excepting the magnetic metals, so much so that in copper it may be neglected altogether, while in air it does not matter what it is, for by the method of twisting one conductor round the other, the magnetisation of the air space by the one current of the circuit rotating in one direction is exactly neutralised by that of the other element of the circuit rotating in the opposite direction. Now, β, in two parallel conductors conveying currents of the same sense, that is flowing in the same direction, is retarding (Fig. 2), and is therefore a positive quantity, but when the currents flow in opposite directions, as in a metallic loop (Fig. 3), they tend to assist each other and are of a negative character. Hence in a metallic telephone circuit we may neglect L *in toto*, as I have done. I have never yet succeeded in tracing any evidence of electro-magnetic inertia in long

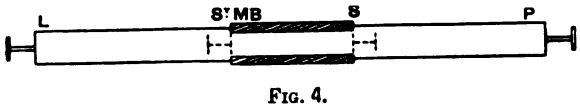

Fig. 4.

single copper wires, while in iron wires the value of L may certainly be taken at ·005 henry per mile.

In short, metallic circuits, say of lengths up to 100 miles, this negative quantity does not appear, but in the Paris-London circuit this helpful mutual action of opposite currents comes on in a peculiar way. The presence of the cable introduces a large capacity practically in the centre of the circuit. The result is that we have in each branch of the circuit between the transmitter, say, at London and the cable at Dover, extra currents at the *commencement* of the operation, which, flowing in opposite directions, mutually react on each other and practically prepare the way for the working currents. The presence of these currents is proved by the fact that when the cable is disconnected at Calais, as shown in Fig. 5, and telephones are inserted in series, as shown at D and D', speech is as

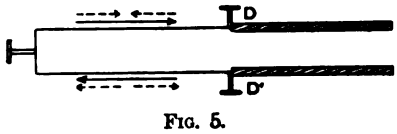

Fig. 5.

perfect between London and St. Margaret's Bay as if the wires were connected across, or as if the circuit were through to Paris. Their effect is precisely the same as though the capacity of the aerial section were reduced by a quantity (M), which is of the same dimension or character as K. Hence our retardance equation becomes

$$R\,(K-M)=t.$$

Thus it happens that the London-Paris telephone works better than was expected. The nature of M is probably equivalent to about ·0075 ϕ per mile, and, therefore, K should be also about ·0075 ϕ, instead of ·0156 ϕ per mile. This helpful action of mutual induction is present in all long circuits, and it is the reason why we were able to speak to Brussels and even to Marseilles. It also appears in every metallic loop, and vitiates the measurements of electro-magnetic inertia and of capacity of loops. Thus, if we measure the capacity of a loop as compared with a single wire, the amount per mile may be 50 per cent. greater than it ought to be; while if we measure the capacity of one branch of a circuit under the conditions of the London-Paris telephone line, it may be 50 per cent. less than it ought to be. This effect of M is shown by the dotted line in Fig. 1.

Telephonic currents, that is, currents induced in the secondary wire of an induction coil due to the variation of microphonic currents in the primary wire, are not alternating currents. They do not follow the constant periodic law, and they are not true harmonic sine functions of the time. The microphonic currents are intermittent or pulsatory, and always flow in the same direction. The secondary currents are of the same sign, as are the currents in a Ruhmkorff coil, and as are the currents in high vacua with which Crookes has made us so familiar. Moreover, the frequency of these currents is a very variable quantity, not only due to the various tones of voices, but to the various styles of articulation. Hence the laws of periodic alternate currents following the sine function of the time fail when we come to consider microphones and telephones. It is important to bear this in mind, for nearly everything that has hitherto been written on the subject assumes that telegraphic currents follow this periodic sine law. The currents derived from Bell's original magneto-transmitters are alternate, and comply more nearly with the law. The difference between them and microphones is at once perceptible. Muffling and disturbance due to the presence of electro-magnetic inertia become evident, which are absent with microphones. I tested this between London and St. Margaret's, and found the effect most marked.

7. *Lightning.*—A metallic telephone circuit may have a static charge induced upon it by a thunder cloud, as shown in Fig. 6. Such a charge is an electric strain, which is released when the charged cloud flashes into the earth or into a neighbouring cloud. If there be electro-magnetic inertia present, the charge will surge backward and forward through the circuit until it dies out. If there be no E.M.F. present it will cease suddenly, and neutrality will be attained at once. Telephone circuits indicate this operation by peculiar and characteristic sounds. An iron wire circuit produces a long swish or loud sigh, but a copper wire circuit like the Paris-London telephone emits a short, sharp report, like the crack of a pistol, which is sometimes startling, and has created fear, but there is no danger or liability to shock. Indeed, the start has more than once thrown the listener off his stool, and has led to the belief that he was knocked down by lightning.

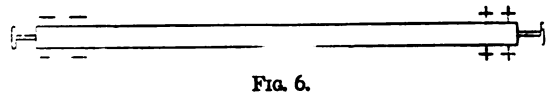

Fig. 6.

8. The future of telephone working, especially in large cities, is one of underground wires, and the way to get over the difficulties of this kind of work is perfectly clear. We must have metallic circuits, twisted wires, low resistance, and low capacity. In Paris, a remarkable cable, made by Fortin-Herman, gives an exceedingly low capacity, viz., only ·069 ϕ per mile. In the United States they are using a wire insulated with paper which gives ·08 ϕ per mile. We are using in London Fowler-Waring cable giving a capacity of 1·8 ϕ per mile, the capacity of gutta-covered wire being 3 ϕ per mile.

ON THE TELEPHONING OF GREAT CITIES.*

BY A. R. BENNETT.

A matter which has never yet been seriously faced is how the demand for telephonic exchange connection, which, after the lapse of a few more years, is bound to arise in all large cities, is to be met. What is possible in this direction under the influence of moderate rates and a reasonably efficient service has already been demonstrated in certain localities, chiefly in Scotland, where towns boasting of next to no manufactures or staple trade possess exchanges far exceeding in importance those of many English towns of three and four times the population, the principal supporters of such exchanges, after the manufacturers and merchants, being professional men, as doctors, solicitors, and accountants; householders; and shopkeepers, as grocers, butchers, and druggists. The efficiency and the readiness with which a large town or city can be telephoned so as to meet the ever-increasing demands of the inhabitants will depend, in a very great measure, on how the work is laid out and set about in the initiatory stage. If London were telephoned in the same proportion as Galashiels, it would possess 28,000 subscribers; but that number does not nearly represent the

* Abstract of a Paper read before the British Association, in Section G, at Cardiff, August, 1891.

Digitized by Google

possibilities—far from it. We must certainly anticipate one telephonic exchange connection for every 50 inhabitants in London in time to come; a modest estimate, if we consider that there is already one for every 200 inhabitants in Galashiels and some other towns, which are the merest hamlets in comparison. With London's present population of 5,600,000 such a proportion would represent 112,000 subscribers, and, as the population increases and the boundaries extend, more and more will grow the demand, until even that great number will appear inadequate and insignificant. As an indication of how the telephone idea is taking root, I may mention that the builders of a new block of business offices in Manchester propose to put a permanent connection to the Mutual Telephone Company's Exchange into each suite of offices, paying the subscriptions themselves, and charging their tenants nothing extra. This is one of the first-fruits of cheap rates.

The establishment of an effective and popular telephone exchange in a large town, and one that can be added to and extended freely and economically, without pulling down what has already been done, involves the fulfilment of several indispensable conditions. Firstly.—Speech must be loud and distinct, and privacy of communication complete; and a subscriber's line and apparatus must be adapted equally well to speaking to another across the street or to one five hundred miles away. There must, furthermore, be an absence of all disturbing sounds. Secondly.—The arrangements for connecting the subscribers together, subsequently disconnecting them, and, if required, immediately re-connecting them to others, must be so complete that eight or ten seconds should be the maximum time occupied within the compass of the largest town. Thirdly.—The rates must be within the reach of even small householders and shopkeepers, and should not exceed £8 per annum. Fourthly.—The general design must permit of the addition of new subscribers in every direction and to any extent, without interfering with the work already done. All these conditions can be complied with. What is necessary to do to meet them can be broadly indicated under three headings. (1) The universal use of metallic circuits, and the absence from the line of intermediate electro-magnets and other signalling devices which tend to damp and deform the electrical vibrations which constitute telephonic speech. (2) The provision of means by which certain and instantaneous communication can be established between subscriber and operator, and between one operator and another, (3) The division of the town to be telephoned into districts or sections not exceeding a square mile in area, each of which is worked from a switch-room placed at or near its centre.

The fulfilment of these necessary conditions is easy, provided the undertakers are in possession of the right to open the streets. So long as the execution of any scheme is subject to the caprice or the blackmailing propensities of individual proprietors, a proper telephonic service, such as London, the first city of the world, ought to possess, will remain an aspiration and nothing more. Legislative assistance to the extent of placing the undertakers of telephone exchange systems on an equal footing with the ministers to other public wants is indispensable to the carrying out of a scheme designed not only to meet the requirements of the moment but those of a reasonable number of years to come. Without such legislative assistance, which, I contend, cannot consistently be withheld, seeing that it is granted as a matter of course to railway, tramway, and other companies, the efficient and economical telephoning of great cities verges so near to the impossible that, during the remainder of my Paper, I shall assume that it will be forthcoming at the proper time.

As already indicated, the system of the future for all large towns must be founded upon the use of multiple switch-rooms, each serving its own immediate neighbourhood. All the subscribers' lines will then be short and economical to construct, while the switching apparatus, owing to sub-division, will be simple and cheap. These conditions will enable the annual payments by subscribers to be kept down to a minimum. All subscribers' lines will be metallic circuits. To the British Post Office (in the person of Mr. W. H. Preece) belongs the honour of being the first to insist on the necessity of double wires for telephone exchanges. When the Mutual Telephone Company started in Manchester, I advised them to have nothing to do with single wires, but to secure privacy and freedom from disturbing noises by using nothing but metallic circuits.

To obtain an efficient service with multiple switch-rooms by the aid of the switching apparatus ordinarily used in this country, with its intermediate electro-magnets and numerous complications, would be out of the question. A radical departure from existing practice must be made in this, as in other particulars. Fortunately, the way out of the difficulty lies ready to our hand.

For a good many years now a system known as the "Mann" has been operated with the greatest possible success in several districts, principally in Scotland. This system is unrivalled in many respects. It enables connections to be obtained with certainty and celerity; it renders easy the task—on some of the older exchanges an arduous and frequently impossible one—of getting rid of one connection and obtaining another. It simplifies and cheapens switching apparatus to an almost incredible degree, and it permits of connections being made through many switch-rooms without the intervention of intermediate electro-magnets, so that no retardation and indistinctness of speech results. The system possesses other conspicuous merits, but it is unnecessary to enlarge on them here. In one respect, and in one only, is the "Mann" system apparently more complicated and more expensive to instal than the ordinary. It necessitates the taking into each subscriber's office of a branch from a common service wire, on which all communications with the operators are conducted, and the addition to each subscriber's instrument of an extra piece of apparatus. But the complication is more imaginary than real, while the extra cost of the service wire and fittings is saved many times over in the switch-room, where an infinity of complicated and expensive apparatus is dispensed with, and where faults, and attendance by skilled electricians, are reduced to a minimum.

The main feature of the system is the service wire already mentioned. One such wire is allotted to every 60 to 100 subscribers, according to the amount of traffic passing. During the busy hours of the day operators are always listening on the service wires, so that subscribers may speak and be heard without any premonitory signals. By means of specially-constructed telephones, weighing but a little over two ounces, attached to the head by springs, the girls are enabled to listen continuously without fatigue, and at the same time keep both hands free for operating purposes. The subscriber, on his part, can at any moment place himself in communication with the operator by depressing a small lever, which has the effect of changing his instrument temporarily from his main line to the service wire. The mere depression of the lever suffices to secure her attention at any moment, so that mistakes can immediately be rectified and an explanation asked of any delay. The

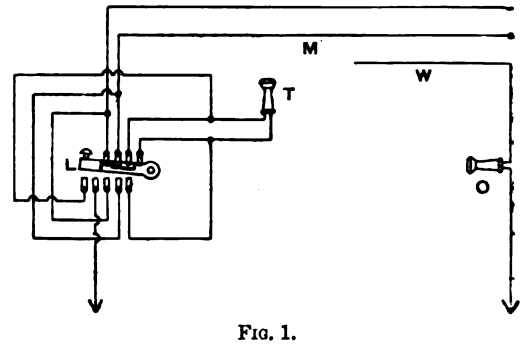

FIG. 1.

L, Subscriber's lever, changing his telephone from metallic circuit to earth.
M, Subscriber's metallic circuit forming, when lever is depressed, the subscriber's side of the condenser.
O, Operator's telephone.
T, Subscriber's telephone.
W, Insulated wire, forming operator's side of the condenser,

operators have not to do any ringing at the Exchange, the subscribers working their own call bells, thus leaving the girls to perform only the acts of connecting and disconnecting, a feature which greatly contributes to the rapidity for which the system is famed. A deal of labour is also saved by the absence of the ordinary shutter indicators, the putting up of which, after they have been dropped by the subscribers, constitutes a large part of the operator's work with other systems. The operator's telephone is always earthed: those of the subscribers only when their levers are depressed.

The experience gained at Manchester has enabled the one objection to the "Mann" system—the necessity of taking an additional wire into each subscriber's office—to be overcome. After having designed and partially constructed the Manchester Mutual Exchange on the "Mann" system, it occurred to me that it might be possible to convey the service messages between subscribers and operators by means of electrostatic induction between the subscriber's metallic loop and a special single wire run out for a sufficient distance from the Exchange amongst each group of metallic circuits.

On arranging the wires and apparatus in the manner indicated in Fig. 1, it was found that such a plan was really practicable. The connections of the subscriber's instrument were altered in such a way that, on depressing the lever, the metallic circuit (represented by M in the Diagram) was put to earth through the telephone. The metallic circuit then acted as a single wire of double area, and, whether insulated at the switch-board or connected through to another circuit, practically formed one plate of a condenser, the other plate or plates of which were any of the adjacent wires that happened to be earthed at their extremities. It was, therefore, only necessary to put the operator's instrument in permanent connection with one or more wires running parallel to the subscriber's metallic circuit for a short distance, to enable

Digitized by Google

any of the subscribers, whose instruments were so fitted, to communicate with the operator by depressing their levers. When the levers were not depressed, the telephones were looped in the metallic circuits as usual, and the operators could neither hear nor be heard.

When cables were used containing 36 or even 72 metallic circuits, it was only necessary to connect the operator's telephone to a single wire placed in the centre of the cable, or to the metallic sheathing of the cable, to obtain perfectly good speaking when the metallic loops were earthed by the subscribers depressing their levers.

When a connection has to be obtained through more than one switch-room it is asked for by each operator in succession by depressing a lever which puts her in communication with a service wire on which the operator at the next switch-room is listening.

I have recently devoted considerable thought to the problem of telephoning a great city like London. I have taken as a groundwork an area of 32 square miles, measuring eight from west to east, and four from north to south. Such an area would comprise the greater part of London, from Shepherd's Bush to Limehouse, and from Primrose Hill to Kennington Oval, and include the chief of the telephonic wealth of the metropolis.

In considering my plan, I have kept steadily in view the conditions I have stated to be indispensable, putting efficiency first and economy second, although, as it happens, I have found the two march well together. With the Mutual system vanishes the whole costly and complicated paraphernalia of American switch-room apparatus which has been so blindly copied in this country. As an instance of the economy effected, I may mention that in a switch-room fitted for 5,000 subscribers the first cost per subscriber on the American plan is about £3. 10s. for switching apparatus alone; on the Mutual plan adopted at Manchester, the cost per subscriber is about 10s. The difference in cost of maintenance is even more striking, while the efficiency is altogether in favour of the cheaper method.

As already indicated, I propose to telephone any large town by dividing it into sections about a square mile in area. In the centre of each square I would place a switch-room, making 32 sectional or branch switch-rooms in an area of 32 square miles. According to the configuration and general requirements of the town, I would establish one or two central switch-rooms. The subscribers in each section would be connected, each by a metallic circuit, to their appropriate switch-room, and the sectional switch-rooms would, in their turn, be connected to the central rooms by as many metallic circuits as the traffic passing through them may be found to require. In addition there would be, between the switch-rooms, a sufficient number of service wires—that is to say, metallic circuits reserved entirely for service communications between the operators. The mode of operation may be either the "Man" plan pure and simple, or the modification of it, which I have described. The subscribers' lines could be distinguished, as is usual, by numbers. The use of very high numbers could be avoided by assigning each switch-room a distinguishing name or code-word, and numbering its subscribers from one upwards. The central switch-room need not be exclusively reserved for operating junctions. It would probably be found advantageous to connect direct to it subscribers in its immediate vicinity, and for these a separate switch-board could be provided.

APPENDIX.

On an existing exchange worked according to Mann's system, each operator in ordinary course of business, deals with 180 connections per hour, or exactly three per minute, of which about half have to be obtained from, or given to, operators at other switch-rooms. On a special trial being made, by several inspectors being put on an operator's service wire, with instructions to supplement the ordinary traffic by demanding connections incessantly, the operator successfully dealt with 357 connections in exactly one hour. She therefore got through 5·95 per minute for 60 consecutive minutes, which gives an average for each connection, *including subsequent disconnections* of 10·09 seconds. Of these she completed 92 herself, 223 had to be asked from another switch-room, and 42 were given to another switch-room. All the usual incidental work was properly performed, such as informing callers that the subscriber wanted was engaged; ringing up callers, and notifying that the subscriber previously advised as engaged could now be had; answering repeated demands from impatient callers for engaged or dilatory subscribers; informing operators at other switch-rooms that subscribers wanted could not be had, with the reasons, and subsequently advising that they were free.

Special tests were made to ascertain the rate at which connections involving the attention of three different operators could be completed and subsequently got rid of. For this purpose a model conversation was arranged, each subscriber, on being rung up, being told, "This is the Telephone Manager's Office; is there one of my inspectors at your place just now?" Two tests were made, in each case 20 consecutive connections being demanded with subscribers taken at random from the list, except that only those were selected whose connections, owing to the position of their premises, would have to be handled by three operators. It was agreed before hand that if any subscriber called for left his bell unanswered for 60 seconds the experimenter would tell the operator to disconnect and give another. The tests took place during busy hours of the day, and were imposed on the ordinary traffic. Test A.—Twenty connections were made, but the twelfth subscriber asked for did not answer within the regulation minute, so that only nineteen model conversations were held. The first connection was asked at 10h. 1m. 0s., and the twentieth was done with at 10h. 19m. 40s. Deducting one minute lost over the subscriber not obtained, the average for the nineteen conversations had was 55·8 seconds. Test B.—Twenty connections were asked for, but one subscriber was engaged, and two others did not answer within the regulation minute; consequently only seventeen model conversations were held. The first connection was asked at noon precisely and the twentieth was done with at 12h. 14m. 20s. Deducting three minutes lost over the three not obtained, seventeen conversations were completed in 11m. 20s., giving an average of 40 seconds per conversation. Of the 680 seconds occupied, only 136 were taken up in asking for and making the connections; the balance was consumed in ringing the subscribers called, by their delay in answering, in putting the model question, and receiving the replies, which were not always confined to a monosyllabic negative.

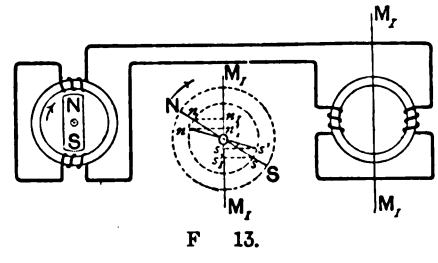
THE ELECTRIC TRANSMISSION OF POWER.*

BY GISBERT KAPP.

LECTURE III.

(Concluded from page 448.)

Owing to the low efficiency and small power of the two-wire revolving field motor, its employment is necessarily restricted to cases where these defects are of little consequence, but for the transmission of large powers over long distances it is not suitable. For such a purpose we must have three wires, but this is not a great drawback since the cost of the line is but little increased by the necessity of splitting up the total weight of copper into three instead of into two wires. The revolving field motor has, however, the defect that it is not self-regulating. Its speed may be anything between zero and that speed which will give synchronism between the two machines accordingly as the mechanial load varies from a maximum to nothing. This defect can be overcome by combining with the armature in the motor a real magnet which will force the armature to keep step with the current, and thus insure a constant speed at varying loads. The motor will thus start with great power by virtue of the currents induced in the armature-winding by the revolving field, and having reached the synchronising speed it will keep there by virtue of the interaction between the revolving field and the revolving magnet; it will, in fact, behave just like an ordinary alternator run as a motor, with this difference, however, that the ordinary alternator, if overloaded by 50 or 100 per cent., will be thrown out of step and come to rest, whereas the combined Ferraris and synchronising motor will always be ready to recover itself after the overload has been removed.



F 13.

Since the discovery of Ferraris has been made public, many engineers have turned their attention to revolving field motors, and especially to a modification of this principle, according to which three sets of coils are employed instead of two sets only. As far as I have been able to trace the history of this invention, the first to suggest the use of three coils were M. Tesla and Charles Bradley. The latter applied in the United States for a patent in 1888, which bears the number 409,450, and was granted on August 20, 1889. Next comes Wenstrom with his British patent, No. 5,423, of 1890, and at about the same time Dobrowolsky, in Berlin, had worked out a similar system. About a year ago, when I visited him at the works of the Berlin Electrical Company, he showed me such a three-wire motor in action, whilst shortly afterwards Charles Brown, of Oerlikon, took the matter up, and it may interest you to learn that he is at the present

* Cantor Lectures delivered before the Society of Arts, February and March, 1891.

Digitized by Google

moment putting up a 500 H.P. transmission plant on this system between Bülach and Oerlikon, a distance of 15 miles. This transmission is intended to supply all the power required in the Oerlikon Works. The general principle forming the basis of the work done by these various inventors is illustrated in Fig. 13. The generator contains a revolving field magnet, and an armature wound with three distinct coils. The end, O, of each coil is joined to a wire, W, common to all, and the three free ends are joined with the three-line wires. At the receiving station there is a three-legged magnet, the coils on the legs being in connection with the line wires on the one side, and jointed by a common wire, W, on the other side. It is easy to see that the rotation of the field magnet in the generator will produce successive polarities in the legs of the receiving magnet, and that the general effect will be that of a revolving field. The armature, A, will, therefore, be set in rotation in the same way as is the case in the original Ferraris motor. This kind of transmission is known in Germany under the name of transmission by the "three-phase current," and it is likely that it will, ere long, become a strong rival to the ordinary alternating current.

The diagrams I have brought before you were all drawn for two-pole machines, as this was the simplest way of making the principles clear; but I need hardly say that, in practice, the machines are made of the multipolar type, in order to bring the speeds down to any desired value.

You will, perhaps, ask why we should go to the complication of three-line wires and a totally new type of motor, seeing that, with the ordinary dynamos and motors, such excellent results have been obtained, and that with only two-line wires. My answer is that, with this new system, we can greatly extend the distance of transmission. I have spoken, a short time ago, of the difficulties which the high voltage required in long-distance transmission raised in connection with the commutators and general insulation of machines. Now, in the three-wire system of transmission, by alternating currents, we have no commutators, and, in fact, not even rubbing currents. One of our difficulties has, therefore, already vanished. As to the other, which has reference to the general insulation of the machines, it is easy to see how this may be overcome. We need only, instead of working direct, work through transformers. The insulation of transformers offers no difficulty whatever. I have here on the table a transformer of the type made by Messrs. Johnson and Phillipps, which has been designed specially for high-pressure currents, and is provided with oil insulation. I have recently used two of these transformers for testing a Brook's line. In one transformer the pressure was raised from 2,400 to 17,000 volts, the high-pressure current was sent through the line, and, at the other end, it was again transformed down to 2,400 volts, and, finally, to 100 volts, for lighting glow-lamps. The apparatus was kept running for several days without any difficulty. Mr. Brown informs me that he has with oil insulated transformers, even gone up to 36,000 volts without breaking down the insulation, and the Bülach-Oerlikon transmission will be made at 25,000 volts, whereas the machine will work only at a few hundred volts. There is thus no difficulty in adopting whatever voltage is most economical in each case, and yet avoiding all danger, either to the attendant or to the machines themselves, at the generating and motor station.

I feel that I owe an apology for having occupied so much of your time with discussing a branch of power transmission which, to many of you, must seem to be purely theoretical, and hardly ripe for discussion. My excuse must be that I am very strongly convinced that some form of alternate current working will be the ultimate solution of the problem how to transmit power—possibly over all distances, but certainly over very long distances—and that I was desirous of directing the attention of electrical engineers to a subject in which much work may still be done.

Electric Machine Tools.

In concluding my lectures, I wish to bring before you a few examples of short distance transmission as applied to electric machine tools. This branch of our subject has of late years received considerable development at the hands of various English firms, and, thanks to their enterprise and perseverance, is now a well-established method in several engineering works.

As an example, I may mention the Leven Shipyard of Messrs. Denny Brothers, at Dumbarton, and Mr. Archibald Denny has been good enough to give me some particulars of the work carried on by his firm in this direction. I cannot do better than quote his words:—"In our yard and engine works we have numerous instances of electric transmission of power. In our experimental tank we drive our model cutting machine and small lathes by means of a 3 H.P. Immisch motor. In our upholstery department we drive six sewing-machines with a 2 H.P. Immisch motor; of course in this case there is a large margin of power. In our experimental tank we have also used small motors for driving small model paddle wheels in our experimental models, and have obtained in this way most valuable data, which we could not have got by any other means. The power for all this work is obtained from a dynamo driven by an ordinary line of shafting in our joiner's shop. We also use a 3 H.P. motor in the yard for boring the stern tubes in place; before this we used a portable engine, which necessitated an attendant to fire the boiler and carry water to it. During the holidays, when all the boilers are off except one, we occasionally put down a motor for driving some lathes to do repair work, and this saves an attendant at more than one boiler. In our engine works the pattern shop is driven by a 15 H.P. Manchester motor, the dynamo being driven off the line of shafting in the fitting shop."

You see, Messrs. Denny Brothers find electric power transmission so handy, economical, and convenient, that they make extensive use of it. They employ a special tool for drilling the sole plates of engines, which I now show on the screen. The weight of the machine is sufficient for the pressure required on the drill, and the whole apparatus being mounted on wheels it can be rapidly shifted. The machine will drill 1¼in. holes through two thicknesses of inch plate in three minutes.

Another machine used at Leven Shipyard is a special drill for butt straps. The motor and gear are mounted on a stout vertical column with horizontal arm, so as to give adjustment in both directions, the column being bolted to the strap, as shown. The machine will take in straps 50in. deep by 23in. between outer rows of holes, and is chiefly used for drilling sheer strake double butt straps. The outside strap is first punched and counter-sunk, and the machine drills through the plate and inside strap. The machine is worked by two men—one hole-borer and one labourer—and will do three straps, or about 180 holes per day.

The rivet holes in boiler furnaces are also drilled by an electric tool, which I illustrate on the screen. The machine has a tripod stand arranged to go inside the furnace, but it has also holding-on magnets for outside work. One man with this machine does the work which formerly required three to four men.

No account of electric machine tools would be complete if it did not include the work done by Mr. Rowan, who has been very successful in developing this branch of power transmission. Amongst the improvements Mr. Rowan introduced is that of holding-on magnets, whereby the tools are firmly held in place while at work, and yet by the mere turning of a switch become liberated and can be shifted to a new position with the greatest ease. You see on the screen some of Mr. Rowland's drillers as applied to ship work. The apparatus is suspended on a chain over the ship's side, and supplied with current by means of two flexible wires. I need not detain you with a description of the picture on the screen because I can show you the actual machine at work, thanks to the kindness of Messrs. M'Whirter, Fergusson and Co., the makers, who have sent me one of their latest machines for this lecture.

I am also indebted to Mr. Webb, the locomotive superintendent of the London and North-Western Railway, for the loan of one of his electric tube cutters, which you see before you, and which I shall now work. A diagram of this machine to an enlarged scale is on the wall.

These few examples of what are properly called electric machine tools must suffice for this lecture, but there is another class of apparatus, namely, electric mining machines, which ought to be included in our subject. Several firms, both here and abroad, have of late years devoted considerable attention to the application of electric power to mining operations, such as pumping, hauling, coal-cutting, and drilling. Messrs. Goolden and Co., for instance, have during the last four years steadily and perseveringly worked out many of the difficult problems in connection with this subject, and I am indebted to this firm for the loan of the apparatus you see here, and also to Mr. Atkinson for assisting me in setting the machines up. After the excellent Paper which Mr. Atkinson read at the Institution of Civil Engineers, only a few weeks ago, it would be occupying your time uselessly if I were to give any lengthy description of these machines. I shall, therefore, merely show two types of mining motor on the screen, and show you a drill at work.

I have in these lectures not attempted to treat exhaustively any one branch of the subject, but have rather endeavoured to pass the various branches in rapid review, so that you may know what electric transmission of power can do and what it cannot do. We hear now-a-days very frequently the assertion that electricity is but in its infancy and will ere long be the sole motive power, driving our main-line trains, speeding our vessels across the ocean, and running our factories. These are idle dreams, ideas put forward by persons who have forgotten, or have never learned, the fundamental laws of nature. Do not waste time over such ideas, for there are other more hopeful problems, such as the utilisation of water-power generally, of waste coal at the pit's mouth, the working of railways in mountainous districts, where water-power is abundant all along the line, the working of tramways, underground town railways, the application of electric power to such purposes for which now small auxiliary steam engines are employed, and last, but not least, its application to machine tools and other special machinery, of which I have given you examples to-night.

THE LIGHTING OF RAILWAY TRAINS ELECTRICALLY.*

BY ILLIUS A. TIMMIS.

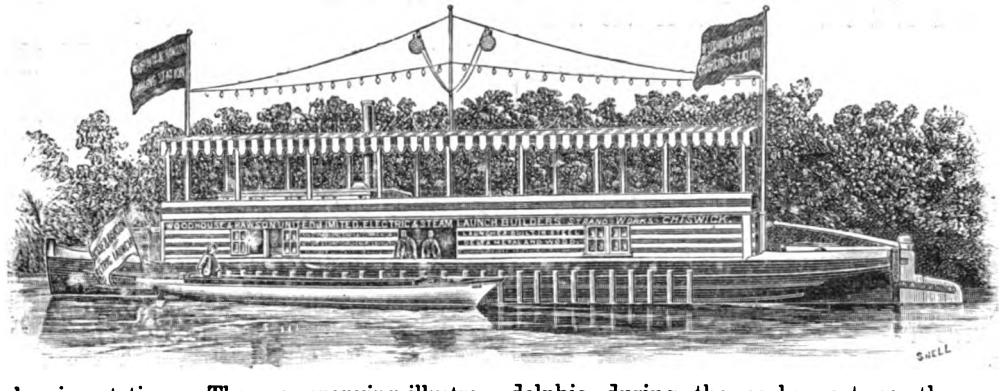
The author is of opinion that it is not advisable, here, to enter on any lengthened dissertation as to the relative merits of oil or gas or electricity as a means of lighting, as such, to be complete, would involve many intricate side issues connected with the expense of first cost, and the attendant and complex ones of maintenance and labour.

After stating the primary conditions to be observed in train lighting by electricity, and discussing the relative merits of axle driving, driving from a special engine on a train, and charging accumulators from plant employed to light large stations and goods-yards, the author describes the arrangements which he has found most suitable and economical for carrying out the above conditions and getting over all difficulties. He fits the carriages with 16 c.p. 50-volt lamps, and lights these lamps either with a special engine and dynamo on the train, or with a battery consisting of 26 accumulators placed in the guard's van. But as each carriage ought to carry its own store of electricity, and as it is not practicable to put 26 (or even 18) cells in each vehicle, he has worked out the following arrangement, his main object being to minimise the weight and cost of electric batteries. In addition to the main lighting, he places low voltage lamps (eight volts) in the carriages and a small four-cell battery in each carriage to light them. These small lamps are so arranged that as soon as a pair of couplers are separated they are automatically lighted in the carriages that are separated from the main circuit by the small batteries. They are also under the control of the guard. The small batteries are very light (weighing per carriage less than 1cwt.), they are not costly, and they are kept charged by the engine and dynamo or the main battery in the guard's van as required. Thus every carriage is free to be used in any train, and the only batteries that require special arrangements for charging, if any, are those in the guard's vans.

It must be remembered that the only times the auxiliary lamps are used are when a vehicle is taken off a train and perhaps put, for a few minutes, at the longest, into a siding and then joined on to another train, or when a vehicle is slipped from a train and while it is brought to a stop at the station, and during this time the auxiliary batteries give 6 to 8 c.p. in each auxiliary lamp. In the case of division of a train, for instance, where a long train of some 20 or more coaches splits up into, say, three divisions, then each division has at least one guard's van, and so it is, electrically and otherwise, if main batteries are used, a complete train; and if special engines and dynamos are used, the lighting is equally complete.

ELECTRIC LAUNCH FLOATING CHARGING STATION.

The number of electric launches upon the upper reaches of the Thames is constantly on the increase, and the business proves exceedingly remunerative to those engaged in it. An indispensable adjunct to an electric launch fleet are conveniently situated and well organised charging stations. The accompanying illustration shows a floating charging station, in appearance very similar to a house-boat. Each station consists of a river barge 80ft. long and 14ft. beam. The machinery is placed in a compartment at one end, and consists of a semi-portable steam-engine plant and dynamo of sufficient output to charge the accumulators on six launches simultaneously. The remaining portion of the boat contains a store-room, an office, sleeping apartments for the attendants, and an engineer's room, where a lathe is fixed and attendants are kept constantly in readiness to effect any repairs to launches which may be required.



Messrs. Woodhouse and Rawson United, to whom this floating station belongs, have also established stations at Kew, Chertsey, Windsor, and Abingdon.

* Abstract of a Paper read before the British Association, in Section G, Cardiff, 1891.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *August* 15, 1891.

Meeting of the Edison Association.—The annual meeting of the Association of Edison Illuminating Companies has been held at the Murray Hill Hotel in this city during the present week. A large number of Papers were read, some of them of great interest, but as usual the meetings were secret, and consequently no information of any value has crept out. A report of the proceedings has been furnished to the journals for next week, but it has been edited to such an extent as to prove of very little real value. Of course facts showing that the operation of the Edison station is not always perfect will crop out with unfortunate frequency, and these must be suppressed at all hazards. The Edison Company, by the way, has been losing some of its best engineers recently; Mr. Jackson, the Western district engineer, resigned a short time since to take the position of professor of electrical engineering in the University of Wisconsin, and Mr. H. Ward Leonard, for some time the head of the light and power business of the Edison Company, has also found it to his interest to abandon that organisation and go into business for himself. The reasons alleged for this move are various, but such changes have become sufficiently frequent since the last reorganisation of the Company to attract very little attention; in fact they are expected. Mr. Leonard has formed a new company and will occupy himself with general electrical engineering.

Electric Railway Work.—Of the large electrical companies there is comparatively little to be said. The Thomson-Houston Company is exceedingly busy, and doing an immense amount of work, especially in the railway and motor departments. The Edison Company is confining itself more strictly than ever to incandescent lighting, and the railway business especially seems to be slow in developing. Of the new single reduction gear motors, manufactured by this Company, and mentioned in one of my letters some time since, nothing has been heard. It is reported that orders have been taken and some machines have been sent out, but everybody is in profound ignorance as to where they have gone, or whether the machine is a success. The Westinghouse Company is going quietly along, and transacting quite a little business in spite of its financial embarrassments.

Waddell-Entz Accumulator Car.—The Waddell-Entz accumulator car, which made such a successful showing in Philadelphia during the early part of the summer, has been undergoing tests at Chester, Pa, and has acquitted itself remarkably well. The batteries seem to hold out well, and the motor leaves little to be desired. In view of the very broad Brush decision *re* storage batteries, the advent of this latter system is particularly interesting, although it is claimed by some that it—like the lead batteries—will be swept up by the "drag-net" claim that Brush was allowed to pass through the Patent Office, and that has been since sustained.

The Greathead Tunnel System in New York.—The report of the first half-year's working of the City and South London Railway has attracted a great deal of attention here, especially among practical railroad men. A very strong clique in this city favours the adoption of the tubular iron tunnel for the

Digitized by Google

rapid transit system to be at some time in the dim future laid down on Manhattan Island. Just what organisation is pushing this particular matter it is impossible to determine. Mr. F. J. Sprague, the well-known electrical engineer, has come out in its favour in such an outspoken fashion as to suggest that he will be likely to take a hand in the electrical work if the aforesaid system should be used. The engineers of the Rapid Transit Commission are still engaged in their secret deliberations, working up an agglomerated plan at the expense of the unfortunate experts who have put time and money into laying well-considered methods of construction before the Commission. It is generally understood that the engineers are working on a combination of the Greathead iron tunnels and a double-deck single tunnel to accommodate four tracks.

SCANDINAVIAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

COPENHAGEN, *August* 22, 1891.

Although Norway cannot vie with Sweden as regards the use of the telephone, this instrument is being more and more adopted there. The number of subscribers in Christiania now exceeds 2,700. In addition, there are 300 subscribers to independent telephone companies, outside Christiania, that have connection with the Christiania Telephone Company. The number of conversations is about 15,000 per working day.

The Swedish State Telegraphs have had printed a complete catalogue over their telephones, which is quite a formidable volume, consisting of 379 pages, with maps and tables of the various rates for telephoning. Since the last catalogue, which was published on November 15th, last year, the number of subscribers has increased by 2,189 (from 987 to 3,176). The number of exchanges has risen from 34 to 73.

The Swedish State Telegraphs have obtained the permission of the Government to immediately commence work on the following telephone trunk lines:—Gothenburg-Malinö, Gothenburg-Jönköping, Stockholm-Upsala, Pitea-Glaporonda, Uddevalla-Strömstad. The new lines are calculated to entail a total expenditure of about £9,600. The Swedish State telegraphs had, at the beginning of the present year, cables and lines of an aggregate length of 8,785 kilometres, and wires of an aggregate length of 22,884 kilometres. The rated telegrams, during 1890, numbered 1,755,345, those not rated 65,331, making altogether 1,820,676 messages, or 46,593 more than during the previous year. The receipts on the telegrams paid for amounted to 1,969,895kr., of which 1,412,619kr. represent the net taking of the telegraphs, being 18,286kr. in excess of the figures for the previous year. The length of the telephone lines under the State telegraphs amounted to an aggregate of 12,779 kilometres at the beginning of the present year. During 1890 a sum of 914,067kr. (£45,700) were expended in the development of the State telephones.

The works in connection with the Copenhagen Central Electric Station are now being energetically pushed on. The laying of the cables in the streets is in full swing, and the whole installation is expected to be ready towards the close of the present year.

The month of August has been singularly prolific in thunderstorms in both Denmark, Norway, and Sweden—more so, however, in Denmark than in the neighbouring countries. A large number of casualties have occurred, many fires have been caused by lightning, and a great many lives have been lost. On one day early in this month no less than seven persons were killed by lightning in Denmark alone, all isolated cases, in different parts of the country, some in the fields and two or three in the houses. The cattle have also suffered severely.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

August 17, 1871.

13,865. E. EDWARDS. London. Improvements in apparatus for giving notice, by means of electricity, of the heating of bearings. (A. Backhaus, Germany).

August 18, 1891.

13,917. D. H. SMITH. Glasgow. Improvements in telegraphing.

13,926. L. B. ATKINSON, C. W. ATKINSON, and F. HURD. London. Improvements in electric locomotives and in electric conductors for use therewith.

13,927. H. VAN HOEVENBERGH. London. A unison apparatus for printing telegraphs.

13,942. T. PARKER, J. H. WOODWARD, and E. S. G. REES. London. Improvements in or connected with apparatus for completing and interrupting electric circuits.

August 19, 1891.

13,961. A. R. BENNETT. London. Appliances for an electrical parcel exchange system.

14,023. C. RAAB. London. Improvements in electrometers.

14,040. H. H. LAKE. London. Improvements in electric lighting and extinguishing apparatus for gas burners. (A. Orling, Sweden).

14,042. O. T. COOPER. London. Improvements in electric lamp-holders.

14,063. A. MARR. Manchester. Improvements in telephonic transmitters.

14,067. D. RYLANDS and B. STONER. Stairfoot. Improvements in moulds and machinery for the manufacture of glass switch slabs for electrical and other purposes.

14,084. J. APPLETON and W. T. BURLEY. London. Improvements in electrically actuated time checking apparatus.

14,089. A. RECKENZAUN. London. Improvements in electrical measuring apparatus.

14,096. J. G. THOMPSON. London. Combination electric lock.

14,150. H. MORGAN. London. Improvements in electric fire detectors or alarms. (C. Dion, France).

TRADE NOTES AND NOTICES.

TENDERS INVITED.—The Corporation of South Shields is desirous of receiving proposals for the laying down, manufacture, supply, and working of the electric light in the borough, a Provisional Order for which has been obtained. Tenders to be sent to Mr. Joseph M. Moore, town clerk, by September 16th.

FOR SALE.—Our advertisement columns contain particulars of a complete electrical installation for sale, in good order, consisting of:—Two pairs of engines, each 75 H.P., high-pressure, non-condensing, 12in. cylinders, 10in. stroke, and two 4-pole Elwell-Parker dynamos, producing 450 amperes at 100 volts, speed 500 revolutions. Further particulars may be obtained of The Manager, Hotel Victoria, Northumberland-avenue, London, W.C.

PERSONAL.—We are informed that Messrs. Drake and Gorham have severed their connection with the Electrical Accessories Company, Limited.

THE GENERAL ELECTRIC COMPANY.—This Company are issuing illustrated particulars of the "Lancashire" Pendulum Movement, which they claim to be efficient, easily mounted, cheap, and reliable. The Company announce that they are able, in consequence of the large demand for the Pendulum Indicators, to make the reductions in price which are set out in the particulars now issued.

MESSRS. DRAKE AND GORHAM.—The electric lighting of Wynyard Park, the seat of the Marquis of Londonderry, is now practically complete, and the light is stated to give great satisfaction. The installation consists of two Davey-Paxman horizontal engines, supplied by two Lancashire boilers, each engine driving a 40-unit Kapp dynamo manufactured by Messrs. Johnson and Phillips. A subsidiary plant has also been installed, consisting of a Robey engine, driving a 15-unit dynamo every night, or when only a small current is required. Upwards of 1,000 lamps are arranged chiefly upon the massive fittings which form a special

Digitized by Google

feature at Wynyard. The boilers also supply steam for other purposes, such as pumping and for driving a fire engine. The whole of the installation was designed by Messrs. Drake and Gorham, and carried out under the superintendence of Mr. A. A. Campbell Swinton.

THE RECENT ST. PANCRAS ELECTRICAL EXHIBITION.—We have received from Messrs. H. F. Joel and Co., of Wilson-street, Finsbury-square, E.C., a letter referring to a circular issued by the Committee of this Exhibition, in which Messrs. Joel and Co. figure as debtors on account of their exhibit. Messrs. Joel and Co. complain that they have not been fairly treated, but the grievance is a personal one, and the amount in dispute is very small.

THE IMPROVED BENARDOS PROCESS OF ELECTRIC WELDING.—Messrs. Lloyd and Lloyd inform us that they are enlarging their installation of this process, which they claim to have successfully applied to the manufacture of iron and steel tubes and fittings. A very extensive series of some hundreds of tests has been made by Messrs. David Kirkaldy and Son of bars of various brands of iron and steel, in order to test the nature of the welds, and Messrs. Lloyd and Lloyd state that the results obtained show that a fibrous fracture can be relied upon at the weld with iron, and a silky fracture with steel, and that the contraction of area at fracture and extension, as well as the ratio of weld to solid, are all maintained at high average figures. The firm intend shortly to invite a number of leading engineers to inspect the process at their Works.

"ARCAS" PLATING.—We have received particulars relating to the "Arcas" system of plating on metals. It is claimed by the London Metallurgical Company (Limited), who are the owners of the patents, that the "Arcas" system nas many advantages over silver and nickel electro-plating, and is peculiarly adapted for electrical fittings, instruments, and similar metal work. Some testimonials, which accompany the particulars, speak highly of the work done by the Metallurgical Company.

NEW COMPANIES, STATUTORY RETURNS, &c.

COMBINATION TYRE COMPANY (LIMITED).—This Company was registered on August 22, 1891, with a capital of £2,000 in £1 shares. The objects are:—To acquire and carry on the business of "Markus and Co." To carry on the business of mechanical and electrical engineers, machinists, tube makers, galvanisers, electro-platers, tyre manufacturers, india rubber merchants, &c. Registered without special articles.

DARLASTON CYCLE COMPANY (LIMITED).—This Company was registered on August 18, 1891, with a capital of £10,000 in £10 shares, by Jordan and Sons, 120, Chancery-lane, W.C. Its objects are:—To manufacture cycles of every description, and to carry on the business of mechanical and electrical engineers, electro-platers, wire drawers, metal tube manufacturers, iron and brass founders, machinists, &c. Office: Atalanta Works, Foster-street, Darlaston, Stafford.

ELECTRIC WELDING COMPANY (LIMITED).—This Company has been formed with a capital of £460,000, divided into 45,000 ordinary shares of £10 each, and 1,000 founders' shares of £10 each. The prospectus states that the present issue consists of 25,000 ordinary shares, and the founders' shares, of which issue the vendors take 8,333 ordinary shares. The shares are payable—10s. on application, £3. 10s. on allotment, and £2 two months after allotment. The ordinary shares will be entitled to a cumulative dividend of 10 per cent., and the surplus is to be divisible, one half each upon the ordinary shares and upon the founders' shares. The Directors include Captain A. H. Chapman, J.P., of Messrs. Clarke, Chapman, and Company Victoria Works, Gateshead-on-Tyne; Mr. William F. Gooch, J.P., Managing Director of the Vulcan Ironworks Company, Limited; and Mr. Joseph Kincaid, of the York Engineering Company, Limited. The consulting engineer is Sir Frederick Bramwell, Bart. The secretary (*pro tem.*) is Mr. Robert Gordon, and the offices are situate at 2, Tokenhouse-buildings, King's Arms-yard, E.C. The object of the Company is to acquire the British patents in respect of Elihu Thomson's inventions for the electric welding and working of metals. In America a foundry exists in which about 250 hands are employed in producing the machines. The prospectus contains a number of favourable reports from various firms who are using the machines. It is not proposed to sell the machines right out, but they are to be delivered for a specified sum, and a small royalty is to be paid to the Company for their use. It is estimated that in the United Kingdom there are sufficient works, trades, &c., to create a great demand for electric welding machines, and that if only a small proportion of such works are supplied the profits from royalties alone will make a good return upon the capital of the present Company. The lists of application will close on or before to-morrow (Saturday).

ESTATES IMPROVEMENT COMPANY (LIMITED).—This Company was registered on August 20, 1891, with a capital of £25,000 in £100 shares. The objects are:—To acquire and develop lands and buildings in the County of Middlesex, to construct, maintain, improve, develop, and control electric power, heat, and light supply works, telephone works, &c. The regulations of Table A mainly apply.

GENERAL SAFE DEPOSIT SYNDICATE (LIMITED).—This Company was registered on August 22, 1891, with a capital of £5,000 in £10 shares. The objects of the Company are, amongst others, to carry on the business of mechanical and electrical engineers, safe manufacturers and dealers, locksmiths, &c. Registered without special articles. Office: 3, Pope's Head-alley, Cornhill, London, E.C.

GEORGE SPENCER, MOULTON AND COMPANY (LIMITED).—This Company was registered on August 22, 1891, with a capital of £233,130 in £10 shares, by F. J. Abbott, 40 and 42, Queen Victoria-street, E C. The objects are:—To acquire and take over as going concerns; first, the business of india-rubber manufacturers carried on by Stephen Moulton and Co., at Bradford, Wiltshire, and second, the business of india-rubber spring manufacturers, carried on by George Spencer and Co., at 77, Cannon-street, E.C., and 81, Southwark-street, S.E., and to carry on the business of india-rubber and gutta-percha manufacturers. The first Directors are H. Moulton, J. Moulton, E. S. Stidolph, A. G. Spencer, A. Spencer, and F. Spencer.

LLANBRADACH LAND AND BUILDING INVESTMENT COMPANY (LIMITED).—This Company was registered on August 24, 1891, with a capital of £10,000 in £10 shares, by Jordan and Sons, 120, Chancery-lane, W.C. It intends to acquire and develop property of all kinds. To construct, maintain, work, and control gas and water works, roads, tramways electric power, heat and light supply works, telephone works, &c. Registered without special articles. Office: Court House-street, Pontypridd.

MARTINY (LIMITED).—This Company was registered on August 20, 1891, with a capital of £200,000, divided into 40,000 ordinary and 10,000 Five per Cent. Preference Shares of £4 each, by Michael Abrahams, Sons, and Co., 8, Old Jewry, E.C. The objects are:—To acquire and take over as a going concern the business of The New Asbestos Company (Limited), upon the terms of an unregistered agreement dated July 2, 1891, between The New Asbestos Company (Limited) of the one part, and John Simpson of the other part. To acquire and take over the business of Messrs. Martiny and Co., of Paris, india-rubber, gutta-percha, and cable manufacturers, upon the terms of an unregistered agreement, dated June 19, 1891, between Martiny and Co., of the one part, and J. Simpson, for this Company, of the other part. To carry on the above businesses in all their respective branches. To manufacture among other articles, telegraph and other cables and wires, india-rubber, gutta-percha, and asbestos goods of every description. The number of Directors is not to be less than three nor more than seven. Qualification, £1,000 shares or stock. £900, with an additional £100 for the chairman, will be divided annually among the Directors as remuneration, together with a sum equal to one-tenth of the profits after the payment of the preferential dividend and 6 per cent. on the ordinary shares.

OXFORD ELECTRIC COMPANY (LIMITED).—This Company was registered on August 24, 1891, with a capital of £100,000 in £5 shares, by Walter Webb and Co., 23, Queen Victoria-street, E.C. The objects are:—To carry on in the City of Oxford and neighbourhood the business of an Electric Lighting Company in all its branches. To produce and supply electricity and electrical energy for the purposes of light, heat, or motive power. To enter into an agreement with the Electric Construction Corporation (Limited). To manufacture, sell, deal in, and let out for hire, engines, machinery, wires, lamps, instruments, and apparatus of all kinds for the production, storage, supply, measurement, use, or application of electricity. The subscribers are:—

	Shares.
J. Irving Courtenay, M.A., Trinity College, Oxford	1
H. Musgrove, Seymour Villa, Anerley	1
George Offor, 4, Great Winchester-street, E.C.	1
J. Ebbsmith, 86, St. James's-street, S.W.	1
R. Buckell, 32, Beaumont-street, Oxford (Mayor of Oxford)	1
T. Lucas, North Land, Oxford (Sheriff)	1
T. Green, 25, Leckford-road, Oxford (Alderman)	1

The number of Directors is not to be less than three nor more than seven, the first to be appointed by the subscribers. Qualification, £250. The Company in general meeting will determine remuneration.

BRITISH ELECTRO-CHEMICAL AGENCY (LIMITED).—The registered office of this Company is situate at Worcester House, Walbrook, London, E.C.

ENERGY GAS, ELECTRIC LIGHTING AND POWER COMPANY (LIMITED).—The registered office of this Company is situated at 5, Chancery Lane London, W.C.

MUNICIPAL ELECTRIC LIGHT AND POWER CORPORATION (LIMITED).—The annual return of this Company, made up to December 31, 1890, was filed on August 18, 1891. The Company was registered on June 5, 1889, with a capital of £25,000, divided into 2,490 ordinary shares of £10 each and 100 founders' shares of £1 each. 37 ordinary and 30 founders' shares have been taken up; upon all of the ordinary the full amount has been called. The 30 founders are considered as fully paid. The calls paid amount to £210, and unpaid to £160. The annual return, made up to August 14, 1891, was filed on August 18, 1891. The same number of shares are taken up, and all the calls are paid, amounting to £370. Office: 33, Old Broad-street, E.C.

UNION ELECTRICAL POWER AND LIGHT COMPANY (LIMITED).—In the High Court of Justice, Chancery Division, Mr. Justice Chitty (at Chambers). Upon the application of Harrington E. Broad, the official liquidator of the above-named Company, it was ordered that since the affairs of the Company had been completely wound up except the application of £217. 9s., the solicitors of the Company, Messrs. Linklater and Co., of 2, Bond-court, Walbrook, should receive £157. 13s., 2d., being the amount o their taxed costs, and that the liquidator be at liberty to retain the remainder (£59. 15s. 10d.) in full discharge for all his claims. It was also

Digitized by Google

ordered that the said Company be dissolved as from June 26, 1891. This Company was registered on December 6, 1886, with a capital of £500,000, in £5 shares, which capital was, by a special resolution passed March 4, 1887, and confirmed March 22, 1887, reduced to £100,000, in £5 shares. Since its incorporation only 70 shares have been taken up, nothing being paid thereon.

With reference to a note under this heading in our last issue, Messrs. Laurence. Scott and Co. write us:—"We notice in your last issue, under the heading of New Companies, Statutory Returns, &c., an abstract of agreement made between us and the Ipswich Electricity Supply Company (Limited). This abstract would lead your readers to suppose that we have disposed of our business, which is not the case. The agreement referred to does not in any way interfere with our regular business, but was made simply to facilitate the development of the supply of electricity in Ipswich by transferring the existing supply station from us to the Ipswich Electricity Supply Company, in which company we retain a substantial interest. It will be seen, therefore, that the agreement in question concerns the Ipswich Supply Company only."

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the past week were £4,186.

CITY AND SOUTH LONDON RAILWAY COMPANY.—The traffic receipts of this Company for the week ended August 23rd amounted to £728.

LONDON PLATINO-BRAZILIAN TELEGRAPH COMPANY (LIMITED).—The half-yearly coupon on the Six per Cent. Debentures of this Company, due on September 1st, will be paid at the banking house of Messrs. Glyn, Mills, and Co., Lombard-street, E.C.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended August 21st, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company were £2,812.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 694.—Vol. XXVII. FRIDAY, SEPTEMBER 4, 1891. Price Fourpence.

NOTES.

The Electrical Standards Committee, which was appointed by the Board of Trade in December last, practically concluded its labours on July 23rd, when the Report, published last week, embodying the resolutions which had been arrived at was finally agreed to and passed. It now only remains for the Committee to receive and adopt the specification with regard to the preparation and use of the Clark cell, and to approve of the specifications referred to in the schedule of the Draft Order in Council, appended to the Report. The Clark cell was the subject of considerable discussion, although the task of drawing up the specification relating to it was, at an early stage in the proceedings, delegated to a Sub-Committee, composed of Lord Rayleigh, Mr. R. T. Glazebrook, and Major Cardew, in whose hands it is still left. However satisfactory a standard the Clark cell may be when constructed with scrupulous care by skilled and experienced individuals, and used by them with due precautions, it apparently leaves something to be desired when made and used by the "average man," in accordance with concise written instructions.

If anyone was apprehensive lest the consultations of the Committee should result in the legalisation of "abstractions," the schedule appended to the Draft Order in Council, which, together with the Report, will be found in another column, will be eminently consolatory. The ohm is no longer "1,000,000,000 in terms of the centimetre and the second of time," but "the resistance offered by the coil of metal marked . . . . ." Similarly the ampere is that current which when passed through a certain marked instrument exerts a certain electromagnetic effort, balanced at Westminster by a certain marked platinum weight, and in much the same way the volt also develops into an unmistakable "concrete."

Although the resolutions, as finally agreed to, do not differ in any material respect from those contained in the Draft Memorandum, published in *The Electrician* of February 13th, much labour was expended on verbal refinements, with the laudable view of attaining something like mathematical accuracy of definition. In the case of Resolution No. 13, or, as it then was, Resolution No. 11, the strivings after the ideal were particularly painful.

As originally drafted, the clause ran as follows:—"That the standard of electrical pressure should be denominated the volt, being the pressure which, if steadily applied, will produce a current of one ampere in a conductor whose resistance is one ohm, *provided that the current is doing no work.*" Around the words we have italicised there immediately arose a remarkably energetic controversy. Mr. Glazebrook thought the adjective "external" should be interpolated. On the other hand, Sir William Thomson, Lord Rayleigh, and Mr. Preece, were for lopping off the offending member. The Electrical Adviser to the Board of Trade advocated the retention of the final sentence; the resistance might, he said, be the armature of a dynamo, a chemical solution, a thermo-electric couple, or what not. Sir William Thomson was prepared to defend the clause, without the reference to work, before the whole world, "Taking all the text books that have ever been written, taking all the definitions of ohm, separating them from deposits of polarisation, this stands unambiguous," was his emphatic declaration. Nevertheless, the Electrical Adviser to the Board of Trade ventured to reopen the question at the next meeting of the Committee. With all respect to Sir William Thomson, he "did not much like no allusion being made to the possibility of there being an electromotive force." "Homogeneous metallic conductor at rest in an unvarying magnetic field" was thereupon suggested. This proposal immediately started a discussion on another point, which continued, notwithstanding Lord Rayleigh's remark that "if you want to state everything you will have to write half a treatise on it." Finally, the Committee gave up the attempt, and left the resolution as it now stands, it being, in Prof. Carey Foster's opinion, "perfectly intelligible with a little common sense applied to it."

The only resolutions which have been added to the first draft are Nos. 8, 15, and 16. Two more were, however, brought forward, one defining the "volt × ampere," and christening it the "watt;" the other defining the Board of Trade unit of electrical supply, and labelling it the *bot*. Not meeting with general acceptance, these clauses were cheerfully withdrawn by their originator.

In a letter to *The Times* of August 20th, the Duke of Marlborough, who has already on several occasions raised the question in the House of Lords, has a good deal to say about the telephone. He announces that "a new company, which possesses a licence from the Postmaster-General, is about to promote a Bill before Parliament next Session with the object of establishing a complete twin-wire telephone service for the whole of London on the basis of a £10 a year rental." We

Digitized by Google

sincerely trust that this promising concern has good technical advisers and ample financial support behind it, for the task of ousting the National Company from the metropolis will, indeed, be no light one. Some little time ago we ventured to hope that either the metropolitan rates would come down, or the efficiency of the service would go up, but here we are led to expect both boons simultaneously. Meanwhile, to quote Mr. FAITHFULL BEGG's letter to *The Times* of yesterday, some may be of opinion that "the best possible thing to be done will be to let the proposed new Company try it and give us the benefit of their experience."

MR. BEGG, whose letter will be found elsewhere in our columns, takes up the cudgels on behalf of the National Company, and certainly succeeds in making out a strong case for it. All that concerns the London public, however, is how best to secure an efficient telephone service at a reasonable rate; and at first glance, we must confess we do not see why in the present instance order should be evolved out of the chaos of competition. If, after a proper period has elapsed, the National Company should fail to rise to the occasion, perhaps the strong arm of the Post Office would prove a more effective weapon than joint-stock competition.

THE *Philosophical Magazine* for August contains an interesting Paper by Prof. PERRY, detailing the results of many laborious calculations with reference to the behaviour of transformers. As was necessarily the case, the transformer studied was of the pure mathematical type, and Prof. PERRY excuses the assumptions made of constant permeability, and the absence of losses due to hysteresis, and eddy current losses, on the grounds that the laws of a transformer are not yet known even under these conditions, and that if these laws are found out it will be possible, by comparing the theoretical results with those obtained experimentally with actual transformers, to obtain useful information concerning the influence of the neglected phenomena. This process may be objected to on account of the impossible efficiency, sometimes as high as 99 per cent., which such a transformer possesses. On the other hand, it must be admitted that the assumptions made by various writers, in order to make their calculations fit with actual results, have often been somewhat reckless, while the practical difficulties in the way of accurate testing are far too great for the experiments hitherto published to be reliable in detail. The numerous tables of calculations accompanying the Paper contain results which no experiment could have detected. For instance, angles of lag are given accurately to the sixth figure, whereas lags of from 175deg. to 180deg. could hardly be distinguished from each other by measuring instruments.

THE most important results of the investigation are those referring to the influence of magnetic leakage. The effect of such leakage is to considerably increase the angle of lag between the primary volts and amperes. The efficiency of the transformer is, however, affected but little. If there is no magnetic leakage the product of primary volts and amperes is very approximately equal to the power supplied in watts for nearly the whole range of load for which the transformer is intended. If, however, magnetic leakage occurs, this is by no means the case, and the product is greater than the true watts, even for heavy loads.

IT has been somewhat longer on the way than we anticipated, but it is satisfactory to find that nevertheless it has at last arrived. We refer to the enunciation in the daily Press of the theory of the possibility if not probability of the existence of some hidden connection between the late thundery weather and the recent development of electric lighting in London. Can any clever meteorologist explain the phenomenon which some persons have already attributed to the electric light, says a contributor to the *Daily Graphic* of August 22nd? "Without committing oneself to any wild theory, which may be easily started by the ignorant, one may be allowed to question whether, even among scientific men, any idea can be formed of the consequences of permeating London with the electric fluid as it is at the present moment. This permeation is daily increasing, and in a few years' time the whole of London will have wires running in every direction, on a system as elaborate as the nerves in the human body. Experts should be able to tell us whether there lurks any danger in this universal wiring."

Shoreditch Vestry.—This Vestry has decided to obtain power to supply electricity within the parish of Shoreditch for public and private purposes.

New Books.—Messrs. Whittaker and Co. are about to bring out a book by Mr. W. Perren Maycock, entitled "A First Book of Electricity and Magnetism."

The Telephone in the Field.—The headquarters of the four army corps now manœuvering in the vicinity of Bar-sur-Aube are all connected by telephone, the utility of which is to be thoroughly tested.

Telephone Line between Leipzig and Dresden.—The telephone line between Leipzig and Dresden (80 miles) was opened on the 26th ult. The charge made is one shilling for three minutes' conversation.

University College of North Wales.—Prof. Andrew Gray will begin, in October next, a systematic course of instruction in electrical measurement and practical electricity at this college. For further particulars see our advertisement columns.

Train Lighting in France.—It is reported that, after several successful experiments with the electric lighting of the trains on the Paris, Lyons, and Mediterranean line, the Company have definitely decided to light the whole of their trains in that manner.

Personal.—Mr. J. Edward Waller, who has for many years been associated with Mr. Joseph Kincaid as his manager, has entered into partnership with Mr. Edward Manville, consulting electrical engineer. Messrs. Waller and Manville will carry on business at 39, Victoria-street.

Guernsey Electric Railway.—As the Channel Islands are outside the jurisdiction of the Board of Trade, the supervision of the erection of this line is being carried out by the Special States Committee, who have appointed Mr. Bernard Drake as their electrical adviser.

Manchester.—The City Council have passed a resolution to apply to the Local Government Board for sanction to borrow £150,000 for Corporation electric lighting scheme. Sir John Harwood stated that the whole arrangements had been placed in Dr. Hopkinson's hands.

Institution of Electrical Engineers.—At a "special general meeting of members only," held at the offices of the Institution, on Monday last, Mr. Alexander Siemens, vice-president, in the chair, the special resolution passed at the meeting of August 13th was unanimously confirmed.

Digitized by Google

Technical Education.—We understand that the Professorship of Physics at Aberystwith College is now vacant, owing to the resignation of Prof. D. E. Jones, who has accepted an appointment as Organising Secretary or Director of Technical Instruction to the Staffordshire County Council.

Obituary.—We regret to have to record the death of one of the members of the Old Students' Association, at the age of 22. Mr. George T. S. Muller, who was well known to most of the members of this association, was drowned at Hampstead bathing-pond on Friday morning, August 28th, being suddenly seized with cramp.

Copper.—According to Messrs. H. H. Merton and Co., the total stocks on the 31st ult. amounted to 58,829 tons, as compared with 57,782 tons on the 31st of July and 69,959 tons a year ago. Deliveries during August, as during July, have been on a low scale, amounting only to 8,306 tons, as against an average of 10,672 tons per month for the preceding eleven months.

Telegraphic Communication with Mashonaland.—The telegraph has been continued from Fort Tuli to Fort Victoria, and one month ago it had been extended 60 miles north of the latter place, or for nearly 300 miles north of the former station. The wire is carried on iron poles as far as Fort Tuli, and the British South Africa Company has expended as much as £60,000 in establishing telegraphic communication with Mashonaland, which is thus brought within five hours, telegraphically, of London.

Conservatory Lighting.—The Société Electricité et Hydraulique of Charleroi has obtained the contract for lighting the conservatories attached to the King of the Belgians' palace at Laerkin. The palm houses were experimentally illuminated by electricity in the spring, and the effects produced were so charming that it was immediately decided to light up all the conservatories in the same way. About 1,000 incandescents and 40 arcs will be required and the three-wire system will be used.

Telegraphic Communication with Brazil and the River Plate.—The Western and Brazilian Telegraph Company announces that, under the arrangements recently concluded with the Brazilian Government, its system has been strengthened by loop cables being laid from Pernambuco to Bahia, Bahia to Rio de Janeiro, and Rio de Janeiro to Santos, thus giving a complete duplicate service of cables from London to Pernambuco, Bahia, Rio de Janeiro, and Santos, in Brazil, and thence a direct cable for the service with the River Plate. These new cables will afford greatly increased facilities in the working of the traffic between South America and Europe.

The Electric Lighting Accident on the Great Northern Railway.—The accident in connection with the electric lighting apparatus, which occurred on Thursday morning last week, to the 9:17 Great Northern train from Barnet to Moorgate-street, was scarcely of as alarming a character as the daily papers would have us believe. The fire was a very small affair and caused little or no damage. It arose through a slight accumulation of dust from the brushes, and this heating caused the wood covering to get charred. No electrical attendant was travelling with the train, as they only travel occasionally for the purpose of oiling and cleaning.

The Growth of Electric Lighting in London.—The able article on this subject which appeared in *The Times* for August 19th has drawn several letters from well-known electrical engineers. Mr. R. E. Crompton contributed a letter a column long to *The Times* of Saturday last, in which he maintained his familiar thesis that the Electric Lighting Act of 1882 cannot be accepted as a blessing in disguise, because it killed unsound speculation and prevented crude work. Mr. Crompton states that he was as well able to design a low-pressure station in 1883 as in 1891, and that *bonâ fide* investors were frightened at the same time that speculation was crushed out.

The Telegraph in Morocco.—According to a Reuter's telegram from Tangier, the Angera tribe, in the vicinity of Tangier, have stubbornly opposed the erection of telegraph posts, by Spaniards, within their territory. The Spanish Minister to Morocco, therefore, made strong representations to the Minister for Foreign Affairs against the hostile attitude of the people, in consequence of which the Moorish Minister immediately despatched a courier to the Governor of Tetuan, under whose jurisdiction the Angera tribe is placed, but without any satisfactory result, the Sheikhs of Angera refusing to obey the Governor's orders.

Extension of the Clermont-Ferrand Electric Railway.—Permission has been given to prolong the electric railway connecting Clermont-Ferrand with Royat-les-Bains (4½ miles distant) to the summit of the Puy-de-Dôme, which is 5,000ft. above the level of the sea. The extension will be completed in about eighteen months, and will comprise examples of the ordinary adhesive system of traction, as well as of the rack and funicular methods. The line between Clermont-Ferrand and Royat has been in successful operation for some little time past. The current is supplied at a pressure of 300 volts, an overhead conductor and rail return being employed. The conductor is a slotted copper tube, inside which runs a sliding contact, consisting of a string of bronze balls connected together by a piece of wire. Each car carries 50 passengers, and is worked through Vaucanson chain gearing by a 40 H.P. motor.

Thunderstorms.—On Friday, the 21st ult., at Port-Laing, near Inverkeithing, a man was struck by lightning while sheltering under a tree, and was killed on the spot. Severe storms, during which much damage to property was caused by lightning, occurred last week in Scotland, the Midlands, the Western Counties, and the South. On the 26th ult. a terrible thunderstorm passed over the Goerz district. At the village of Dobra a woman, who was standing by her fireside, was struck by lightning and killed. At Tualis, on the other side of the Italian frontier, the lightning struck a church during mass time, when it was filled with worshippers. A scene of the utmost confusion and alarm ensued. When calm had been restored it was found that three women had been killed. At Pian a huntsman was struck dead on the hills, and four of his comrades were temporarily paralysed. In the early hours of Tuesday last many houses were set on fire by lightning in the Departments of Saone-et-Loire and of Isère. Three houses were destroyed by fire at Sergenave, and two at Aslay. During a storm near Montbrisson, a farm labourer of Chazelles was standing with his family round a wood fire, when the house was struck by lightning, and the mother and two children were killed.

The Crystal Palace Electrical Exhibition.—The Crystal Palace Electrical Exhibition has now received the sanction of the Board of Trade, and is duly certified as an International Exhibition, under the provisions of the Patents, Designs, and Trade Marks Act, 1883. This Act provides for the publication of any description of the invention during the period of the Exhibition, or the use of the invention for the purpose of the Exhibition, or its use by any person elsewhere without the privity or consent of the inventor, without prejudicing the right of the inventor to apply for and obtain provisional protection, and a patent within six months of the opening of the Exhibition. The right of application for registration of designs is also protected by this Act for a period of six months from the opening of the Exhibition. The exhibits of Her Majesty's Government will include historical telegraphic and electrical apparatus, instruments, and appliances, as well as the modern apparatus and instruments now in use in the Postal Telegraph Department. This exhibit will be arranged under the direction of Mr. W. H. Preece.

The New Central Telegraph Office at Brussels.—The Brussels Post Office authorities are just now busily engaged in preparing the new Hôtel des Postes in the Place de la Monnaie. In the telegraph department the telephone will figure largely. Specially-constructed *cabines* will be reserved for those who wish to hold telephonic communications with Paris, Antwerp, Amsterdam, and other important towns, and a numerous corps of *employés* will be detailed for the sole purpose of transmitting by telephone, to such subscribers as may care to pay for the privilege, the contents of telegrams addressed to them. For the past six months experiments have been in progress for the purpose of testing "sounder," with the result that it has been decided to substitute it, as far as possible and as soon as possible, for the Hughes and Morse apparatus. The total number of instruments about to be installed in the new central office is 160, viz., 32 Hughes, 100 Morse, and 28 sounder instruments. The number of operators will amount to about 270. The new

Digitized by Google

Hôtel des Postes will be lighted throughout by electricity, and will be connected by pneumatic tube to the Bourse. In future all telegraph material is to be obtained from Belgian firms.

Electric Lighting in Auckland, N.Z.—At a special meeting of the Auckland City Council, convened to consider the Auckland Electric Lighting Bill, a letter which had been received from Mr. D. De Castro on the subject was read. Mr. De Castro asked that the matter should be brought before the Council, and some assent or refusal obtained from them in regard to a system of overhead wires being introduced into Auckland. This was to enable him to bring the Bill properly before Parliament, and he would not dream of proceeding with it unless he had some assurance that the Council would not object to overhead wires. The Bill was drawn on the lines of the private Acts, which he said were granted by the score in England every year lately. If the underground system would not pay in Melbourne it would not pay in Auckland, and the thing amounted to overhead electric lighting or no electric lighting at all. After consideration, it was unanimously resolved:—"That the Council refuses its consent to the Auckland Electric Lighting Bill because, among other objections, it vests the control of the undertaking in an outside Board, in the appointment of which the Council has no voice, and that the Mayor be instructed to take such steps as he may deem necessary to oppose the passing of the Bill."

Electrostatic Capacity and Electric Light Cables.—If it is not permissible, says a correspondent in the *Electrical Engineer* of New York, from considerations of safety to life, to operate high-tension continuous currents on grounded circuits, with, or without, static capacity, is it safe, for similar reasons, to operate high-tension alternating currents on circuits of large electrostatic capacity, even though their insulation be very perfect? I recently laid two submarine cables, half-a-mile in length, whose insulation resistance was 2,000 megohms, but whose static capacity was very large, due to the high specific inductive capacity of the compound used as insulation. The cables were connected to an alternating current dynamo giving a pressure of 1,100 volts and a frequency of 125 per second, supplying current for the lighting of a small village, which could only be conveniently reached by cable. In order to test the effect of the cable's capacity, I connected one end of the primary of a transformer to one wire leading from the dynamo, and grounded the other end of the primary, when a lamp attached to the secondaries immediately lighted up to nearly full candle power. I considered this due to the electrostatic capacity of the cables, and believe it would be very disastrous, indeed, to the one who would be unfortunate enough to get himself in a position similar to the primary of the converter. Perhaps the matter may be of interest to the New York Board of Electrical Control, as so many lead-covered cables are being used in New York at present.

Chagford (S. Devon.)—An electric lighting station has been erected at Chagford, in an old woollen factory about half to three-quarter mile outside the town, where a water wheel was already fixed. At one end of the room there is a countershaft. The wheel is a 14ft. by 14ft. breast backshot, with ventilated buckets, making about eight revolutions a minute. The electrical plant consists of two 20-unit 2,000-volt Siemens alternators, running at 850 revolutions, excited from two shunt-wound Crompton dynamos. The mains consist of two lead-covered cables, $\frac{7}{16}$ B.W.G., manufactured by the Norwich Insulated Wire Company. The cable is laid underground in stout oak casing, tarred outside. A considerable part of the road had to be blasted before the cable could be laid. The 2,000-volt mains run to five distributing points, where transformers of the "Hedgehog" type are fixed. The distribution by low-pressure wires radiates from these points. The secondary wires are taken along the back of the housetops, so that from the road it is difficult to discover where the wires are run. The material was supplied by Crompton and Co., and the work was carried out under the direction of Mr. G. H. Reed, of Chagford. Trial runs of a few hours each have been made every night since Tuesday, 25th ult., with perfect success. Some 120 lights, representing 24 customers, were connected on the first night. This interesting little installation affords examples therefore of three of the very latest ideas, viz., sub-stations, "Hedgehog" transformers, and the use of water power. It also shows that a well-constructed water wheel will run perfectly steady for lighting purposes.

The Search Light at Iquique.—Mr. J. Acton Lomax, an electrical engineer, associated with Mr. W. Hoffmann, the Thomson-Houston agent in Chili, has, says the *Electrical Engineer* of New York, recently arrived in New York from the seat of hostilities. Being stationed at Iquique, he was called upon by the Congressionalists to furnish a light for an island about 1,000 yards from the shore. The first plan was to put eight 1,200 c.p. arcs inside a parabolic reflector, 6ft. in diameter and 8ft. in length. But the plant could not be got to work satisfactorily. They then borrowed from the engineer of the "Cochrane" one of the old mirrors from her search light. This they rigged up with one of the 1,200 c.p. lights, put the combination in a box and tried it near the dynamo house, getting steam for the engine from the fire brigade engine-house, where steam was always kept up. Next came the question of a circuit to the island. Finally this was fixed up. At this juncture the Congressionalists did not want to pay, whereupon the plant was shut down. Then one night the Presidential torpedo boat "Condell" ran into the bay, darted all round the shipping, sent off a torpedo, and "played the devil" generally. The Congressional party, in a great scare, paid for the plant, and it was set going. It was arranged that any of the Congressional launches, cruising about all the time, should show certain lights, whenever the beam of light caught them. At last the search light picked up two craft coming in together, showing no light whatever. These suspicious craft made no responsive signal, so the ray was kept steadily on them. Very soon they got tired of this exposure, turned around and made for the open sea. They were evidently Presidential torpedo launches. After this object lesson of its utility the light was kept going nightly.

The Changes of Voltaic Energy of Alloys during Fusion.—In the *Comptes-Rendus* for June 10, 1878, J. Regnauld observed that liquid gallium was electropositive to solid gallium in a neuter solution of gallous sulphate. In the *Phil. Mag.* for July, Dr. Gore describes some experiments, the object of which was to ascertain whether the change of physical state of an alloy from solid to liquid by fusion, and the large absorption of heat which then occurs, was attended by a correspondingly large increase of electromotive force, and whether the converse effect occurred during solidification. Three electrolytes were used, viz., one composed of one part by weight of absolute hydrochloric acid in 100 of water; a second, of one part of chloride of sodium and 100 of water; and a nearly saturated solution of that salt. On applying heat, the heated portion of the alloy became gradually electropositive to the cold portion up to its fusion point; and a more or less sudden increase of electromotive force occurred during the further heating of the alloy and the electrolyte up to the boiling point of the latter, and this sudden increase appeared to coincide in point of time with the melting of the alloy. Substantially the reverse of these phenomena happened after removing the flame. The following alloys were experimented with:—Bismuth 70 parts, lead 40, tin 20, and cadmium 15; bismuth 8 parts, lead 8, and tin 3. Experiments were also made with mercurial amalgams. In the case of an amalgam of one part cadmium and four parts of mercury, easily liquefied in boiling water, when it was heated and had become pasty, the current began to increase; but just previous to complete liquefaction the current suddenly and considerably decreased, and the liquid amalgam became electronegative to the solid one; the period of reversal was very brief, and on further heating the current suddenly increased to a slightly higher point than it was at previously. By repeated experiments with this amalgam it was found that the sudden decrease of current was greater with the freshly prepared substance than with that which had been remelted several times. The mixture of metals which produced the most sudden increases of current in these experiments were those which exhibited the most sudden liquefaction. The results of the experiments show that changes of voltaic energy may be used in the above manner to detect physical and chemical changes in metallic alloys.

SKETCH OF THE PROCEEDINGS OF SECTION A OF THE BRITISH ASSOCIATION AT CARDIFF.

BY DR. OLIVER LODGE, F.R.S.

The unfortunate time of year selected for the Cardiff meeting was responsible for the absence of a good many of those whom we have grown accustomed to welcome at these annual gatherings; and letters of regret and explanation were numerous. The principal ingredient in the programme for this year was Astronomy, rather than Electricity; and although the communications to Section A maintained their usual high level, and represented scientific work of a very high order, it may be admitted at once that to electricians in the narrow sense they were not specially attractive or important. Under these circumstances it is evidently just as well that the idea of constituting an Electrical Section which has been several times mooted has not received much support. Understanding that the readers of *The Electrician* who were not present may nevertheless like some account of what went on in the Section I proceed to give a brief sketch as usual.

The President's address, after dealing with colour photography and one or two other discoveries of the year, advocated at some length the establishment of a National Physical observatory or laboratory for quantitative and long continued physical research; especially for the exact determination of such physical constants as are required for practical purposes, to maintain the various standards in a state fit for use, and to arrange for the comparison and certification of authorised copies. After pointing out the advantages and use of such a permanent national institution, an institution which France and Germany already possesses or are acquiring, the address lapsed into metaphysics, and became unworthy of further notice.

The first Paper on the list was one of great importance, by Prof. H. A. Newton, of Newhaven, in the United States, who is the greatest authority in the world on the subject of meteorites, and whose researches have done so much towards identifying comets with meteoric streams. He has been mathematically investigating the action of large planets, especially of Jupiter, on these small bodies as they pass within its range of attraction. A certain percentage are diverted from their natural parabolic orbit round the sun and swung into an elliptic orbit so that they become permanent members of the solar system, always thereafter revolving round the sun and receding from him to about the distance of Jupiter. A few, however, are affected still more seriously; they go so near Jupiter as to be caught and checked. Their prodigious rush, of a dozen or so miles a second, is taken out of them, and they are left quiescent in space; so that there is no help for them, they simply drop into the sun. All large planets thus feed the sun with meteors, but the number thus struck dead and dropped is not great; and only the larger planets are able to do it. The earth, for instance, is not able. By the time a meteorite reaches the earth it is flying with a speed of 26 miles a second, and in order that the earth may be able to wipe out this velocity by gravitative attraction, its centre must approach the meteor as close as 3,000 miles. Now it is impossible for the earth to get as near a body as this, for its own radius is 4,000 miles, hence the earth cannot act in the way just described. It may perturb a few and cause them to move in elliptic orbits, but its action is insignificant when compared with that of the giant planets Jupiter, Saturn, Uranus, and Neptune. All these planets have been the means of introducing a number of comets or meteoric streams into the solar system, which thereafter circled in elliptic orbits whose greatest distance (or aphelion) is usually something not very different from the distance of the planet which introduced them, though in a few cases it may be less.

Prof. George Forbes mentioned that he had already called attention to the fact that a number of cometary orbits ended at about the distance of a planet, and had shown that the position of Neptune could have been roughly estimated by this very method. He has also predicted the existence of two trans-Neptunian planets, by considering the aphelion of other cometary orbits, and has endeavoured to calculate the present position of one of those hypothetical planets next beyond Neptune. Since its distance is about double Neptune, it must be an excessively faint object, but modern processes of stellar photography ought to be able to detect it. If it exists it will show itself on the photographic plate as a slightly oval—not perfectly round—spot, by means of its proper motion; or if its speed is hardly enough for that, it can be detected by comparing two plates of the same part of the heavens taken on different dates.

Mr. Isaac Roberts, whose stellar photographs have been the admiration of all astronomers, rose in the meeting and said that he had now photographed that part of the heavens where Prof. Forbes had located his hypothetical planet, and had critically scrutinised all the plates of this region, except two, without finding any trace of it. Either the planet was on those two plates, which are shortly to be examined, or it does not exist.

If a planet should ever, by means of cometary disturbances, be discovered, it will be a beautiful instance of the progress which this department of astronomy has made, and of the perfection to which the study of those obscure bodies, the meteorites, is now attaining. The General Committee subsequently requested Prof. Newton to allow his Paper to be printed *in extenso* in the annual volume of the Association. It contains a quantity of solid mathematical work, and only a general account of a few of the results was attempted to be given before the section.

Mr. W. E. Wilson followed with an account of some interesting observations he is making on the radiation received from different parts of the sun's surface. To this purpose he has applied Mr. Boys' radio-micrometer, over the disc of which he allows a very large image of the sun to slowly transit; the motion of the spot of light reflected from the mirror of the instrument being recorded on a travelling sheet of sensitised paper. It will be remembered that the radio-micrometer is a microscopic thermopile and galvanometer in one, the thermopile circuit being a single loop of fine wire suspended in a strong magnetic field, after the fashion of the siphon recorder. It is enormously more sensitive than any other radiation indicator, it is also very quick in its response and very dead-beat in its motion. All these are immense advantages when it is applied to examine celestial objects. With it Mr. Boys has readily detected heat in the radiation of the moon, and shown how it varies according to the angle of incidence of sunlight on its surface, no heat being received from the unilluminated body of the moon itself. He has further tried to detect heat from the stars, but has found no perceptible trace from any of them. Mr. Wilson's curve of intensity from different parts of the sun shows how greatly absorption in the solar atmosphere modifies the radiation, so that from the limit we receive very much less heat than from the central portions. From the corona and general solar surroundings we appear to get no appreciable quantity. Prof. G. E. Hale, of Chicago, gave an account of the appearance of the H and K lines in the solar prominences as photographed by a Rowland's grating and powerful telescope. Some of the appearances and reversals were very extraordinary, but it remains to be proved that these are not due to peculiarities introduced by the photographic process.

The last communication on the first day was a long and valuable report, which had been drawn up by Mr. G. H. Bryan, of Cambridge, partly in conjunction with Dr. J. Larmor, at the request of the Section, at its Leeds meeting, and which the author now handed in. It relates to the present state of our knowledge of thermo-dynamics, especially the much debated and criticised "second law." The report will appear in the annual volume, and is one of those documents which the British Association most prides itself on occasionally inducing learned but secluded and modest students to indite. The labour of drawing up such critical and precise reports is very great, and the men competent to write them are naturally not numerous.

Friday opened with a mathematical note by Prof. Andrew Gray, of Bangor, with reference to the Faraday rotation of the plane of polarisation of light in a magnetic field. Sir W. Thomson had illustrated the matter by a chain of gyrostats, and shown how a rotation of some kind round the lines of force was essential to the explanation of the phenomenon. Prof. Gray now considers a chain of molecular magnets arranged along the lines

Digitized by Google

of force, and applying to them Maxwell's electro-magnetic equations, obtains a differential equation for the propagation of radiation along the lines of force, which is the same as that obtained by Sir W. Thomson with the chain of small gyrostats, and which, therefore, gives the observed rotation of plan of polarisation in the same way. Dr. Larmor remarked that probably any kinetic theory would lead to the particular term in the differential equation, on which the rotation of the plan of polarisation depended. No theory but a kinetic one would serve to explain the phenomenon, but kinetic theories would only differ in the particular kind of rotation postulated, whether material, etherial, or vaguely magnetic.

The present writer then gave a preliminary account of some experiments he is making to ascertain the effect of a rapidly moving body on the ether in its neighbourhood. It has long been a question whether the earth, for instance, moved freely through the ether without disturbing it in any way, or whether it dragged some of the ether with it. He proposes to attack the question by direct experiment, and to this end sends a beam of light, split into two equal portions, half of it with, and half of it against, the motion of a rapidly revolving disc or pair of discs. The two beams of light are then brought together and allowed to interfere. The observation consists in showing whether the system of interference bands shift their position when the discs are set into rapid rotation. If they do, it shows that one-half the light is accelerated, and the other half retarded, by the action of moving matter in its immediate neighbourhood. The discs selected are a pair of plates of hammered Sheffield steel, one yard in diameter, clamped together, and mounted on a vertical axle, which consists partly of a Mather and Platt "Manchester" dynamo, set up on end. The whole is supported by a strong cast-iron frame, and is bolted to masonry. A carbon block rheostat, by Rousseau, of Finsbury, is in circuit with the armature, and enables the speed to be regulated by varying the current supplied by a storage battery. The speed so far obtained is about 1,500 revolutions a minute, and the light has been passed several times round, each way, in the space between the discs. A pulley on the axle serves for a brake, and a syren disc above enables the speed to be quickly estimated. So far as experiments have yet gone, it may be asserted that the velocity of light is not affected in the neighbourhood of moving matter by so much as one-thirtieth of the velocity of the matter. But this result is quite preliminary, and it will be some time before the investigation is concluded.

Prof. Horace Lamb and several members expressed some interest in the apparatus, and in the question to be settled by it. Dr. Johnstone Stoney doubted whether the discs could hope to move the ether much, when the much larger mass of the earth itself might be effective in keeping it still; and Prof. Osborne Reynolds warned the experimenter of the danger arising from the rapidly whirling steel discs, pointing out that though to simple traction a tenacity of 67 tons per square inch might be attained, yet the conditions of surface strain in both directions to which the discs were subjected were very different, and not much was known about them. In this connection it may be interesting to remark how enormous centrifugal force may be compared with any intensity of gravity met with anywhere in the solar system. For instance, if a pound mass were put into a hollow drum, one foot in radius, spinning 100 times a second, it would fly up against the side, and press on it with a force of four tons weight. No wonder that cream is rapidly produced in milk-whirlers, which are often driven much faster than this.

Dr. J. Larmor next gave a general account of some mathematical investigation of the theory of electric radiation, starting from a Hertz vibrator as source. He did not say very much about his methods or results, but he found that reflecting surfaces behaved very differently to waves of great and waves of small length. Waves of great length, say much longer than a centimetre, are reflected by all conductors about equally well, without regard to small differences in their conductivity, without much regard to the substance that is. But very short waves, say much shorter than a centimetre, experience an effect due to the conductivity of the reflecting substance; and accordingly waves of light, so small as to be visible, feel every difference in the state of polish of a surface as well as in the material of which it is made.

Prof. D. E. Jones, of Aberystwith, described some experiments he had been recently making in Prof. Hertz's laboratory at Bonn, with the object of observing the rate of propagation and the rate of damping out of waves along wires. He does it by inserting a thermo-couple in the course of the wire, so that electric oscillation set up in the wire shall surge through it and heat it perceptibly. If the couple is placed at a node, however, no heating effect should be experienced. In the middle of a vibrating segment, the heating effect should be a maximum. Prof. Jones finds no absolute nodes or places of no electric current in a finite wire of considerable length, along which short Hertz waves are travelling and being reflected; but he finds places of minimum heat. The damping out of the waves prevents the interference of direct and reflected waves from being complete; there is a certain proportion of stationary waves, and a certain proportion of progressive waves, the latter disturbing the thermopile equally, whatever its position. One of the most interesting things observed was that if the receiving plates attached to the wires were placed very near to the vibrator, then scarcely any waves were excited; the energy of the vibrator seemed to be consumed by the receiver; the two probably oscillating together in opposite phases, and leaving very little disturbance to be propagated to a distance. Or it may be expressed by saying (as Mr. Blakesley suggested the other day at the Physical Society) that the virtual self-induction of the emitter was so much reduced by the mutual induction of the receiver that no sufficient inertia was left, and the oscillations were almost killed—the discharge being made dead-beat. It is a question whether the thermopile and galvanometer can be a very good plan of detecting nodes and ventral segments along wires; and it is surprising that it is sufficiently sensitive to show them. The fact that it is so, and that loops of thin iron, such as lead to the galvanometer, do not seem to disturb the position of the nodes is interesting.

Next a Paper was read from Mr. W. Thorp, relating some experiments he had made in Prof. Fitzgerald's laboratory, on the propagation of Hertz waves along very thick and very thin wires. Elementary theory indicates that the velocity of pulses along thin wires should be the same as in air, and along thick ones a trifle slower. But Mr. Thorp finds that the velocity (as indicated by wave length) is greater along brass gas-pipe of about an inch diameter than it is along copper wire less than the tenth of a millimetre thick. If this observation is confirmed, it will want serious consideration. Many observers measured the rate of travel along wires, and found it practically equal to the velocity of light, but they have not examined thicknesses so different as those Mr. Thorp uses. It remains to be found whether the resistance of excessively thin wires is able to retard the pulses, and cause them to travel much more slowly than they otherwise would. At present Mr. Thorp's observation is a most interesting possibility, which needs confirmation and development.

An important Paper from Lord Rayleigh concluded the work of this day. It was purely optical, and relates to the amount of light reflected at the polarising angle from clear liquids. Brewster's simple law of polarisation, that the tangent of the polarising angle was equal to the index of refraction, or that the reflected and transmitted rays were perfectable to each other when the reflected light is completely polarised, has been shown by Janin to be only an approximate statement. It does give the angle of *maximum* polarisation, but the polarisation is not complete except for substances whose index of refraction is about 1·5. For all other substances some amount of elliptic polarisation was produced by the reflexion, and no completely polarised light could be obtained. But now Lord Rayleigh, experimenting on almost absolutely clear liquid surfaces, finds that the ellipticity is much less—in fact, a thousand times less—than Janin supposed. And he evidently surmises that the faint residual trace of elliptic polarisation is due to a still remaining trace of surface impurity, or to an imperfectly sharp transition from one medium to the other. Thus, at any rate, to a high degree of accuracy, Brewster's law is restored in all its simplicity, and will probably be found to apply to all transrapent substances whose surfaces are absolutely clean. The

Digitized by Google

ellipticity detected by Janin and other observers has its origin in that fine layer of dirt on the surface of bodies which only considerable skill and care can remove.

On Saturday the Section found it unfortunately necessary to divide, and to sit half of it for pure mathematics and the other half for electrolysis and physical chemistry. A very valuable table involving an immense amount of compilation work was handed in by the Rev. T. C. Fitzpatrick, of Christ College, Cambridge, as part of the report of the Committee on Electrolysis. It endeavours to summarise and tabulate all that is known concerning the conductivity of solutions of the various salts at different strengths. It will, no doubt, be printed in the annual volume, and be long useful as a work of reference.

Mr. J. Brown criticised the recent writings of Prof. Ostwald and the arguments adduced by him in support of the dissociation theory of electrolysis, pointing out that many of them were equally reconcileable with the simple Grotthus chain theory In particular, he criticised an experiment which excited a good deal of interest at Leeds last year, viz., where copper nodules make their appearance on the face of a partition of ferrocyanide of copper interposed in the path of the current, as if they were filtered out by a "semi-permeable membrane," and left behind. Mr. Brown has examined this substance, the ferrocyanide of copper, and found it slightly metallically conducting. Now directly a conducting partition is interposed in the path of a current in metallic salt solution, nothing is more natural than to get a metallic deposit from it. Hence, he concludes that the experiment of Ostwald has no bearing whatever in favour of one theory rather than another; that it is in fact of no particular interest. Mr. Preece said that the nodules of copper found on the porous cells of Daniell's batteries were due to specks of conducting matter in the clay, and that by more carefully selecting the cells no such deposits were obtained. Unless something fresh can be adduced by Prof. Ostwald, there seems, therefore, to be no further mystery or interest in this dropping out of ions from the path of a current; a phenomenon which might have had considerable theoretical import, and which, apart from this conductivity explanation, was very puzzling.

Mr. Chattock gave an account of an elaborate series of measurements which for two years or more he has been making on the discharge of electricity from points. Many very interesting facts are being brought to light by this research; he has elaborated a method of measuring the atomic charge in gases, and has shown that it is something comparable to the known charge on atoms in electrolytes. His investigations also go to confirm the theory of Prof. J. J. Thomson with reference to molecular chains—a string of short Grotthus chains—which, by breaking down, bring about the electric discharge observed. All this work of J. J. Thomson in vacuum tubes, and of Chattock on ordinary and rarefied air near points, is closely related to the phenomena of electrolytic conduction in liquids, and before long the three sets of facts will certainly throw considerable light upon each other.

Prof. Ramsay described an ingenious method of measuring surface-tension by observing the size and flotation of a bubble of vapour in a narrow tube of liquid, especially with reference to the behaviour of ether near its critical point. And there were two other minor communications from Mr. R. L. Mond and Mr. Swinburne.

On Monday, among the most striking Papers was one by Dr. Copeland on the nature of the bright streaks on the moon, which are now for the first time explained and illustrated by a very beautiful model. The peculiarity of the well-known streaks radiating from Tycho and a few other craters is that they are only visible at full moon—that is, to an eye looking along the line of illumination. Dr. Copeland's plaster of Paris model, with very minute glass beads appropriately disposed on its surface, imitates this behaviour exactly.

Dr. Johnstone Stoney gave some account of his examination into the behaviour of atomic motions, subject to mutual perturbation of a kind similar to those which planets and satellites experience. He endeavours thus to account for the peculiarities observed in spectra, especially for the very frequent occurrence of double lines. He believes, indeed, that most lines will be found double when examined with sufficiently high power; and Dr. Webster on this head recounted some recent observations of Michelson by a very powerful interference method, whereby he had obtained evidence of doubleness in lines which have never been seen as otherwise than single. Evidently some very important progress is being made in this direction, viz., in ascertaining both by theory and observation the kind of inter-atomic motion and vibration to which the particular kind of radiation emitted by molecules and analysed in the spectroscope is due.

Mr. Clayden exhibited a number of beautiful meteorological photographs, taken by observers in different parts of the world; photographs of clouds, of lightning, of hoar frost, and of many other meteorological and interesting evanescent effects. The photographs of lightning are especially valuable, and the ribbon appearance so often seen is found to be produced even when the camera is quite fixed. True multiple effects likewise, however, occur, and these have been imitated, to some extent, by Mr. Clayden, by photographing simple Leyden jar sparks in the circuit of which greater or lesser resistance is interposed. Prof. Ogden N. Rood used to observe the direction of lightning by watching a cardboard disc, with radial spokes drawn on it, twirled on a shawl-pin during a thunderstorm on a dark night. Some flashes are instantaneous, others are multiple or intermittent. Doubtless the noisiest and most dangerous are the sudden ones. It is to be hoped that many observers will combine to swell the collection of lightning photographs being made by the committee, of which Mr. Clayden is secretary, and Mr. G. J. Symons chairman; and, if taken with due regard to the instructions which the committee will issue, they cannot help adding largely to our information concerning atmospheric discharges.

On Tuesday, after a report from the committee on Electrical Standards with reference to the minute changes going on among the wire and mercury standard of resistance, Mr. Swinburne gave a summary of a long and detailed piece of work on the causes of variation of Clark cells, which it was very difficult to follow ordinarily, but which will doubtless be very useful to experimenters interested in the practical construction of standard of E.M.F.

A discussion on electrical units was then commenced. The writer spoke on the naming of a coefficient of induction and of a unit of magnetic induction, both of which he believes to be needed in practice. If the secohm is to do for the one, the secvolt will do for the other; and the unit of field intensity would be a secvolt per square centimetre. He believes that a unit of magnetic induction or total number of lines of force passing through an armature coil is more immediately applicable to practical use than is the idea of a certain length of wire moving across a field with a specified velocity, as advocated by Prof. Perry. An induction of one secvolt passing through a coil is such that if the coil be rotated so as to cut out all these lines in one second, the average E.M.F. set up in every turn of it is one volt. It may also be expressed as a secohm × ampere. The secohm, or quadrant, or whatever it is to be called, is an inconveniently large unit, but *perhaps* it is better to adhere to the systematic arrangement, and not introduce any fresh multipliers, not even one-thousandth. It is for practical men themselves to decide this question, and the particular names to be employed for these units is also a matter of taste. Mr. Preece was expected to continue his advocacy of enlarging the present volt and ampere each 10-fold, and the present watt 100-fold, a procedure for which there is much to be said. Likewise, for altering the name of the microfarad to a farad, so that submultiples of it may conveniently be named, the farad itself being absurdly too big—greater than the capacity of the solar system. He did not, however, bring forward anything very revolutionary. Prof. W. Stroud, of Leeds, strongly advocated the change from present volt to one ten times as big, and from present ampere to the simple C.-G.-S. unit, which is likewise ten times as big; and pointed out that this simple change would get rid of all the present no-system of having to use 10, 10^7, 10^8, 10^9, and the reciprocal of these quantities as factors to count for C.-G.-S. units; and would make all the practical units be derived straight from the C.-G.-S. unit by multiplying either by 10^9 or by unity. It

Digitized by Google

is a great pity that this 10^9 system was not adopted at first, but the meeting was evidently averse to any sort of change being introduced now. The tables drawn up by Prof. Stroud, showing the advantage of the changes advocated by him, were very thoughtful and well considered. Dr. Johnstone Stoney, who had had so much to say at the birth of the C.-G.-S. system, and who stood out for a more immediately metric system, because he saw that the dyne and erg would be too grotesquely small for engineers, said that, however much he regretted the adoption of the centimetre, it was too late now to alter it, and he proposed adhering to present units with a them simple method of naming multiples or submultiples of by any power of ten or one-tenth, which he had previously advocated,and which is frequently already used for wave-lengths.

A number of speakers followed, each pursuing his own line of thought, and the closing hour decided on by the sectional committee arrived before anything like agreement could be come to on any one point, and long before the discussion was half over. The extra subject of mechanical units (moments of inertia, and the like) remained perforce untouched. Some remarks were made deprecating the idea that resistance was really a velocity or capacity, or self-induction a length; and the need for retaining one of the unknown quantities k or μ, as a factor until further knowledge tells us its dimension and numerical value, was, as usual, insisted on.

At the University College adjacent to the Section Prof. J. Viriamu Jones exhibited in action his beautiful form of Loveni's method of determining the ohm. By means of a rotating disc inside a coil he determines the absolute specific resistance of mercury direct, aiming at an accuracy of one part in 10,000. He speaks of issuing absolute standards of very low resistance, say, one-thousandth of an ohm, &c., provided with tapping terminals as well as main terminals, so that an electrometer applied to them may be used for measuring very powerful currents.

The last Wednesday of the meeting was fully occupied by Section A, although all the other sections had concluded their labours. Prof. S. P. Thompson showed a delightfully handy rough spherometer, made by the Geneva Company, of Chicago, which, applied to a spectacle lens, gave its power in "dioptrics" at once, by the motion of an index; on the assumption, however, that the index of refraction of the glass was of average and fixed value.

Mr. Trouton described some curious and purely magnetic observations he had made on large iron rings submitted to a magnetising helix conveying an alternating current, and having another helix connected with a telephone arranged as feeler, and moved about over the ring. He thus found, to his surprise, nodes, or places of telephonic silence, as if the magnetic pulses took time to travel, and formed a system of stationary waves with nodes and ventral segments at regular intervals round the ring. Dr. Larmor suggested that the ring might be thrown into mechanical or Jouleian vibrations by the alternating current, and that the telephone coils might be affected by these slight motions, so as to give equal opposite effects on opposite sides of certain regions or nodes. The nodes could hardly be real magnetic interferences, because a galvanometer failed to show them. A telephone was essential.

Mr. W. Barlow showed some remarkably beautiful models of coloured beads, strung so as to imitate the arrangement of the atoms in various crystalline minerals. The physical characteristics of particular crystals were shown to be brought out by the atomic grouping necessitated by simple principles of symmetry, regarding each atom as a mere centre of force. Thus zinc blend showed its structural appearance. Quartz exhibited a spirals tructure, which might be either right or left handed, and which was known to be competent to explain its rotation of the plan of polarisation of light. Iceland spar had a complex structure, which had a twin or image of itself in a mirror, into which it could be forced over by appropriate displacement. It appears probable that, by long study of these matters, Mr. Barlow has been able to penetrate pretty far into the secrets of crystalline form and arrangement.

The remaining five Papers had, for want of time, to be taken as read. Thus ended a meeting which, though, perhaps, nothing specially brilliant or sensational can be asserted of it, maintained its usually high scientific level, and was representative of the immense amount of first-class work which is at the present time being accomplished in physical science.

REPORT OF THE ELECTRICAL STANDARDS COMMITTEE.

To the Right Honourable Sir MICHAEL HICKS-BEACH, Bart., M.P., President of the Board of Trade.

In compliance with the instructions contained in your minute of December 16th last, that we should consider and report whether any, and, if so, what, action should be taken by the Board of Trade under Section 6 of the Weights and Measures Act, 1889, with a view to causing new denominations of standards for the measurement of electricity for use for trade to be made and duly verified, we have the honour to submit the following report:—

1. Before coming to a decision as to the points referred to us, we were anxious to obtain evidence as to the wishes and views of those practically interested in the question, as well as of Local Authorities who are concerned in the administration of the Weights and Measures Acts.

2. With this view we prepared draft resolutions embodying the proposals which, subject to further consideration, appeared to us desirable, and forwarded copies to the representatives of various interests for criticism. Copies were also forwarded to the Press. The following bodies were also invited to nominate witnesses to give evidence before us:—

The Association of Chambers of Commerce of the United Kingdom.
The Association of Municipal Corporations.
The London County Council.
The London Chamber of Commerce.

3. In response to this invitation the following gentlemen attended and gave evidence:—

On behalf of the Association of Chambers of Commerce, Mr. Thomas Parker and Mr. Hugh Erat Harrison.
On behalf of the London Council, Prof. Silvanus Thompson.
On behalf of the London Chamber of Commerce, Mr. R. E. Crompton.

The Association of Municipal Corporations did not consider it necessary to offer any oral evidence, but the following resolution passed by the Law Committee of that body, was adopted by the Council of the Association:—

"The Committee are of opinion that, assuming that the science of electricity has advanced so far that it is now possible properly to define the three units referred to in the Board of Trade letter" (*i.e.*, the ohm, ampere, and volt) "and to construct an instrument for the purpose of standard measurement, the time has arrived for the Board of Trade to take action thereon."

4. In addition to the witnesses above referred to the following gentlemen were invited to give evidence, and we are indebted to them for valuable information and assistance.

Dr. J. A. Fleming.
Dr. Alexander Muirhead.

5. We also had the advantage of the experience and advice of Mr. H. J. Chaney, Superintendent of Weights and Measures, who, at the request of our chairman, was present at our meetings.

6. After a careful consideration of the questions submitted to us, and the evidence given by the various witnesses, we have agreed to the following resolutions:—

RESOLUTIONS.

1. That it is desirable that new denominations of standards for the measurement of electricity should be made and approved by Her Majesty in Council as Board of Trade standards.

Digitized by Google

2. That the magnitudes of these standards should be determined on the electro-magnetic system of measurement with reference to the centimetre as unit of length, the gramme as unit of mass, and the second as unit of time, and that by the terms centimetre and gramme are meant the standards of those denominations deposited with the Board of Trade.

3. That the standard of electrical resistance should be denominated the ohm, and should have the value 1,000,000,000 in terms of the centimetre and second.

4. That the resistance offered to an unvarying electric current by a column of mercury of a constant cross-sectional area of one square millimetre, and of a length of 106·3 centimetres at the temperature of melting ice may be adopted as one ohm.

5. That the value of the standard of resistance constructed by a committee of the British Association for the Advancement of Science in the years 1863 and 1864, and known as the British Association unit, may be taken as ·9866 of the ohm.

6. That a material standard, constructed in solid metal, and verified by comparison with the British Association unit, should be adopted as the standard ohm.

7. That for the purpose of replacing the standard, if lost, destroyed, or damaged, and for ordinary use, a limited number of copies should be constructed, which should be periodically compared with the standard ohm and with the British Association unit.

8. That resistances constructed in solid metal should be adopted as Board of Trade standards for multiples and submultiples of the ohm.

9. That the standard of electrical current should be denominated the ampere, and should have the value one-tenth (0·1) in terms of the centimetre, gramme, and second.

10. That an unvarying current which, when passed through a solution of nitrate of silver in water, in accordance with the specification* attached to this report, deposits silver at the rate of 0·001118 of a gramme per second, may be taken as a current of one ampere.

11. That an alternating current of one ampere shall mean a current such that the square root of the time average of the square of its strength at each instant in amperes is unity.

12. That instruments constructed on the principle of the balance, in which, by the proper disposition of the conductors, forces of attraction and repulsion are produced, which depend upon the amount of current passing, and are balanced by known weights, should be adopted as the Board of Trade standards for the measurement of current whether unvarying or alternating.

13. That the standard of electrical pressure should be denominated the volt, being the pressure which, if steadily applied to a conductor whose resistance is one ohm, will produce a current of one ampere.

14. That the electrical pressure at a temperature of 62°F. between the poles or electrodes of the voltaic cell known as Clark's cell, may be taken as not differing from a pressure of 1·433 volts, by more than an amount which will be determined by a sub-committee appointed to investigate the question, who will prepare a specification for the construction and use of the cell.

15. That an alternating pressure of one volt shall mean a pressure such that the square root of the time average of the square of its value at each instant in the volts is unity.

16. That instruments constructed on the principle of Sir W. Thomson's Quadrant Electrometer used idiostatically, and for high-pressure instruments on the principle of the balance, electrostatic forces being balanced against a known weight, should be adopted as Board of Trade standards for the measurement of pressure, whether unvarying or alternating.

7. We have adopted the system of electrical units originally defined by the British Association for the Advancement of Science; and we have found in its recent researches, as well as in the deliberations of the International Congress on Electrical Units, held in Paris, valuable guidance for determining the exact magnitudes of the several units of electrical measurement, as well as for the verification of the material standards.

8. We have stated the relation between the proposed standard ohm and the unit of resistance originally determined by the British Association, and have also stated its relation to the mercurial standard adopted by the International Conference.

9. We find that considerations of practical importance make it undesirable to adopt a mercurial standard; we have, therefore, preferred to adopt a material standard constructed in solid metal.

10. It appears to us to be necessary that in transactions between buyer and seller a legal character should henceforth be assigned to the units of electrical measurement now suggested, and, with this view, that the issue of an Order in Council should be recommended, under the Weights and Measures Act, in the form annexed to this report.

(Signed) COURTENAY BOYLE. RAYLEIGH.
WILLIAM THOMSON. G. CAREY FOSTER.
P. CARDEW. R. T. GLAZEBROOK.
E. GRAVES. J. HOPKINSON.
W. H. PREECE. W. E. AYRTON

(Signed) T. W. P. BLOMEFIELD, Secretary.
July 23, 1891.

The following schedule is contained in the Draft Order in Council appended to the report:—

SCHEDULE.

I.—*Standard of Electrical Resistance.*

A standard of electrical resistance, denominated the ohm, being the resistance offered by the coil of metal marked ———— to the passage of an unvarying electrical current when the coil is in all parts at a temperature.

II.—*Standard of Electrical Current.*

A standard of electrical current, denominated the ampere, being the current which is passing in and through the coils of wire forming part of the instrument marked ————, constructed as described in a specification marked ————, when the instrument, being adjusted and used in accordance with the instructions contained in the said specification, indicates a balance between the electro-magnetic force resulting from the current in the said coils, and the force exerted by gravity in Westminster upon the platinum weight marked ————, and forming part of the said instrument.

III.—*Standard of Electrical Pressure.*

A standard of electrical pressure, denominated the, volt being one-hundredth part of the pressure applied between the terminals forming part of the instrument marked ————, constructed as described in a specification marked ————, when, the instrument being adjusted and used in accordance with the instructions contained in the said specification, its indicating needle points to the centre line of three lines delineated upon the dial face of the instrument between ———— degrees and ———— degrees.

In the use of the above-named standards the limits of accuracy attainable are as follows:—

For the ohm.—Within one hundredth part of one per cent.

For the ampere.—Within one tenth of one per cent.

For the volt.—Within one quarter of one per cent.

The coils, instruments, specifications, &c., referred to in this schedule are deposited at ————.

Note.

(1.) The standard ohm has the value of 1,000,000,000 in terms of the centimetre and the second of time.

The Board of Trade have found that the value of the standard of resistance constructed by a Committee of the British Association for the Advancement of Science, in the years 1863 and 1864, and known as the British Association Unit, may be taken as 0·9866 of the standard ohm.

(2.) The standard ampere has the value one-tenth (0·1) in terms of the centimetre, the gramme, and the second of time.

The Board of Trade have found that an unvarying current which, when passed through a solution of nitrate of silver in water, in accordance with the specification marked ————, deposits silver at the rate of 0·001118 of a gramme per second, may be taken as a current of one ampere.

(3.) The standard volt is a pressure such that, if steadily applied to a conductor whose resistance is one ohm, it will produce a current of one ampere.

The Board of Trade have found that the electrical pressure at a temperature of 62°F. between the poles or electrodes of the voltaic cell, known as Clark's cell, may be taken as not differing by more than ———— parts in one thousand from a pressure of ———— volts.

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

Advertisement Rates, &c., forwarded on application as above.

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday. Renewals of expiring advertisement orders and alterations to standing advertisements should be in Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday.*

SMALL PREPAID ADVERTISEMENTS *accepted up to 4 p.m. Thursday.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, 1891, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with well-written Biographical Notices of leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1891 should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Prospectuses free.

ELECTRICAL BOOKS AND PUBLICATIONS

All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad*

"THE ELECTRICIAN" *Series at present consists of—*

THE ALTERNATE CURRENT TRANSFORMER IN THEORY AND PRACTICE. By Dr. J. A. FLEMING. Vol. I. Price 7s. 6d., post free.

THE ART OF ELECTROLYTIC SEPARATION OF METALS (Theoretical and Practical). By Dr. GEORGE GORE. Price 10s. 6d., post free.

PRACTICAL NOTES FOR ELECTRICAL STUDENTS. By A. E. KENNELLY and H. D. WILKINSON. Vol. I. Price 6s. 6d., post free.

THE STEAM ENGINE INDICATOR AND INDICATOR DIAGRAMS. Edited by W. W. BEAUMONT. Price 3s. 6d., post free.

ELECTRO-CHEMISTRY. By Dr. GEORGE GORE. Price 2s., post free.

Several Further Volumes in Active Preparation.

NOW READY, IN TWO VOLUMES.

"THE ELECTRICIAN" PRIMERS.

Fully Illustrated.

Price: Stout paper covers, 2s., post free, 2s. 2d. each; strong cloth, 2s. 6d., post free, 2s 9d. each. Single Primers, 8d., post free, 8½d. Abroad postage extra.

STEEL-PLATE PORTRAITS

Of W. H. Preece, F.R.S.; Michael Faraday (out of print); Sir John Pender, K.C.M.G.; Sir William Thomson, F.R.S. (Past-President of the Institution of Electrical Engineers); C. H. B. Patey, C.B. (Late Secretary of Telegraphs, G.P.O.); Dr. John Hopkinson, F.R.S. (Past-President of the Institution of Electrical Engineers); Dr. Oliver J. Lodge, F.R.S.; Prof. William Crookes, F.R.S. (President of the Institution of Electrical Engineers); Willoughby Smith (out of print); and Prof. von Helmholtz, have been issued as Supplements to "THE ELECTRICIAN."

A few Copies of these admirably-executed Steel Engravings can be supplied, price 1s. each, post free on roller, 1s. 2d. Or framed in neat Black Pillar or Brown Ornamental Frames, price, 4s. 6d, carriage paid (U.K.)

THUNDER.

Concentrating itself round the art of making efficient lightning conductors, some study has been made and some knowledge has been arrived at as to the behaviour of that awe-inspiring nuisance with which Jove was armed. The world is not so densely populated that anyone must needs dwell on the slope of an active volcano, unless impelled by the interests of science to live in a laboratory; and those who must perforce spend their days in a country tossed and riven by earthquakes may thankfully adopt any of the numerous unpatented devices for ensuring the stability of their houses, whether by the massive pendulum of the pagoda, by the "ball-bearing" foundation, or by the simplicity of a structure composed of bamboo and paper. But both Greek and barbarian, prince and pauper, are occasionally subjected to the visitation of thunderstorms, and have the highest scientific authority for doubting their immunity from sudden death, unless they seek refuge in a solidly constructed iron house, or, perhaps, the nearest Safe Deposit.

The phenomena of A and B discharges and the experimental study of laboratory lightning have presented considerable difficulties, both as regards explanation of the results, and more particularly as to the practical deductions which are to be made from them. Meanwhile, thunder, which to many persons is quite as terrible as lightning, has been completely disregarded, though it appears to us that some of its features are worthy of consideration, as throwing light on the nature and behaviour of lightning. While it is difficult to estimate the comparative loudness of thunder, we can very easily measure the distance of it, or perhaps of some part of

Digitized by Google

it, by observing the time which elapses after the lightning flash. Sound travelling at 370 yards per second takes about 4¾ seconds to the mile, but as accuracy is not possible owing to the irregular occurrence of the lightning, and the uncertain commencement of the thunder, five seconds to the mile is quite near enough. Nineteen seconds corresponds with a distance of four miles, and beyond this thunder is not often heard, though lightning is frequently seen. Those philosophers who do not put their heads under the bed-clothes during a storm may make nocturnal observations by counting five and a-half pulse-beats to a mile. This estimate allows for the effect of the recumbent posture, but takes no account of nervous agitation for which a personal coefficient must be used. One of the first facts to be learned by thus reckoning the distance, is, that the noise of the thunder-claps, and presumably therefore the magnitude of the flashes, or, more strictly speaking, the energy expended in the flashes, vary perceptibly; but it is very rare that a flash one mile distant makes no more noise than an average flash three miles off, and presuming that the noise of distant thunder varies as the square of the distance, it appears that a discharge one-ninth of the magnitude of the average is uncommon. A very little attention will resolve thunder into three or four different parts, the crackle, the roar, the bang, and the rumble. The last is, without doubt, due to echo from neighbouring clouds, and is much more prominent in a mountainous country. The crackle is only heard in connection with a loud discharge, and more careful observation would probably show that it is only heard at comparatively short distances. The roar and the bang are generally associated, but each is frequently to be heard alone. Several bangs are often heard after a flash which appears to be single. The crackle invariably precedes the more noisy part of the clap, if it is heard at all.

It is generally, and with good reason, assumed that a flash of lightning raises to incandescence the air along its path, and that thunder is the result of the thermal expansion of the air, but it is not clear whether the vibrations are set up directly by the sudden expansions, or by the collapse of the surrounding atmosphere upon the partial vacuum. It would appear, at first sight, as though the crackle might be due to the disruption and sudden expansion of the air, and that the thunder is caused by the collapse, but if this were the case, a similar result should be produced by the free explosion of any detonating compound, and we are not aware that any such double sound has been heard. The crackle must, therefore, be due to something which precedes the flash, and may be caused by a few small local discharges during the building up and concentration of the stress at the ends of the impending flash. The succeeding roar and bang can be easily accounted for, and it seems clear that the roar is by no means the same as the rumbling echo. Taking, as a simple case, a nearly straight flash of lightning a mile in length, the observer being stationed at a distance, in the direction of the flash, the noise travelling to him from all parts of it will come upon him continuously for a period of nearly five seconds; and this is a plausible explanation of a roar. If, on the other hand, he receives a broadside, being stationed so that all parts of the flash are equidistant from him, he will hear a bang. If lightning followed the conventional zig-zag path with which artists have made us familiar, but which is conspicuously absent from actual photographs, a number of bangs connected by roars would be the natural result of the above reasoning. It is possible that some of the complications of a peal of thunder may be due to the successive arrivals of the sound from different parts of a single flash, but they are probably due in most cases to multiple or successive flashes. Many photographs of lightning show the branching of a single discharge into a number of separate paths, and even if all these exist simultaneously they will be at different distances from an observer, and the thunder will, of course, consist of a number of explosions corresponding to the number of branches. Explanations of successive flashes have been given by Dr. Oliver Lodge, and the quivering appearance which is often presented by a flash of lightning has been resolved by a moving camera into a number of separate discharges. When these flashes follow practically the same path, the whole series lasting, as often happens, less than half a second, the thunder would not differ much from that of a single flash. Very frequently the first bang is not the loudest, but a long peal works up to a maximum and then seems to expend itself gradually. Photographs of branched flashes afford an explanation of this. The whole thunder clap is produced practically at the same instant, but the noise due to those outlying branches which are nearest to the observer form the commencement of the peal, the others follow, and being succeeded by the farthest stragglers, suggest a series of explosions.

But however much windows may rattle and buildings tremble, we never hear of a pane of glass being broken by *thunder*, yet a cannon of no extraordinary size will break every window in the neighbourhood by the concussion of its discharge; the glass, for some reason not clearly explained, always falling outwards. The sound of cannon fire can, moreover, easily be heard at fifteen or twenty miles, and occasionally at two or three times this distance. Even on this slender basis it seems safe to argue that the volume of air which is heated by a flash of lightning is considerably less than that of the gases liberated by a charge of powder in a large cannon. The traditional tribute of awe which is paid to it notwithstanding, thunder, it would therefore seem, is but a small scale operation after all, and as much inferior from the point of view of mere "bigness" to the manufactured article, as lightning is for all useful purposes to a 30,000 volt "rotary current."

ELECTROMAGNETIC THEORY.—XV.

BY OLIVER HEAVISIDE.

(*Continued from page 441*).

§ 82a. But the magnetic stress has other work to do than to move elastically magnetised matter under the circumstances stated. Wholly independent of magnetisation, it produces the very important moving force on conductors supporting electric current, first mathematically investigated by Ampère.

The lateral pressure of the stress here comes prominently into view, when we ignore the stress in the interior of the conductors, so that the stress vector in the air at the boundary of a conductor represents the moving force on it per unit area. Thus, two parallel conducting wires supporting similar currents attract one another, because their magnetic forces are additive on the sides remote from one another, rendering the lateral pressure on them greater there than on the sides in proximity. But when the currents are dissimilar the magnetic force is greater on the sides in proximity, and, therefore, the lateral pressure of the stress is greater there, producing repulsion.

Proceeding further, and considering the stress within the conductor also, according to the same law, we find this peculiarity. In the case of unmagnetisable conductors (typified practically by copper), there is no superficial discontinuity in the stress, and therefore no surface forcive of the kind stated. This may be easily seen from § 79, translating the results from the electric to the magnetic stress. There is no tangential discontinuity in the stress because the normal induction and tangential magnetic force are continuous; and there is no discontinuity in the normal component of the stress because (since

Digitized by Google

there is no difference of inductivity) the normal magnetic force and the tangential induction are also continuous.

In (5), (6), (7) turn E to H, and D to B, and U to T, and note that (5), as transformed, are true when the force and flux are exchanged, so that the transformed expressions (6) or (7) vanish.

In the case of a real conductor, therefore, with finite volume density of electric current, the moving force is distributed throughout its substance; and the variation of the stress indicates that the translational force per unit volume is expressed by

$$\mathbf{F} = V\mathfrak{C}\mathbf{B}, \quad . \quad . \quad . \quad . \quad . \quad . \quad (16)$$

where $\mathfrak{C}$ is the current density. This is what Maxwell termed "the electromagnetic force," and it is what is so extensively made use of by engineers in their dynamos, motors, and things of that sort. It is probable, I think, that in grinding away at the ether they also stir it about a good deal, though not fast enough to produce sensible disturbances due to etherial displacement.

§ 83. There is next the force on intrinsically magnetised matter to be considered in connection with the magnetic stress. This is, perhaps, the most difficult part of magnetic science. Although, so far as the resultant effect on a magnet is concerned, we need not trouble about its internal state, but, as before, merely regard it as being pushed or pulled by the stress in the surrounding air, such stress being calculable from the distribution of magnetic force immediately outside it, as modified by the magnet itself, yet it is impossible that the real forcive can be represented merely by the surface traction $\mathbf{P}_N$.

Now, it is possible to find a distribution of magnetification over the surface, which shall be externally equivalent to the interior magnetisation, or to whatever other source of induction there may be. Then we may substitute for the surface traction $\mathbf{P}_N$, another traction, namely, upon the surface magnetification.

Or, we may find a distribution of fictitious electric current upon the boundary of the magnet, which shall be externally equivalent to the interior sources, and then represent the forcive by means of fictitious electromagnetic force on this current, § 82.

Or we may combine these methods in various ways. Evidently, however, such methods are purely artificial, and that to obtain the real forcive we must go inside the magnet. This can only be done hypothetically, and with precarious validity. One way of exhibiting the mechanical action on a magnet, or on magnetised matter generally, is that given by Maxwell in his chapter on the stresses (Vol. II.). This I believe to be quite erroneous for many reasons, the principal being that it does not harmonise with his scheme generally, and that it lumps together intrinsic and induced magnetisation, which have essential differences and are physically distinct. There are many other ways of exhibiting the resultant force and torque as made up of elementary forces, acting upon magnetisation, or on free magnetism, or on the variation of magnetism estimated in different ways. It is unnecessary to enter into detail regarding them. Nobody would read it. It will be sufficient to point out the particular way which harmonises with Maxwell's scheme in general, in the form in which I display it, with a special estimation of magnetic energy. Proportionality of force and flux is assumed. The want of this proportionality is quite a separate question. Given a definite relation between force and flux, the accompanying change in the stress vector, in accordance with the continuity of energy, can be estimated. This I have recently shown how to do in another place, which shall not be more explicitly referred to.

Intrinsic magnetisation possesses the peculiarity that it is, in a manner, outside the dynamical system formulated in the electromagnetic equations, inasmuch as it needs to be exhibited in them through the medium of an impressed force, although this is disguised in the ordinary mode of representation. Calling this intrinsic magnetic force $\mathbf{h}_0$ (any distribution), as before, the induction due to it in a medium of any inductivity (varying continuously or abruptly, if required) is found in the same way as the displacement due to intrinsic electric force in a non-conducting medium of similarly distributed permittivity; or as the conduction current due to the same in a medium of similar conductivity; or, to make a fourfold analogy, as the magnetic conduction due to $\mathbf{h}_0$ current in a (fictitious) medium of similar magnetic conductivity.

I may here point out that a clear recognition of the correct analogies between the electric and magnetic sides of electromagnetism is essential to permanently useful work. Many have been misled in this respect, especially in comparing Maxwell's displacement with magnetic polarisation. The true analogue of $\mathbf{D}$ is $\mathbf{B}$. Investigations based upon the false foundation mentioned can lead to nothing but confusion. There are enough sources of error without bringing in gratuitous ones.

Now, presuming we have induction set up by $\mathbf{h}_0$, how is the energy to be reckoned? I reckon its amount per unit volume to be $\frac{1}{2}\mathbf{HB}$ generally, whether outside or within the magnet; or, in the usual isotropic case, $\frac{1}{2}\mu H^2$ or $\frac{1}{2}\mu^{-1}B^2$. This makes the total work done by $\mathbf{h}_0$ to be $\mathbf{h}_0\mathbf{B}$ per unit volume, if $\mathbf{h}_0$ is suddenly established; of which one half is wasted, and the rest remains as stored magnetic energy. That is,

$$\Sigma T = \Sigma\tfrac{1}{2}\mathbf{h}_0\mathbf{B} = \Sigma\tfrac{1}{2}\mathbf{HB}, \quad . \quad . \quad . \quad . \quad (17)$$

if the Σ indicates space-summation. If $\mathbf{h}_0$ be suddenly destroyed, the energy ΣT is set free and is dissipated, mainly by the heat of currents induced within the magnet itself and surrounding conductors. This is the meaning of $\frac{1}{2}\mathbf{HB}$ being the stored energy per unit volume. But it may not be immediately available. To take an extreme case, if we have a complete magnetic circuit, so magnetised intrinsically that there is no external field, the energy, as above reckoned, is the greatest possible, since $\mathbf{H} = \mathbf{h}_0$. But it is now not at all available, unless $\mathbf{h}_0$ be destroyed. On the other hand, Maxwell would appear to have considered the energy of a magnet to be $\Sigma\frac{1}{2}\mu(\mathbf{H}-\mathbf{h}_0)^2$, which is zero in the just mentioned case. This reckoning does not harmonise with the continuity of energy, although it has significance, considered as energy more or less immediately available without destruction of $\mathbf{h}_0$. The connection of the two reckonings is shown by

$$\Sigma\tfrac{1}{2}\mathbf{h}_0\mathbf{B} = \Sigma\tfrac{1}{2}\mathbf{h}_0\mu\mathbf{h}_0 - \Sigma\tfrac{1}{2}(\mathbf{H}-\mathbf{h}_0)\mu(\mathbf{H}-\mathbf{h}_0); \quad . \quad (18);$$

or, when $\mathbf{H}$ and $\mathbf{B}$ are parallel,

$$\Sigma\tfrac{1}{2}\mathbf{h}_0\mathbf{B} = \Sigma\tfrac{1}{2}\mu\mathbf{h}_0^2 - \Sigma\tfrac{1}{2}\mu(\mathbf{H}-\mathbf{h}_0)^2 \quad . \quad . \quad . \quad (19).$$

Now, according to the reckoning (17) of the stored energy, and the consequent flux of energy, the stress vector derived therefrom indicates that the moving force per unit volume is

$$\mathbf{F} = V\mathbf{j}_0\mathbf{B}. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (20),$$

where

$$\mathbf{j}_0 = \text{curl}\,\mathbf{h}_0. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (21).$$

The interpretation is that the vector $\mathbf{j}_0$ represents the distribution of (fictitious) electric current, which would, under the same circumstances as regards inductivity, set up, or be associated with, the same distribution of induction $\mathbf{B}$ as the intrinsic magnet is. It may be remarked that the induction due to an intrinsic magnetic force does not depend upon *its* distribution primarily, but solely upon that of its curl.

Substituting this current system for the intrinsic magnetisation, equation (20) indicates that the moving force is "the electromagnetic force" corresponding thereto, according to (16), § 82. The accompanying surface distribution of current, representing the abrupt cessation of $\mathbf{h}_0$, must not be forgotten; or we may let it cease gradually, and have a current layer in the skin of the magnet. It may be far more important than the internal current, which may, indeed, be non-existent. For instance, in the case of a uniformly longitudinally magnetised bar, the equivalent current forms a cylindrical sheet round the magnet. In general, the surface representative of $\mathbf{j}_0$ is

$$V\mathbf{N}\mathbf{h}_0 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (22)$$

where $\mathbf{N}$ is a unit normal drawn from the boundary into the magnet. It should also not be forgotten that if the inductivity changes, there is also the moving force (15) or (14) to be reckoned, besides that dependent upon the intrinsic magnetisation.

§ 84. The electric analogue of intrinsic magnetisation is intrinsic electrisation, represented in a solid dielectric in which

Digitized by Google

"absorption" has occurred, and perhaps in pyroelectric crystals. It seems very probable that there is a true electrisation, quite apart from complications due to conduction, surface actions, and electrolysis. When formulated in a similar manner to intrinsic magnetisation, by means of intrinsic electric force $\mathbf{e}_0$ producing displacement according to the permittivity of the medium (which displacement, however, is now also affected by the presence of conducting matter), and with a similar reckoning of the stored energy, viz., $\frac{1}{2}c\mathrm{E}^2$ per unit volume, where $\mathbf{E}$ includes $\mathbf{e}_0$, we may expect to find, and do find, a moving force analogous to (20), viz.,

$$\mathbf{F} = \mathrm{V}\mathbf{D}\mathbf{g}_0, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (23)$$

where

$$\mathbf{g}_0 = -\operatorname{curl} \mathbf{e}_0 \quad . \quad . \quad . \quad . \quad . \quad . \quad (24).$$

That is, magnetoelectric force on the fictitious magnetic current $\mathbf{g}_0$ which is equivalent to the intrinsic force $\mathbf{e}_0$. And, similarly to before, we may remark that the flux due to $\mathbf{e}_0$ depends solely upon its curl.

§ 85. Now bring together the different moving forces we have gone over. On the electric side we have

$$\mathbf{F}_e = \mathbf{E}\rho - \tfrac{1}{2}\mathrm{E}^2\nabla c\,[+\mathrm{V}\mathbf{D}\mathbf{K}] + \mathrm{V}\mathbf{D}\mathbf{g}_0, \quad . \quad . \quad (25),$$

and on the magnetic side

$$\mathbf{F}_m = [\mathbf{H}\sigma] - \tfrac{1}{2}\mathrm{H}^2\nabla\mu + \mathrm{V}\mathbf{C}\mathbf{B} + \mathrm{V}\mathbf{j}_0\mathbf{B}, \quad . \quad . \quad (26),$$

where the third term on the right of (25), and the first on the right of (26), in square brackets, are zero; $\mathbf{H}\sigma$ being force on magnetification and $\mathrm{V}\mathbf{D}\mathbf{K}$ the magnetic analogue of $\mathrm{V}\mathbf{C}\mathbf{B}$. The other component forces can all separately exist, and in stationary states.

Passing to unrestricted variable states, with motion of the flux-supporting media also, the electric and magnetic stress vectors indicate that the moving forces arising therefrom are obtainable from those exhibited in (25), (26), by simply changing the meaning of the electric current and the magnetic current symbols in the third terms on the right. Above, they stand for conduction current only, and one of them is fictitious. They must be altered to $\mathbf{G}_0$ and $\mathbf{J}_0$, the "true" currents, as explained in § 66. Thus

$$\mathbf{F}_e = \mathbf{E}\rho - \tfrac{1}{2}\mathrm{E}^2\nabla c + \mathrm{V}\mathbf{D}(\mathbf{G}_0 + \mathbf{g}_0), \quad . \quad . \quad (27)$$

$$\mathbf{F}_m = [\mathbf{H}\sigma] - \tfrac{1}{2}\mathrm{H}^2\nabla\mu + \mathrm{V}(\mathbf{J}_0 + \mathbf{j}_0)\mathbf{B}, \quad . \quad . \quad (28)$$

express the complete translational forces due to the electric and magnetic stresses (31), (32), § 72.

The division of the resultant translational force into a number of distinct forces is sometimes useless and artificial. But as many of them can be isolated, and studied separately, it is not desirable to overlook the division.

The equilibrium of a dielectric medium free from electrification and intrinsic forces, which obtains when the electric and magnetic forces are steady, is upset when they vary. There is then the electromagnetic force in virtue of the displacement (electric) current and the magnetoelectric force in virtue of the magnetic current; that is,

$$\mathbf{F} = \mathrm{V}\dot{\mathbf{D}}\mathbf{B} + \mathrm{V}\mathbf{D}\dot{\mathbf{B}} \quad . \quad . \quad . \quad . \quad . \quad (29)$$

$$= \frac{d}{dt}\mathrm{V}\mathbf{D}\mathbf{B} = \frac{1}{v^2}\frac{d\mathbf{W}}{dt}, \quad . \quad . \quad . \quad . \quad (30),$$

where $\mathbf{W}$ is the flux of energy. Here we neglect possible small terms depending on the motion of the medium.

That there should be, in a material dielectric, moving force brought into play under the action of varying displacement and induction does not present any improbability. But it is less easy to grasp the idea when it is the ether itself that is the dielectric concerned. Perhaps this is, for some people, because of old associations—the elastic solid theory of light, for instance, wherein displacement of the ether represents the disturbance.

But if we take an all round view of the electromagnetic connections and their consequences, the idea of moving force on the ether when its electromagnetic state is changing will be found to be quite natural, if not imperatively necessary. We do know something about how disturbances are propagated through the ether, and we can, on the same principles, allow for bodily motion of the ether itself. Further, reactions on the ether, tending to move it, are indicated. But here we are stopped. We have no knowledge of the density of the ether, nor of its mechanical properties in bulk, so, from default of real data, are unable to say, except upon speculative data, what motions actually result, and whether they make any sensible difference in phenomena calculated on the supposition that the ether is fixed.

(To be continued.)

MAGNETISM IN IRON AND OTHER METALS.*—XLVIII.

BY PROF. J. A. EWING, F.R.S.

(Continued from page 407.)

§ 166. **Molecular Theories: Poisson and Weber.**—We know that when a piece of iron, or other magnetic metal, is magnetised, the magnetic state permeates the whole piece. A steel bar magnet may be broken up into small pieces, and every piece is found to exhibit magnetic polarity. Assuming the structure to be molecular, it is inferred that each molecule of the magnetised bar is a magnet. Taking a row of molecules in the direction of the magnetisation, we have the north pole of one contiguous to the south pole of the next, and so on along the row—with the result that it is only at the ends of the row that free poles appear. Imagine the row to be broken into two or more parts, however, and each segment of it has free poles at its ends.

The individual molecules of a magnetised bar, then, are magnets, and the question next arises whether they become magnets only when the bar is magnetised. Does the process of magnetising consist, as Poisson suggested, in making each molecule become a magnet? Or are we to adopt Weber's view, according to which the molecules are always magnets, showing no aggregate polarity in an unmagnetised piece, only because their axes point in all directions at random, but turning into line when a magnetising force is applied? According to Poisson, there is no need to suppose the molecules capable of moving within the bar, but we must suppose that magnetic polarity can be induced in the individual molecules. In other words, the question how induction happens is only shifted from the bar to the molecule, and is brought no nearer to a solution. According to Weber, on the other hand, the molecules are to be conceived as free, more or less, to turn and take up a new alignment, very much as a pivotted compass needle will turn when it is directed by a magnetic field; but there is no need to imagine any development of polarity within the molecule itself. The Weber molecule is a magnet before the force begins to act, and the amount of magnetism in it need suffer no change however widely the magnetism of the bar be altered. Hence Weber's theory explains the process of induction to this extent, that it makes the magnetic change of the bar be brought about by a change in the position of the molecules, and not by any change in the quality of the molecules. Of the two views Weber's is the one that consorts best with our general understanding of the characteristics of molecules. Moreover, it receives strong support from certain of the known facts of magnetic induction.

§ 167. **Experimental Evidence in favour of Weber's Theory from the facts of Saturation, &c.**—It would be difficult, in Poisson's theory, to give any reason for the manner in which the magnetisation of iron tends toward a limit as the magnetising force is increased. If the process consists in the development of magnetic polarity in the individual molecules there is no obvious reason why it should not admit of being extended without limit, nor why the relation between the magnetism of a bar and the magnetising force should have the exceedingly complex character it is known to possess. We should rather expect to find proportionality, or something like proportionality, between magnetism and magnetising force, and we should not expect to find residual magnetism or other phenomena of hysteresis. Weber's theory, on the other hand, implies that there must be a limit to the intensity of magnetisation. The limit is reached when all the molecules have become turned to face exactly in the direction

* All rights are reserved.

Digitized by Google

of the applied magnetising force; no increase of the force beyond what is required for that can add to the magnetisation. The fact that a definite saturation value is now known to exist* adds much probability to Weber's hypothesis. Further, the process by which the molecules are supposed to turn hither and thither under varying magnetising forces, leaves ample room, as we shall presently see, for a satisfactory explanation of all the features which the curves of magnetisation are known to present, and the various manifestations of hysteresis become intelligible. Again, the effects of vibration in augmenting magnetic susceptibility are readily accounted for in consequence of the greater freedom which vibration gives the molecules to fall into line with the magnetising force. Additional evidence is furnished by experiments such as that of Beetz, in which the effects were observed of applying a weak magnetising force to iron at a time when the molecules were peculiarly free to respond to its directive action, namely, while they were in the act of being deposited by the electrolysis of an iron salt. The iron was deposited along a line made by scribing a longitudinal scratch on a straight piece of varnished silver wire. The wire was immersed in the iron salt, and was placed in a magnetic field in such a manner that the lines of force ran in the direction of the length. The silver wire formed one pole of an electrolytic cell, and it was found that the metal deposited on the scratch was so highly magnetised that the subsequent application of a much stronger magnetic field failed to augment its magnetism more than a very little. The molecules had been ranged at the moment when they escaped from imprisonment in the salt, and before they had the opportunity of forming fresh entanglements by their action on one another; just as criminals are said to be most easily diverted into regular courses at the moment of their release from gaol, before they have time to resume the ties of their usual companionship. Not only is Weber's notion of molecular magnets strongly supported by this experiment of Beetz, but the cumulative evidence in its favour which is supplied by many facts of more recent observation may be said to give it almost conclusive proof. We may even build up a model consisting of small permanent magnets, such as Weber's theory postulates, in which all the chief characteristics of magnetic induction can be closely imitated. The study of a model of this kind leaves little room for doubt that the basis of Weber's theory, namely, the hypothesis of permanently magnetic molecules, is essentially sound.

§ 168. **Constraint of the Molecular Magnets in Weber's Theory.**—It is clear that if the process of magnetic induction is to be explained as the turning of molecular magnets so that they tend to face one way, the molecules must be subject to some directive force which prevents them from responding with perfect freedom to the magnetising field. Without some such constraint they would at once take the direction of the applied field, and the weakest magnetising force would suffice to produce saturation. In fact, however, magnetisation goes on progressively as the magnetising force is increased, and at every stage the direction taken by each molecule is determined by a balance between the force of the field which tends to turn the molecule, and some other directive force which opposes the turning.

Weber supposed that in a piece of virgin iron the axes of the molecular magnets point indifferently in all directions, and that when a magnetising force **H** is applied, each molecule is deflected against a directive force, which tends to restore it to its original position. He assumes this force to be that which would be exerted by a magnetic force of some constant value, **K**, acting in the primitive direction of the molecule's axis. The direction in which the molecule points while the magnetising force acts is consequently the direction of the resultant of **H** and **K**, and when the external force **H** is removed, the molecule is brought back by **K** to its primitive position. This theory of the constraint of the molecules gives no explanation of residual magnetism or other manifestations of hysteresiss. According to it, the magnetic susceptibility should be constant for all values of **H** less than **K**, and should diminish for higher values of **H**†. At the stage when **H** becomes equal to **K**, and the proportionality of magnetisation to magnetising force ceases, the value of **I** should be $\frac{2}{3}$ of the final or saturation value. This hypothesis is inconsistent of the fact that the early part of the curve of magnetisation is not straight; that the susceptibility is small at first, and increases with increasing magnetising force. This, indeed, is an example of hysteresis, and for the phenomena of hysteresis the theory, in this form, affords no room.

§ 169. **Maxwell's Modification of Weber's Hypothesis.**—To remedy this defect Maxwell has suggested a further assumption, based on the analogy of magnetisation to mechanical strain, with the object of admitting conditions under which the position of equilibrium of the molecular magnets may be permanently altered. He supposes that when a molecule is deflected by a magnetising force **H** it returns completely to its primitive position on the removal of **H** provided the deflection has been less than a certain value, but returns only partially if the deflection has exceeded that value. In the latter case its axis, when **H** is removed, remains turned through an angle which may be called the permanent set of the molecule. Maxwell has examined the consequence of this supposition at some length, assuming the molecules in a given piece to be all capable of the same or nearly the same amount of elastic deflection, and assuming a constant or nearly constant directive force, **K**, to act on each in the primitive direction of its axis. This hypothesis accounts for the existence of residual magnetism, and for some of the phenomena of hysteresis; it fails, however, to explain why hysteresis should be found when, after the first application, a magnetising force is removed and reapplied, and its postulates about directive force and the condition of permanent set are arbitrary. We shall see presently that by considering the action of the molecular magnets upon one another conclusions are reached which really embody Maxwell's idea of elastic and non-elastic deflection, though the directive force and the amount of elastic deflection is no longer arbitrary and no longer the same or nearly the same for all the molecules.

§ 170. **Hypothesis of Frictional Resistance to the Deflection of the Molecules.**—The suggestion has been made by Wiedemann and others that the deflection of Weber's molecular magnets is opposed by a species of frictional resistance, which not only resists the magnetisation, but accounts for residual magnetism and the effects of hysteresis by tending to hold the molecules from returning after they have been disturbed. A directive force, such as that postulated by Weber, is, of course, still necessary. Several of the observed phenomena might be adduced as supporting this notion; in particular, it harmonises well with the effects which are known to be produced by vibration and other mechanical disturbance in augmenting magnetic susceptibility, and in reducing residual magnetism; and also with the comparative suddenness with which the resistance to magnetisation breaks down when a certain stage in the magnetising process is reached. But if the molecules were held fast by friction until the applied force became sufficiently strong to start them, the susceptibility with respect to very feeble forces, should be zero, whereas, in fact, it has a small positive and initially constant value (§§ 86, 87). To make the notion of frictional control agree with the facts, it would be necessary to assume some further complication, such as that a few of the molecules in any given piece are sensibly free from friction, and may begin to turn under the influence of the weakest forces.

(To be continued.)

* The evidence of this has been fully stated above (§§ 91 to 107).

† See Maxwell's *El. and Mag.*, Vol. II., § 443.

The Electrical Trade Section and the Frankfort Exhibition.—The following letter has just been received by Mr. Kenric Murray from the Electro Technical Congress at Frankfort:—

DEAR SIR: We beg to acknowledge the receipt of your favour of the 21st of August. We are very glad to hear that about twenty members of the Electrical Trade Section of the London Chamber of Commerce will arrive here on the 6th of September for the Congress. In order to reserve the tickets for your members, we beg you to give us a list with the names of these gentlemen. Yet we add, that all your other members arriving here, and not mentioned on the list, may immediately get tickets on their demand. The tickets are not sent away, but are to be got *here* on personal presentation at our office of reception in the Electrical Exhibition, opposite the railway station.

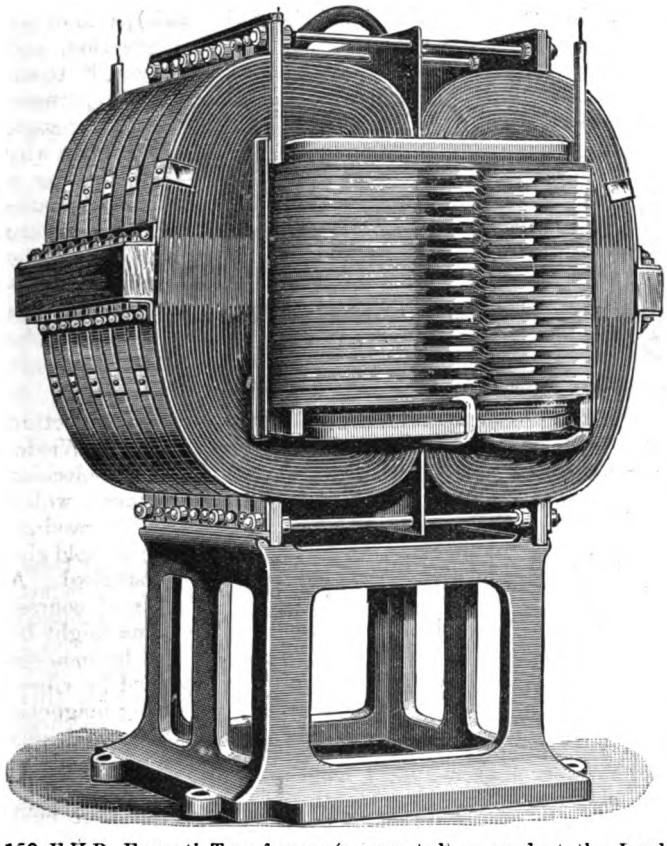
THE FERRANTI SUB-STATION TRANSFORMER.

The accompanying figure shows one of the Ferranti 150 H.P. transformers, specially designed as a sub-station instrument for reducing pressure from 10,000 or 5,000 to 2,400 or 2,000 volts. The transformer consists of three coils—viz., of one high-pressure coil, which is sandwiched in between two low-pressure coils. Each of these coils is composed of copper strip separated by a strip of vulcanised fibre and wound over with shellaced cloth and vulcanised fibre. In forming these coils a number of separate flat coils are built up one over the other, and connected together in series, insulating material being placed between every elementary coil. The high-pressure and low-pressure coils are separated from one another by sheets of ebonite, with a considerable air space between. The iron cores are exceedingly massive and formed of flat bands bent over in opposite directions to form closed magnetic circuits; the various layers of iron bands are separated from one another by an air space of ½in., to provide for ventilation, or, in cases where the transformer is placed in oil, to allow a free circulation to the oil.



150 E.H.P. Ferranti Transformer (unmounted) as used at the London Transformer Sub-stations.

It is advantageous to immerse these high tension transformers under the surface of an insulating fluid, diminishing thereby the liability to electrical discharge between the high-pressure coil and the iron frame, or the low-pressure coil which exists in virtue of the powerful electrostatic field in the neighbourhood of the high potential end of the high-pressure coil.

THE FERRANTI MAINS.

The five-and-twenty miles of concentric trunk mains on the Ferranti system connecting Deptford to the transformer sub-stations in the Metropolis have now been in successful operation for over six months under the "extra-high" pressure of 10,000 volts. This main is made in lengths of 20ft., and is jointed together by electrical or mechanical joints of a very ingenious character, of which, therefore, there are in the above-mentioned distance no less than 6,500. In the manufacture of this main, brazed copper tubes are taken, having equal cross sectional area, either ⅛in., ¼in., or ½in. section, calculated respectively to carry 125, 250, or 500 amperes. In the ¼in. section main, the copper tubes have the following dimensions. The inner conductor, or inner member, is a copper tube (see Fig. 1) of which the inside diameter of cross section will be called D_1, and radius R_1, and the outside diameter D_2, and radius R_2. The outer conduct, or member, is a copper tube of which the inside diameter will be called D_3, and radius R_3, and its outside diameter D_4, and radius R_4. The insulation between the inner and outer members is compressed brown paper and black wax. The values of the diameters and radii of cross section of these tubes are as follows:—

$D_1 = \frac{9}{16}$ of an inch = ·5625 in.
$D_2 = \frac{13}{16}$,, ,, = ·8125 ,,
$D_3 = 1\frac{27}{32}$,, ,, = 1·8437 ,,
$D_4 = 1\frac{15}{16}$,, ,, = 1·9375 ,,

Hence we have—

R_1 = ·281 in. R_1^2 = ·0789
R_2 = ·406 ,, R_2^2 = ·1648
R_3 = ·922 ,, R_3^2 = ·8500
R_4 = ·969 ,, R_4^2 = ·9389

$R_2^2 - R_1^2$ = ·0859,, $R_4^2 - R_3^2$ = ·0889

Hence the area of cross section of the inner member is $\pi (R_2^2 - R_1^2)$ = ·2689 sq. in., and that of the outer member is equal to $\pi (R_4^2 - R_3^2)$ = ·2793 sq. in., or approximately a quarter of a square inch. The copper resistance of the quarter-inch section main is ·324 legal ohms per mile run (including lead and return) when laid. The electrostatic capacity between inner and outer members is ·367 microfarads per mile run, and the capacity between the outer member and the iron casing about ten times as much. The inductance is 286 microhenrys per mile, and the dielectric resistance between inner and outer copper about 700 megohms per mile.

The first process in the manufacture of these mains is to roughly straighten the tube, though in many cases they require no attention. A roll of brown paper, 3ft. wide and several hundred feet in length, is placed at the end of a bench about 20ft. long, and is cut into pieces of this length. Close by are narrow benches, formed of a single plank, having a longitudinal groove near one edge. The copper tube is laid in this groove by a boy, who glues one edge of a strip of brown paper to it. The insulating paper which separates the outer from the inner conductor receives a coating of black mineral wax. A large roll of the paper is placed on trunnions at one end of a hot plate of about 35ft. in length. Beneath this several open fires are kept burning. The paper travels over this at about 20ft. per minute. It is thus thoroughly dried. It then passes over a roller into a tank containing melted ozokerit; it passes under a roller in this tank, and over another roller at the top. It then travels for some distance without touching any support, and during this period the wax sets firm. The paper is finally wound upon a drum. When a drum is full it is taken off and stored. The next process is to cut it up into sheets. A number of these are placed in a convenient position under the rolling machine, at which two or three men are employed in covering the inner conductor. This machine consists of a table, a wax tank, a roller, and turning gear. One of the cores, with its strip of brown paper attached, is brought from the stock, and a square ended plug is driven into each end. It is placed in the machine, and the square ends of the plugs are slipped into sockets which form part of the winding gear, and are fixed by set screws. At the back of the machine is a long tank containing melted ozokerit kept hot by gas burners. Several iron boxes hung from a roller are suspended in the liquid wax. The core being attached to the winding gear, and the brown paper being spread over the table in front of the machine, the iron boxes are lowered by turning the roller by means of a hand wheel and worm gear. The boxes displace the wax, and it flows up over the core. The winding gear is given a turn or two, and a sheet of waxed paper is drawn by two men from the stock of sheets kept below the table. The sheet is laid on the table, and the forward edge is fed in. On starting the winding gear the waxed sheet is caught between the

Digitized by Google

dry paper and the core is wound in, being drawn under the melted wax. As soon as the winding is started, an iron roller is let down and rests on the revolving tube, compressing it well together. Additional sheets of waxed paper are fed on to the plate, overlapping the sheet which is being wound on, and passing under the melted wax. When the proper diameter has been reached, the roll is finished off by a spirally-wound tape. On being removed from the winding machine the square plugs are knocked out and the core is thrust into an outer copper tube, making a loose fit, for it would be impossible to push it in without injuring the paper if it fitted tight. The outer tube projects some six or eight inches beyond the inner, and this portion is flattened down and placed in the jaws of a draw-bench vice.

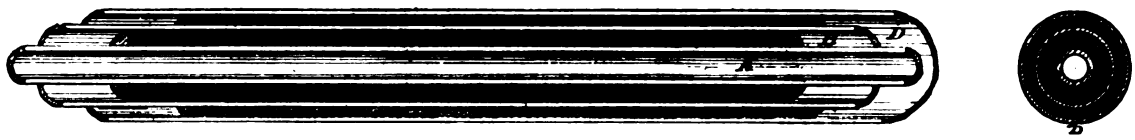


FIG. 1.—Ferranti Main.

A, Inner copper conducting tube. B, Outer copper conducting tube D, Iron protecting tube. (Insulation shaded black.)

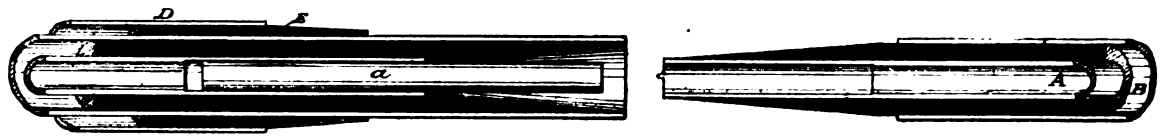

FIG. 2.—Ferranti Main prepared for Jointing.

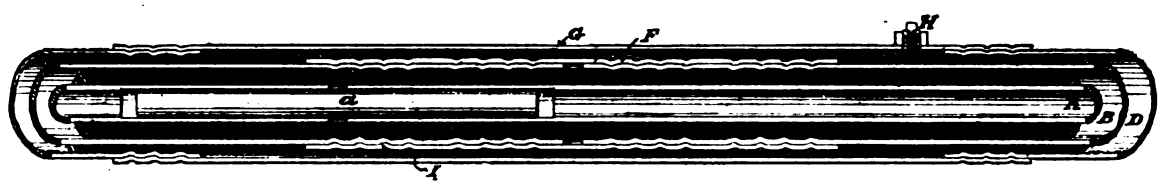

FIG. 3.—Ferranti Main Jointed.

A, B, D, as in Fig. 1. *a*, Copper rod. G, Iron sleeve. F, Copper sleeve. H, Screwhole. I, Interspace filled with melted wax.

The whole is then drawn through a taper die, and the outer tube is forcibly compressed on to the paper, and is, at the same time, slightly elongated. The ends are trimmed off by a circular saw, and as a concentric conductor the length is practically finished. For reasons which have been fully described in a Paper by Mr. Preece, it has been necessary to provide an outer insulation. The outer copper tube is insulated with a thickness of ¼in. of waxed paper, and is slipped into a tube of thin sheet iron, made with a brazed joint. The whole is then placed over an open fire, and melted wax is pumped into a tube drilled in the middle, and is forced outwards to the ends, thus completely filling the interspace with wax.

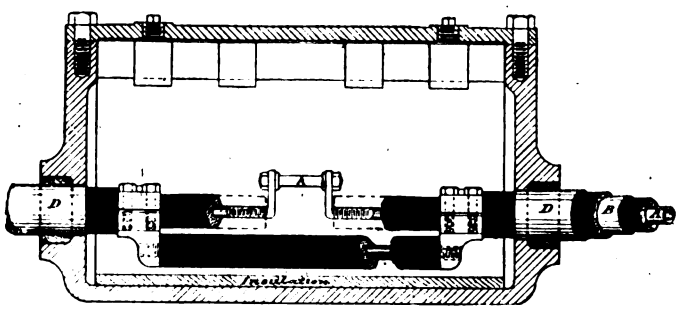

FIG. 4.—Ferranti Street Box. Sectional elevation.

The tubes so prepared, in lengths of 20ft., are then put into a lathe of peculiar construction, and the ends turned down in such a manner that one end is tapered off into a cone, as shown in Fig. 2 on the right, the insulating material being tapered down from the end of the outside copper to the end of the inside copper which projects some way beyond the outer tube. The other end of the main is turned down into a recessed or hollow cone, as shown in Fig. 2 on the left, the two cones being cut to precisely the same angle, so that the outside cone at the end of one main will fit into the recessed cone at the end of another one. The connection between the two inside tubes is made by forcing in a copper rod *a*, which is prevented from going in more than a certain length by a little shoulder on the inner copper tube.

In laying these mains, the process of making the joint is as follows:—The 20-feet lengths of main are laid down underground in wooden boxes, afterwards to be filled in with pitch, and the mains are separated by means of wooden bearers. The lengths of main having been laid down in the proper direction, a copper and an iron sleeve are slipped on over one end of the main. The copper rod is then pushed into the open end of the inner tube, and the two inter-fitting cones of two lengths of the main are forced together by an hydraulic press; the copper rod is rammed half into one inner tube, and half into the other, and forms a good electrical connection between the two inner copper tubes. The copper sleeve is then drawn over so as to connect together the two outer copper conductors, and is corrugated on to them by means of a peculiar tool, which compresses together the outer copper member of each 20-foot length and the copper tubular sleeve which connects them together. This tubular sleeve is

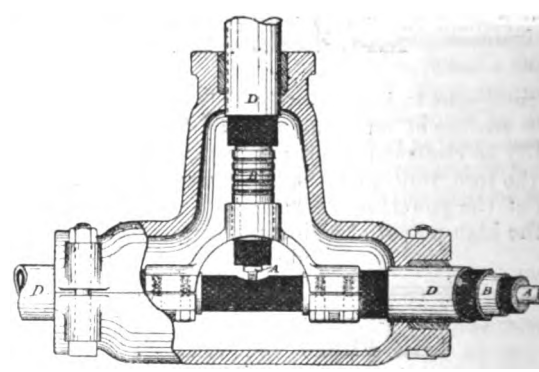

FIG. 5.—Ferranti Main. T Joint.

represented by F in Fig. 3. In the same way the iron sleeve G is then drawn over and corrugated on, connecting together the iron tubes of two adjacent 20-foot lengths, and the interspace I between the iron outer tubular sleeve and the inner copper sleeve is filled in with melted wax, forced in through a screw hole H, which is afterwards closed. In this way a joint is made in which the insulation between the outer and inner copper

Digitized by Google

tubes is perfectly continuous, because the waxed paper cones weld together under the pressure in such a manner that they require very considerable force to pull them apart. In order to allow for expansion, bends are placed at intervals with a slight double curvature of an S shape. The wood troughing in which the mains are laid is then filled up with pitch and a wooden cover is laid over it.

At intervals in the main street, test boxes are inserted so that certain lengths of the main can be isolated for the testing. This street box is shown in elevation in Fig. 4. The ends of the cables are brought into the box at opposite ends, through stuffing boxes, and the inner copper members are approached to within a short distance. The inner copper members are then connected together by means of a crank-shaped copper connection, so made that by slacking the nuts the crank pin can be withdrawn, and the mains disconnected. The connection between the outer conductors is made by a copper clamp, which is wrapped over with waxed paper to insulate it from the box. The cover of the box is then bolted on, the box edges and cover being tooled to true surfaces. The box is finally pumped full of heavy resin oil. A junction is thus effected, capable of easy disconnection, and yet of withstanding 10,000 volts or more, and which is capable of being uncoupled very quickly for the purposes of isolating and testing certain lengths of main.

In cases where the junction has to be effected at right angles a T-joint box is employed of a very similar description. The box parts along the middle line, and the ends of the mains to be connected, are brought in through three stuffing boxes; a junction is effected between the inner members by a screw bolt which screws through the inner copper member of the main, and into the end of the inner copper member of the offset. Waxed paper insulation is then wrapped round this part, and the connection between the three outer copper members is made by a copper fork, clamped on as is shown in Fig. 5. When the joint is made the box is pumped full of resin oil.

THE FRANKFORT EXHIBITION.—IX.

(FROM OUR SPECIAL CORRESPONDENT.)

The following is a short record of the experiments made with the Lauffen-Frankfort plant:—Monday, August 24.—Short circuits caused several times in succession in the secondary wires to test the reliability of the safety fuses in the primary wires. These invariably acted instantaneously. Tuesday, August 25.—Some electric lighting done with the current from Lauffen, 600 16 c.p. 62 volt glow lamps being switched on, and a rotary current motor run without load. Wednesday, August 26.—A rotary current motor run with load. Overheating, however, caused a defect in the insulation, which resulted in a short circuit. The motor is now removed for repairs. Thursday, August 27—Sunday, August 30.—Lighting of 1,000—1,500 16 c.p. 62 volt glow lamps every morning and evening for three or four hours each time. The turbine at Lauffen, up till Sunday, has only run at half load, and the pressure used has, as yet, only reached 20,000 volts at times, the more usual pressure being only 13,000 volts. It is, however, intended to go as high as 25,000, or even 30,000 volts.

In a side room of the Siemens and Halske Exhibition in the Machinery Hall interesting experiments with extra high pressure currents are daily shown to visitors. Alternating current at a pressure of 2,000 volts is obtained from a 450 H.P. dynamo, and transformed up to 20,000 volts. The transformers used are of two kinds, those with and those without oil insulation: the latter being enclosed with glass casing to keep out moisture. A collection of 200 100 volt glow lamps in series is mounted on a large screen on one side of the room to show that the required high voltage has been reached. The experiments with the 20,000 volt arc are very striking, and are similar to those described in *The Electrician* for May 22nd, where an illustration was given of the arc formed.

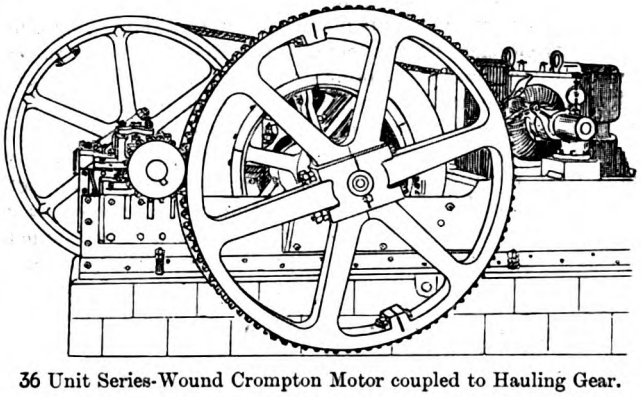
In the experiments seen by me, thin carbon pencils were used to draw out the arc, which usually broke down when the distance between the carbon points was about 6in., the flame of the arc being driven upwards by the hot air, rising to a broad, thick summit, and blazing with a hissing, crackling sound. Plates of glass were also placed between the two poles, and the voltage increased to piercing point. In order to show the phenomena of electric discharges due to electrostatic action, a number of glow lamps were joined to one of the high-pressure terminals of the transformer, and their glass globes put to earth by means of a common plate covering the tops of all. The discharges due to the potential difference between the glass globes and the lamp filaments (10,000 volts) were not brilliant, but could be distinctly observed.

From this department, also, a 20,000 volt current is transmitted for lighting purposes to the Exhibition on the Main. The transformer used is without oil insulation, and enclosed in a glass case to keep it dry, as already stated. The cable used was made by Siemens Brothers, of London, and was tested at the works up to 40,000 volts. The cable is not of the concentric kind, but consists of two cores of copper wire, ·12 inches thick, each protected with a very stout rubber covering, and then twisted into a spiral, and made up to a cylindrical section with jute serving, and finally covered with tape and compound. The cable is simply laid in the ground, and has stood well.

Messrs. Siemens Brothers, besides the above cable, have several other exhibits in the Electric Distribution Hall, and in the Marine Exhibition on the river. In the Hall are patterns of their sea cables, showing the different sizes used according to the depth, and a model of the cable ship Faraday, with cable-laying apparatus; and here are also samples of their lighting, telegraph, and telephone cables. In the Marine Exhibition they exhibit their system of submarine mining for the protection of harbours, &c.

AN ELECTRIC HAULAGE PLANT.

The electric haulage plant which was recently installed (see *The Electrician*, July 31, p. 351) at Abercanaid Colliery, for the Hill's Plymouth Company, in South Wales, shows that mining engineers in that district are beginning to appreciate the advantages of electricity.



36 Unit Series-Wound Crompton Motor coupled to Hauling Gear.

The winding gear was the usual form employed in the main and tail rope system. The motor is a Crompton series-wound machine, built to run at 600 revolutions per minute and take 80 amperes at 450 volts; at starting, when a heavier current is required, it will take 160 amperes without harm. The motor is placed horizontally at one end of a wrought-iron frame (see figure), which forms the bed for the drum and spur-wheel. The drum shaft, which is of steel, is driven from a counter-shaft by means of spur gearing, and the motor drives the counter-shaft by means of six 1in. ropes. The haulage engine is fitted with two drums, 3ft. 6in. diameter and 1ft. wide, which are controlled, as above stated, by clutch and foot-brake. This plant will haul coal from three different parts of the pit, and, although these are not far from the motor at the present time, it is expected that coal will have to be dealt with nearly a mile distant.

The generating plant comprises a Crompton compound-wound dynamo, having an output of 160 amperes at 500 volts

Digitized by Google

when running at 550 revolutions. The cable connecting the dynamo with the haulage plant is 3,200 yards long, and composed of 37/14 copper wire, insulated with vulcanised bitumen. It is protected by a double sheath of No. 8 steel wire, the first stranding being of 30 wires, and the second 36 wires, laid in reverse directions. The cable is carried down the level by the side of the shaft, and between the hauling engines it is fixed on each side of the roadway, and, in case of "falls," the cable has been constructed so that it can stand a shearing strain of ten tons per square inch.

A number of visitors were invited by the Hill's Plymouth Company to see the opening ceremony. The engineer to the Company, Mr. Bailey, stated that his father had put down the first system of rope haulage for mines 30 years ago, and the electric system of haulage now inaugurated would enable the Company to increase its output very considerably. The compressed air system was very costly, and they were thrown on their beam ends, as it were, when Mr. Howell, of Llanelly (Messrs. Crompton's agent) offered to supply this electrical plant. They found that the capital required was only half that for compressed air, while the latter only gave 30 per cent. efficiency, electricity gave 65 per cent., which was a most important improvement. He added that he placed perfect reliance on Mr. Howell's estimates and working, the more especially as since Mr. Howell had erected their electric lighting arrangements at Abercanaid they had never had one hour's stoppage, which spoke well for the machinery and for Messrs. Crompton's work. They found it impossible to go on with horses, and were glad that they had put down an electric haulage plant, and would have great pleasure in showing and explaining it to any others interested in such matters.

THE CAUSES OF VARIATION OF CLARK STANDARD CELLS.*

BY J. SWINBURNE.

It is well known to those who have worked with them that Clark standard cells are not yet to be trusted in very accurate work. It is quite easy to make up a few cells which agree among themselves, but they seldom agree with others made up at different times with different chemicals by different people, and they often take long to "settle down." No one who wanted a standard within less than one-tenth per cent. would set up a Clark and trust it without comparing it with other cells. The measurement of electromotive forces can easily be made within not only one in a thousand, but one in a million, and, as we already have accurate resistances, a standard cell giving even approximately accurate results would be of enormous value. It, therefore, seemed worth while to investigate the causes of variation of Clark cells. The Clark cell has already received the most careful attention from Mr. Latimer Clark and Dr. A. Muirhead, who has, I believe, already gone thoroughly into the chemistry of it; and from Messrs. Wright and Thomson. Lord Rayleigh has, perhaps, gone into the matter more carefully than anyone else; and Messrs. Carhart, Dearlove, Skinner, Fleming, Crompton and very many others have worked at the same subject.

The method I have followed is to take the various parts of the cell separately, beginning at the zinc and eliminating the rest of the cell.

The cell taken as standard throughout most of this investigation was made in strict accordance with the latest Board of Trade Committee's circular. Two were made at the same time, and one, No. 1,614, was sent to the committee, while the other, No. 1,615, was kept for reference. My arrangement for measuring electromotive forces would read about 0·000002 of a volt. Cell No. 1,615, or, as I may call it for reference, the B.O.T. cell, was always kept in the water bath, in which all cells under examination were left. All the apparatus was insulated by being fastened to celluloid plaques fastened to the wall, or by standing on celluloid mats.

* Abstract of a Paper read before the British Association, in Section A, at Cardiff, August, 1891.

Variations due to Zinc.

The following zincs were tried:—1,620 and 1,625 from Townson and Mercer, labelled "free from arsenic"; 1,621 "pure," from Hopkin and Williams; 1,622 Becker's second quality, 1,623, roofing zinc. These were first filed and sand papered, washed in caustic soda, dried with filter paper, washed with dilute sulphuric acid, and then with distilled water. These zincs were suspended in a carbonic acid flask in a saturated solution of zinc sulphate which had been shaken up with barium carbonate and filtered. I need not give the tables of readings of these zincs. At first they varied about 0·4 per cent. The variation increased to more than half per cent. Sometimes one zinc was higher, sometimes another, and on shaking the flask a little the readings were altered. The zincs were cleaned again and dipped for a moment in a weak solution of acid mercuric sulphate and washed. They were thus very slightly amalgamated. After an hour the zincs came within about four in a million. One of them, 1,625, was then thickly amalgamated by dipping in acid mercuric sulphate. Drops of mercury hung to it. It read 0·999910, 0·999976, 0·999988, and finally one in the course of two minutes. The zincs were then put back into solution 1,624, which gave so much trouble before. They now read within one or two in a million. After standing for nearly three weeks they were marked all over, and varied nearly a tenth per cent. among themselves, and more than that compared with 1,621, which had been in another solution acting as a standard in other experiments.

From this it appears that in order to give good results the zincs should be heavily amalgamated. If thoroughly amalgamated practically any zinc will do. The zincs which gave low electromotive forces were always the small ones, that is to say, those which would get the thickest coatings of iron.

To find out whether amalgamating altered the readings an amalgam was made by touching mercury with zinc. It was more than a half per cent. wrong. After dissolving more zinc, the reading was still low, though by stirring in zinc it soon came up to 0·9984 and 0·9994. A series of amalgams was made, containing 25, 12½, 5, 2½, and 1 per cent. of zinc and one with less zinc. These were put in solution 1,628 of zinc sulphate with little iron. The solution was poured in and out many times to secure homogeneity, an important matter to which I will return. The readings obtained were—

25 per cent.	1·000025 and	0·99999
12½ „	1·00008 „	1·000000
5 „	1·000035 „	1·000010
2½ „	1·00005 „	1·000020
1 „	0·997225	
trace	below 0·995	

The second readings, which were taken a few minutes later, are close enough. Amalgams, therefore, having some 2½ per cent. of zinc will do.

Lord Rayleigh has done a great deal of work on amalgam cells, and he found the amalgam always cracked the tube. I made one H cell with amalgam in 1888, which had the platinum led out at the bottom, but it did not crack. I made several other cells at the same time with an internal test tube to hold the amalgam, and none of them cracked. On the other hand the 5 per cent. amalgam broke its test tube. I would suggest that platinum sealed to German glass is always left under constraint, and the crystallisation of the zinc also adds pressure which cracks the tube. My H cell had a little lead glass just round the platinum; moreover, it was very small. The 2½ per cent. amalgam is liquid, so there is no danger from it.

The Zinc Sulphate Solution.

The chief difficulty arises from the presence of iron. Samples were bought from Messrs. Hopkin and Williams, and Becker. These both contained iron. When I say that samples of sulphate of zinc bought as pure from such people as Messrs. Hopkin and Williams contain iron, I mean that they contain enough to cause variation in cells, not enough to get precipitates of Prussian blue. The best method of dealing with iron is to acknowledge its presence and amalgamate the zincs. The best

Digitized by Google

zine sulphate solutions I used were obtained by dissolving granulated zinc in dilute commercial acid, keeping the zinc in excess.

In order to test the effects of various solutions of zinc sulphate, test-tubes with feet were filled with the solutions, and were connected with the standard solution by a siphon tube. This had one end blocked with filter paper to prevent mixture of solutions. It is needless to give tables of readings. Anomalous results were obtained at first, but they were all traceable to the zincs. After amalgamation all the saturated solutions gave the same readings within a few in a million. 1,621, made by dissolving pure zinc in acid, was 100 in a million too low.

To test the effect of acid I added a few drops of "normal," that is, very dilute sulphuric acid, to a saturated solution of Hopkin and Williams's zinc sulphate. Free acid appears to make little difference.

The solubility of zinc sulphate varies enormously with the temperature. If a tube of it is left with crystals collect at the bottom, when it comes to a low temperature all the crystals at the foot. When the temperature rises the upper part can only become saturated again slowly by diffusion. To test this, two zincs were put in a test tube of saturated solution with crystals at the bottom. After a few days the top zinc gave 1·0005 compared with the bottom. The lower zinc was then raised, reading 1. The other zinc was then depressed, reading 0·999475. The difference of density thus causes an error of 5 in 10,000. This tube was 10cm. long, so the error in standard cells may not be so great as this; still diffusion is very slow even in a short cell. This also influences the temperature coefficient. The question of supersaturation has already been dealt with so thoroughly by Lord Rayleigh that I saw no use in experimenting on it.

To sum up, the chief errors caused by the solution are due to traces of iron and variations of density. The zinc should, therefore, be amalgamated. I would suggest that zinc carbonate be omitted. To avoid changes of density, if a saturated solution is imperative, a zinc amalgam must be employed with crystals lying on its surface. This can be done in one of Lord Rayleigh's H cells, or a smaller tube can be slipped into the cell. The surfaces must be on the same level, else all the crystals will collect on the lower one, as that lowers the centre of gravity of the system, thus doing work. A small test tube full of crystals was put inside a larger tube of saturated solution, and this action was found actually to take place.

There is some further complication between the zinc and its solution. Even amalgams will give very large variations if moved about in the solution. This is the case even with dilute solutions. I can scarcely hazard a suggestion.

Mercurous Sulphate.

Samples of mercurous sulphate were bought from Messrs. Becker and Hopkin and Williams. I also had some samples from Hopkin and Williams, Becker, and Griffin, bought in 1888, and some I made myself at the same time. I also prepared some new specimens by heating in an oven a flask with mercury twice distilled in vacuo and redistilled acid. The temperature was kept at 125°C. by a mercury regulator, and only a portion of the mercury was dissolved. The sulphate was washed with distilled water and dried. It is in white crystals. Other samples were made by dissolving mercurous nitrate in water slightly acidified with nitric acid, and precipitating with zinc sulphate. This is perfectly white unless much washed. A yellow colour then appears.

In testing the pastes, some of that used for the B.O.T. cells was used as a standard. Zinc No. 1,621 was kept in a solution of sulphate, and was connected by a syphon with the tube of standard paste, the cell thus made being checked against the B.O.T. standard. After a few days there was never any deflection. The cells seem to tend towards a common value, but that is almost all that can be said. The Board of Trade circular directs the paste to be rubbed up with mercury. This would tend to reduce the persulphate to protosulphate. Mercury cannot be rubbed up with protosulphate, as it does not oxidise the surface, so the mercury is not "killed," and collects in a globule. The mere fact of the mercury mixing shows that the sulphate is bad.

Mercury.

To test the effect of impurities, some amalgam, containing silver, copper, and zinc, was taken. Sodium amalgam was added, and the whole shaken up with salts of lead, iron, antimony, platinum, and tin. The amalgam was then shaken up well with persalts of mercury. The mercuries to be tested were put in little crucibles in a solution of mercurous nitrate. After a few minutes they all agreed.

Temperature Coefficient.

The temperature coefficient of several cells was taken with some care. The following readings were taken, the temperatures being kept nearly constant by adding hot water:—

1,680	0·000287	1,685	0·000492
1,682	0·000421	1,688	0·00085
1,683	0·000324	1,689	0·00042
1,684	0·000756		

Of these cells, 1,680, 1,683, 1,689, had dilute solutions made up of equal weights of water and $ZnSO_4 \cdot 7H_2O$. 1,680 and 1,683 differed only in the mercury; 1,683 gave different coefficients on the two days. The variations in the other cells may be easily explained. If a cell with the zinc at the top has its solution saturated at, say, 15°C, and is then heated, the solution round the zinc is no longer saturated. The temperature coefficient of the cell depends on its past history, in fact, and is lower in spring than in autumn. An H cell, or a tube cell, with crystals of zinc sulphate in contact with the zinc always has its solution saturated at both plates. 1,682 is

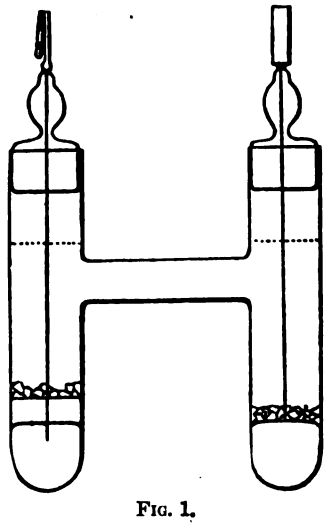


Fig. 1.

an ordinary cell, but the zinc is at the top, hence its low temperature coefficient when heated. If left at 30°C, for a few weeks, and then cooled, no doubt its temperature coefficient would rise to 0·0008, or 80. 1,684 is an H cell, with crystals in both legs. 1,685 is an electrolysis cell, with zinc at the top. 1,688 is a tube cell, with crystals in both tubes, hence its high coefficient. It is thus clear that the temperature coefficient of a cell may vary from day to day according to its treatment, and may, perhaps, vary 100 per cent. between winter and summer. Even a variation between ·0008 and ·0006 means an error that may, in extreme cases, amount to something like a half per cent., that is, it may be outside the limits I have here taken as worth considering. My water bath differed some two or three degrees from one evening to another, and, no doubt, varied more during the day and night. A new cell would thus be saturated at, say, 20°, while the standard was saturated at, say, 15° If the coefficient of one was 0·0008 and of the other 0·0004, the error might easily be 0·0012 due to that alone. To avoid this difficulty the solution must be kept saturated by using the H or tube cell. Some authorities push the zinc into the paste. This may give the same result, but the zinc then amalgamates too much. It would seem better to use a weaker solution. Prof. Carhart and others have proposed saturating at 0°C. It seems much simpler to use a standard solution of sulphate made by weighing.

The construction of the H cell is shown in Fig. 1. One leg contains amalgam with crystals on it, and the other paste.

Platinum wires are sealed through glass stoppers, and end in little bracelet snaps. The stoppers are smeared with vaseline to prevent creeping. Fig. 2 is a tube cell. A test tube with a foot has a cork with two holes in it. Through one of them the tube with internal wire is led to the bottom. The mercury and paste are poured in through a funnel. The zinc tube is then pushed through the larger hole in the cork; it contains the amalgam, and has three holes in the side. It is strong to resist fracture. Solution is poured in gently over the level of the first hole. Rangoon oil is poured in above the level of the second hole. The third lets the air out. The zinc connection is then put in, with its cork fitting the smaller tube. If the solution is saturated, the inner tube must be long, so that the zinc surface is on a level with the crystals on the paste. If a dilute solution is used, the inner tube is shorter. This form of cell is convenient for immersing in a bath, and the zinc tubes can be taken out and changed, or tried in other cells. Though tube cells with dilute solutions and pure mercurous nitrate agree within one in a hundred thousand, it is desirable that such cells should be made up by different people. The questions of the methods of making up standard cells should, therefore, be taken up by a committee.

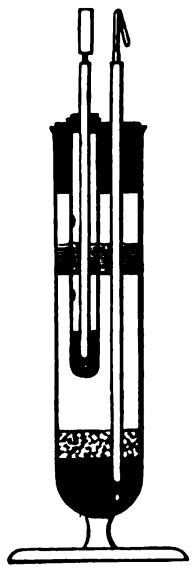

Fig. 2.

Prof. Carhart mentions the effect of pressure on Daniell cells. I tried exhausting a Clark cell a third of an atmosphere, and raising its pressure, but though that must have affected the tendency of the liquid to evaporate, it made no perceptible difference in the reading.

THE BINSWANGER-COATES MICROPHONE.

Messrs. Binswanger and Coates, of the General Electric Company, have recently brought out a microphone which, they claim, possesses the advantage of the vertical form of diaphragm, and also that of being worked best by a single cell. The diaphragm is clamped to the box by means of two brass clamps, without the use of india-rubber. The carbon tension regulators consist of two blocks and two pencils; the blocks are so made that they are clamped to the diaphragm by one screw only, and yet present an angle of about 45deg. to the vertical form of the diaphragm, as shown in Fig. 1. The space between the carbon blocks and the diaphragm is filled by cork, and forms a damping arrangement not influenced by atmospheric changes nor by vibrations—such as, for instance, passing trains in a railway station. Owing to the disposition of the carbon pencils upon the blocks, the vibrations of the diaphragm are transmitted in such a manner that the loose carbon pencils are influenced by gravity alone, and the rolling effect of the pencils, causing that burring and indistinct articulation of pencils in a vertical position alone, is obviated. This position of the cork damper, together with the fact that the vibrations are transmitted from the diaphragm to the carbons by means of two screws only, fixed almost in the centre of the diaphragm, allows the vibration of the diaphragm ample play and full force, so that speech is reproduced not only very clearly, but with increasing loudness.

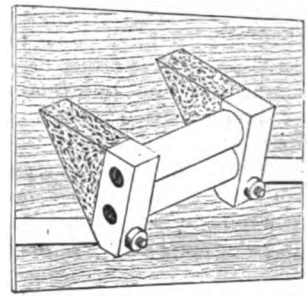

Fig. 1.

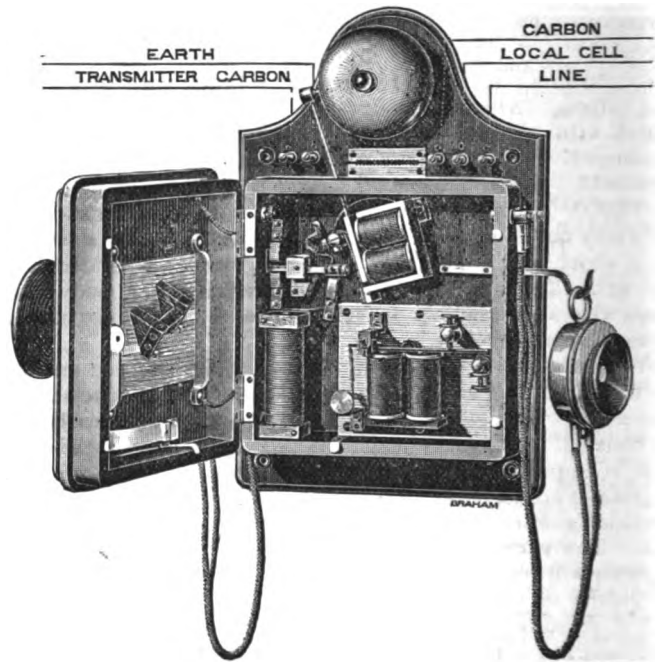

Fig. 2.

A number of railway companies have found these advantages suitable for their purposes, and we illustrate in Fig. 2 a set specially designed with long distance relay for the bells for use in signalling on railways.

RECENT PROGRESS IN THE USE OF ELECTRIC MOTORS.*

BY PROF. G. FORBES.

In the application of electric motors I have noticed three directions in which this country needs the testimony of independent and impartial people to assert the value of applications which in some other countries are generally adopted. These are:—(1) Electric railways. (2) Replacing shafting in shops by electric conductors and motors. (3) Transmitting power to a distance from waterfalls and rivers by electricity.

Electric Railways.—These are thoroughly established in America on the cheapest system, *i.e.*, electricity supplied from a central station by overhead wires. The extensive adoption of electric tram lines in America, and the small number in England, is certainly due to the fact that they allow these overhead conductors, and we do not generally do so. The most trustworthy estimates seem to vary between 4·18 and 6·00 cents per car mile, including coal, attendance, land and buildings, machinery, line, oil, water, and waste. The question of repairs is serious and must be reduced. Most of the lines adopt spur gearing to reduce the speed from the electric motors to the car axles. They generally use two pinions and two spur wheels. This introduces great friction. It is very generally

* Abstract of a Paper read before the British Association, in Section G Cardiff, August, 1891.

Digitized by Google

accepted that 8 H.P. is lost in gear friction, though this seems somewhat incredible, being about 30 per cent. These cars are large, and the motors are of 30 H.P. This enormous power is absolutely demanded to enable them to start on a gradient with facility, and they do this. There is no crawling about these cars. You feel that there is plenty of power for the work. The noise in these cars used to be very considerable, and the injury to watches through magnetisation was at one time an objection. The noise from the gearing, especially when worn, has been deadened by enclosing the motor and gearing in cast-iron boxes. The magnetisation of watches is prevented by adopting a suitable type of motor. Another source of trouble in motors used to be the brushes, for sparking is liable to be very violent with the variable load of a tram motor, and the commutators wore away rapidly. Since carbon brushes have been introduced this difficulty has entirely disappeared.

The loss in double reducing gear and the wear and tear led to all the important companies turning to single reducing gear with rather heavier motors. It would at first appear impossible to go farther, and adopt armatures on the wheel axles without sacrificing the great advantage of gearing, which allows the motors to be independently supported without being subjected to the same shocks as the wheel axles. In spite of this, the Westinghouse Company has introduced a gearless motor, which has strength enough to stand the shocks. But other inventors had the idea of fixing the armature alone on the axle, and supporting the field magnet wholly on springs; to support it partially on springs is of little value. In this direction the most important and promising plan seems to be that adopted by Eickmeyer and Field. They support the whole motor in guides on springs, and connect the motor axle and the wheel axle by cranks and a coupling bar, the cranks on the right and left sides being at right angles to each other. This seems to reduce gearing friction to the minimum, while completely obviating shocks.

In America spur gearing is almost universal, but in Switzerland the Oerlikon Company are introducing worm gearing, which has been so much approved by Mr. Reckenzaun. Storage batteries have not generally been successful in America, but in some trials have worked very well.

Replacing Shafting by Electricity.—The benefit of replacing shafting by electric conductors and motors has been thoroughly appreciated in America. Everyone knows of the hundreds of motors for small work which are supplied with electricity by central stations in Boston and New York, besides other places, and of the large number of electric lifts supplied by the Otis Company with electric motors designed by Eickemeyer. I will only place before English manufacturers two of the establishments where a statement of what has been done is enough to bring conviction to the mind of every shrewd and sensible employer of power. In the great works of William Sellers and Co. shafting has been abolished as far as possible. The second establishment is Baldwin's locomotive factory, whence from 16 to 20 locomotives are sent off every week, and where space is so far valuable that there is no room for shunt lines, and where a 100-ton travelling crane picks up one out of the 20, and puts it down where wanted. This fine travelling crane, and every other crane in this huge part of the works, are driven by electric motors.

Transmission of Power to a Distance from Waterfalls.—With regard to transmission of power to a distance from waterfalls, I have seen little to chronicle in America, and what there is seems rather antiquated; but in Switzerland important work has been done both by continuous and alternating currents. The high tension electrical work in connection with continuous currents that most impressed me was what has been done by Cuenod, Sautter, et Cie. Their six-pole machines, with Gramme commutators up to 2,000 volts, designed by M. Thury, seem to work admirably and sparklessly, and I must here state my conviction, which I did not previously hold, that the insulation of such a machine can be made perfect, as there done, by supporting the dynamo or motor on a number of alternate slabs of vulcanised rubber and porcelain, and by connecting the shafts by Raffard couplings.

I will not take up time with describing different works of this kind, but I will now say something about the use of multiphase alternate, or rotary currents, about the prospective use of which so much has been published. I have seen the machines and transformers in course of construction at Oerlikon, and the insulators which have been used; the mechanical design is excellent. I can quite appreciate the difficulties of regulation of three currents referred to by M. Dobrowolski, but I think that there are further points upon which information is much wanted. I want to know, for hitherto I have utterly failed to see, the advantage of this three-phase synchronising alternator over the simple alternators which do such excellent work. I have been told that calculation shows that Mr. Brown's machine has 96 per cent. efficiency as a dynamo. Well, I reply that an ordinary alternator without iron, not having the hysteresis of Mr. Brown's machine, ought to have a higher efficiency, In the next place I am told by Mr. Brown that while you cannot switch one of these three-phase synchronising motors, with its load, on to an electric circuit, and expect it to get up to the synchronising speed, yet it will do so along with the electric generator of electricity, if the latter be also started from rest. In this it certainly has the advantage over the synchronising alternator with iron, but none whatever over those without iron, which will act in precisely the same way unless the motor happens to be stopped on dead centres, *i.e.*, with the centres of coils (in a Mordey alternator, for example) half way between the poles of the field magnets. If this is the only gain over single phase alternators with self-induction, and if there be no advantage gained over alternators without large self-induction, I fail to see the merit of the complication of three phases. I would not have drawn attention to the absence of advantage, but would have preferred to await the experiments before expressing an opinion, were it not for the great attention directed to the scheme by the Press, altogether out of proportion to the results which Mr. Brown and the Oerlikon managers hope to obtain. The great experiment about to be tried at Frankfort, which interests electricians all over the world, is not to prove that transformation is efficient, but to prove that 30,000 volts can be carried along 112 miles of overhead conductor.

M. Dobrowolski says that whatever load may be put on his motors, there is no serious difference in phase between the poten tial difference applied to the motor and the current, and there is no appreciable lag. If this be so, it would be a decided improvement; but I shall require strong proof before I accept the multiphase motor as a great advance over the Tesla machine. The only advantage which it possesses over synchronising alternators without iron in the armatures and with large momentum, lies in its power to start with the load on. But I do not see that in large applications this advantage is to be compared with what it loses by its want of synchronism. M. Dobrowolski claims that these machines have the further advantage over the synchronisers that they will not stop when overloaded. After having tested Mr. Mordey's synchronising alternators, I have a strong conviction, almost amounting to a feeling of certainty, that it is impossible to put them out of step in ordinary conditions by merely increasing the load. The more you increase the load the more current goes through them to keep them in step. They would rather get red hot than get out of step. They behave just as a continuous current motor or Tesla motor, or a Dobrowolski motor, behaves under the same conditions; it gets hot, but it does not stop.

People seem to be greatly at a loss to explain why it is that some alternators work well as motors, while others do not. The explanation is simply that the former have a large momentum, and the latter have not. I announced this explanation of the difficulty at a meeting of electricians in Paris, last February, and found that M. Hospitalier had arrived at exactly the same conclusion, and quite independently. I feel confident in predicting that the Ferranti dynamo, if supplied with a heavy enough fly-wheel, will be found to work as well as the Mordey machine as a motor.

BRITISH ASSOCIATION.

UNITS AND THEIR NOMENCLATURE.

On Tuesday, last week, a joint discussion took place on the above subject in Sections A and G, under the presidency of Dr. Oliver Lodge.

The PRESIDENT, in the course of his opening remarks, stated that he thought that in the beginning they had better confine themselves to electrical units, and leave the more academical and mechanical until a later period. One of the most pressing points in connection with electrical units was the want of an authoritative statement of the coefficient of self-induction and of mutual induction. Many names had been suggested for this unit, *secohm* and *quadrant* for instance, also that it might be named after some man. The name "secohm" had its advantages and its disadvantages. It expressed the unit of self-induction as derived from the ohm, but the ohm itself was based upon self-induction. If it should be called a quadrant, it must be remembered that a quadrant was an angular measure and it had the disadvantage that it pretended that the thing was a length when it was not a length. He thought they would make a mistake if they fixed it for all time as a length. Some name with a less obvious meaning was desirable, such as that of a man. Was the secohm a convenient size? The C.-G.-S. units were a connected system before any practical units were invented, and were of quite the wrong size for practical engineers. Very few people, he thought, had to deal with coefficients of induction of more than a secohm; this statement he made subject to correction. Would it not be better to make the practical unit some submultiple, $\frac{1}{10^9}$, or something of that sort? The next unit was either the unit of magnetic field or the unit of magnetic induction. There was a C.-G..S. unit of magnetic field which had not yet had a name given to it, but it was too small for engineering purposes; moreover, the definition of the unit was not one which immediately applied to practical engineering.

Mr. W. H. PREECE remarked that the work of the British Association Committee on Electrical Standards had extended over thirty years. It

Digitized by Google

was first formed in 1861, at Manchester, and with much difficulty and trouble they had succeeded in impressing those units over the whole world. During the last year a Committee appointed by the Board of Trade had been considering this work of the British Association, with the result, probably, that steps would be taken to make the ampere, ohm, volt, and so on legal standards. Having worked many years to achieve this result, he was afraid that the British Association would be running its head against a brick wall if it attempted to upset the system it had established; nevertheless, he intended to suggest a change. There is a difficulty in pressing new names into our language, yet new names must be invented to describe new things, and he was a great advocate for the use of words based on the names of the great departed; it was a method of paying a graceful tribute to their memories. Such names sometimes prevented great difficulties, preventing mistakes, for instance, such as those sometimes made in distinguishing power and work. Such words as Watt and Joule never cause confusion. He thought that the names of living persons should not be applied to the units. The time had come when a unit of magnetic force must be adopted. There was once a demand for a unit magnetic pole, but that time had passed. Two great quantities were most important and required much attention; one was the μ and the other k. He always spoke of L, the coefficient of self-induction, as "electro-magnetic inertia," and he wished that they had a unit for that term; he thought that a good name would be *henry*. He thought that the name of Gauss should be applied to a unit; a new table of specific resistances should be made; a new determination of J, the mechanical equivalent of heat, was also wanted. They required to get rid of that useless table of dimensions which encumbered every text book and engineer's pocket book, and they wanted dimensions based on some physical fact. He should be sorry that any decision come to that day should interfere with the old standards now about to be legalised, especially as in 1893 there would be an Electrical Congress in Paris, which would have to adopt our legalised standards, so that, in the end, the British Association electrical standards must become those of the world.

Prof. W. STROUD then read a Paper entitled "Some Revolutionary Suggestions on the Nomenclature of Electrical and Mechanical Units," of which Paper the following is a summary:—

The Present Practical System of Units.—The present practical system of units is very objectionable on these grounds:—(*a*) There is no *primâ facie* reason why the practical unit of current should not be equal to the C.-G.-S. unit. (*b*) The relation between the other practical electrical units of the corresponding C.-G.-S. units is much more complex than need be. (*c*) The units of work and power are far too small for practical requirements. (*d*) If we were starting to devise a practical system to-day, such a system could best be formed by 10^9 cm. as the unit of length, 10^{-9} gr. as the unit of mass, and one second as the unit of time. (*e*) That in the interests of the practical men of the future, and in the interests of the electrical students of both the present and the future, it is highly desirable to initiate a revolution, with the object of dethroning the present practical system of units.

Nomenclature.—(*a*) That the term Dyne, to indicate 10^7 of our present (1891) dynes, is objectionable, as custom has restricted the use of Greek derivatives entirely to C.-G.-S. units. That 10^7 dynes, *if required*, should be called a hebdomadyne, suitably contracted, of course. (*b*) That the classical languages are of little or no service for the provision of names for modern, more or less complex, physical conceptions; and, therefore, this method of coining words it is desirable to abandon. (*c*) That for C.-G.-S. units some system of *automatic nomenclature*, in which every name shall be self explanatory, would prove a boon to the teacher and a blessing to the student, and that such a system is quite capable of being devised. (*d*) That the prefixes *meiza* to indicate 10^9 and *mei* to indicate 10^{-9} may be found useful.

Mr. SWINBURNE thought that they had better stick to the old standards as long as possible, especially as great difficulties are thrown in the way of practical people by the making of changes. He did not think that the idea of self-induction would ever spread much among those engaged in practical work. He hoped that the name of Poggendorf would not be left out from those applied to units.

Dr. G. JOHNSTONE STONEY would like to see the old system maintained intact. He was a member of the original committee which fixed the C.-G.-S. system, and it was pointed out at that committee that no system could be proposed which would not in some cases be too large or too small. Some notes in Prof. Everett's book about his (Dr. Stoney's) opinions on units did not express his opinions at all. He thought that the proper way to deal with the subject before the meeting was to introduce a nomenclature which would indicate multiples and submultiples, as had been done in spectroscopy, and to let practical men select numbers most useful for their purposes. For instance, the microfarad he would call the sixth farad, and it would do for cables; the $\frac{1}{10}$th farad would act for the Leyden jar. Why not have a nomenclature to indicate in each case what was being used? All the measures employed should belong to some definite system. He thought it to be a great misfortune that, as they had just heard, persons engaged in making transformers could not tell what self-induction was, for it would be well that every artisan should know what he was about. He was averse to any revolutionary change in the standards; although he did not think the C.-G.-S. system to be the best, he should be sorry to see any great change in it now. The speaker then showed to the meeting a table of the relations between electrical units.

Continuing, Dr. STONEY said that he thought that the name for the unit of magnetisation should be *gilbert*, and that of the unit of magnetic field should be *gauss*. Weber's name should be brought in, but the difficulty would be that some persons would give it its German pronunciation of Veber, whilst others would call it Webber. The table he had produced was intended to be used merely for conversions, and not for introducing a new system of measures. He thought that the time had come to get rid of the word "force" as applied to that which is only one factor of a force; potentials should be called force factors. Why not speak of these all as energy factors? The word "pressure" was very misleading, and he thought that "voltage" should be substituted.

Prof. CAREY FOSTER was glad to hear Dr. Stoney's conservatism in the matter of the units which have proved so useful; if they were to begin the work over again they would always be uncertain what they meant by their names unless a special adjective were appended to them. Still, they wanted a volt and an ampere ten times as great as those now in use; some name connected with Galvani, "*gal*" for instance, might be given to one of them, and another word found to represent ten amperes.

After a few remarks from Prof. RUCKER,

Prof. SILVANUS THOMPSON said, in relation to the unit of self-induction, that Dr. Lodge had stated that he did not see why its coefficient should be considered as a length, but it *was* a length, and Sir William Thomson had devised an ideal experiment illustrating the point. They needed that a physical fact should be discovered to enable them to determine the absolute value of k or μ.

Prof. ANDREW GRAY thought the phrase "electromotive force" was unfortunate, but that it would cause much inconvenience to drop it. A clear distinction, ought, however, always to be made between *electro-motive force at a point* (that is the *electric force*) and the electro-motive force round a circuit. It would cause serious confusion if one word were used in two senses; if the word "force" were not used alone, but described at the time of speaking, he thought that not much disadvantage would arise. He trusted that more attention would be given to what was of greater importance than finding a name for the unit of inductance, *viz.*, the calculation of coefficients of induction.

After a few remarks from Prof. D. E. JONES,

The PRESIDENT stated that time would not allow the continuation of the discussion; he hoped that it would be continued in the journals, especially as at present it was not quite clear what was actually wanted in practice.

Mr. PREECE thought that it would be objectionable for the British Association to suggest any change in the principle of the unit. The farad was as immense as the universe, and the microfarad very small, but useful; he thought that it would be well to call the microfarad the farad, and that they should call the volt and ampere either the ten-volt and ten-ampere, or the *weber*.

Mr. W. MOON contributed a Paper which was taken as read, and which set forth the disadvantages of the C.-G.-S. system, the units of which were so small that one could form no conception of their value, and that, owing to this smallness, it was necessary to introduce a separate set of practical units for ordinary purposes of measurement. These disadvantages might be overcome by taking as fundamental units L and M larger, or T smaller. Of all the systems of metrical units that could be formed by varying L and T by multiples or sub-multiples of 10, that system was the best which was founded upon the "decimetre, kilogramme, and decisecond." If the name "instant" were given to the decisecond, the system could be spoken of as the D.K.I. system. In the D.K.I. system, "g" = 981, or nearly unity, so that the weight of a kilogramme could be taken as the unit of force for rough calculations. This would be a great improvement, since the simplest way to conceive a force is as the weight of unit mass. A prepared table showed that all the D.K.I. units were sufficiently large to be used for practical purposes, and that all the multiples and sub-multiples of them that would be required could be expressed by the usual Greek prefixes to their names. To express the large numbers required for insulation resistances, and the small capacities of condensers, the Greek prefixes, "Omega" and "Omicra" might be used for powers of 10^{12} and 10^{-12} respectively.

TANNING BY THE AID OF ELECTRICITY.*

BY DR. S. RIDEAL AND A. P. TROTTER.

The slow rate at which a hide is converted into leather in the ordinary process of tanning has induced many inventors to devise methods by which the chemical change might be accelerated without deterioration of the quality of the leather produced, but the want of any definite knowledge as to the precise nature of the interaction which takes place between the gelatin of the raw hide and the various tanning employed in this industry has been a serious obstacle in the development of these methods, and many of the proposals after having been tried on a small scale have been abandoned in favour of the old and slow process. It is necessary to refer to some of these proposals in order to understand the position of the industry a few years ago, when the first important steps towards the employment of electrical energy for hastening the tanning process took place.

One of the earliest patents for accelerating the process of tanning by mechanical methods is that of Francis G. Spilsbury, of Walsall, Staffordshire, and is dated 1823. He used oblong frames of wood and stretched the hides on these, placing a frame between, and thus forming a vessel, having stretched hides for its sides. Into this vessel the tanning liquor was run through a pipe from an elevated tank, pressure being regulated by the hydrostatic head. The hides became distended and the liquor oozed out, forming drops like dew. By this process it is said that the hides could be tanned

* From the *Journal* of the Society of Chemical Industry, No. 5, Vol. X.

Digitized by Google

in six weeks, or in some cases in eight or nine days, instead of a year. The process was abandoned owing to the trouble entailed in closing any holes or tears in the hides and the considerable waste caused by cutting the hides to fit the frames. Another early invention for hastening tanning was that of T. J. Knowles, who employed an air-tight vat. The hides were suspended in the liquor from hooks at regular intervals, and were provided with leaden weights to keep them uniformly stretched. The air was exhausted by a pump, and after an interval the liquor was removed and the air admitted. This process was repeated until the tanning was accomplished.

One of the first applications of mechanical motion was that of W. Brown, of New York, who employed a reel or cylinder, composed of two heads and a number of longitudinal bars, with pins on the outer surface on which the hides were fastened. He also threw them loose into the cylinders, which were slowly rotated by means of ratchet gear. In America, a rocking bar was used, the hides hanging from it and alternately dipped into the liquor and withdrawn from it. A modification of this consisted of a frame moving up and down, dipping the hides in the vat. These and other mechanical methods were used for the simple purpose of obtaining a continually fresh application of the tanning liquor to the surface of the leather, instead of the ordinary daily handling of the hides. These mechanical processes may be broadly divided into two classes: those in which the hides are allowed to hang or are stretched on frames, and those in which they are rolled or churned loose in bulk. In the former class, the stirring of the liquid is practically as efficient as in the latter, but there is no tendency to remove the soluble or soft gelatin and albumen by kneading and churning, and the hides being always surrounded by the liquor the tannage proceeds uniformly in every part.

So far the mechanical processes are designed for an obvious purpose, but when we come to the application of electricity to tanning, we find that the inventors are groping in the dark, using a powerful operator, but with no rational principle or motive. The only *à priori* reasons for applying an electric current to a hide in a tan pit are, that some electrolytic action *may* liberate some tanning agent in a nascent state, and that dialysis is accelerated by the passage of a current, and that there is a relation between osmosis and electrolysis.

As early as 1849 a tanner named Crosse proposed to utilise "electricity or galvanism for tanning purposes." The electrodes consisted of sheets of zinc and lead, immersed in an ordinary tan-pit in which water and the hides were placed, bark or other tanning material being added from time to time, after the skins had been subjected to this action for some days. Ward, in Lancashire, some years later, passed a current of electricity through the tanning liquor in ordinary tan-pits. In 1861, Rebu made several experiments on electrical tannage, employing various metallic salts as well as ordinary liquors in his pits. In 1874, de Meritens, of St. Petersburg, turned his attention to the subject, and has for some years adopted in nearly 600 pits the following plan of electric tanning. A layer of carbon connected with the positive pole of a dynamo is placed at the bottom of each vat, and it is then filled with the alternate layers of moist skin and tan, a plate of zinc forming the negative pole at the top of the pit.

In 1876, Lucien Gaulard and Kresser proposed another process in which they used two parallel plates of carbon, and immersed the hides between them in tanning liquor, passing a continuous current of electricity through from plate to plate. Leather made by this process was exhibited in London in 1883. The process of Landin and Abom has been worked for more than two years in the tanyard of Messrs. Nielson, of Norrköping, in Sweden. Here the hides are attached to wooden frames, and are placed in a pit. Large copper electrodes are provided, and an alternating current is passed.

A simple combination of motion and electrical treatment was patented in France by Worms and Balé in 1887, and consists of a large drum, some 11ft. in diameter, mounted on a horizontal shaft, and filled one-third full of tanning liquor, together with some turpentine, and in this half a ton of hides are placed loose in bulk. The drum is set in motion by steam power, and current of about 10 amperes is passed through the contents by means of copper electrodes placed on the interior surface of the ends of the drum. Nicholson and Palmer (Eng. Pat. 9776, 1889) have also described a similar process, in which the hides are suspended on the positive electrode within the rotating drum, and the current of electricity is caused to flow mainly through the hides.

Another distinct process is to be found in the Groth system of tanning, a description of some of our experiments on which forms the subject of the present communication. In Groth's apparatus there is a combination of motion and electrical treatment, but the motion is of such a nature that the hides being left stretched and suspended in the liquor are not churned about or rubbed one on the other, as in Worms and Balé's process.

The two practical forms in which Groth's invention has been worked at the Grange Works, Bermondsey, are, first, a round vat containing a revolving frame carrying the hides, and, secondly, a rectangular tank in which a similar frame is carried to and fro, running on wheels, and moved by a crank. One of the circular vats placed at our disposal was 7ft. 3in. in diameter and 6ft. 4in. deep. The cubic contents were thus about 315 cub. ft., or nearly 2,000 gallons. The sectional area in a vertical plane is about 43½ sq. ft., the superficial area in plan is 42 sq. ft. A strong central shaft turns in bearings, and is driven by bevel gear, the arrangement being precisely like a brewer's mash tun. Wooden arms are attached to the shaft, and carry cross pieces. These are provided with a number of brass hooks, by means of which the hides are hung vertically, about an inch apart, all the metal work in contact with the liquor being brass or copper. Electrodes are placed against the sides of the vat. These consist of strips of copper arranged gridiron fashion. Four strips, 4ft. 3in. long by 2in. wide, are placed 8in. apart, and are connected at the top and at the bottom by strips of similar width. The whole surface exposed is, therefore, about 4 sq. ft. Experiments were also carried out in a rectangular vat, in which the hides were moved backwards and forwards longitudinally.

The tanning liquors were made of the usual materials, and during the tannage were strengthened from time to time in the usual way, and the hides were prepared for tanning by liming, unhairing, fleshing, and colouring, as practised by most tanners.

The current was varied in different experiments, according to the nature of the hides and strength of liquor. This is important in order to obtain satisfactory results. Previously to our investigation a series of experiments, in which the current varied from 1 to 30 amperes, was employed; best results were obtained with the weak currents, and the considerable loss due to electrolytic action when a greater current was employed was thereby avoided. With a current from 1½ to 4 amperes, the density is from ·375 to 1 ampere per sq. ft. of electrode, and from ·0345 ampere per sq. ft. transverse sectional area of the contents of the vat to ·092 ampere per sq. ft.

For currents from 1·3 up to 2·3 amperes, the total resistance of the liquor at 9°C., sp. gr. 1·01, expressed, for convenience, in ohms, was 8·7. On another occasion, at 7°C., sp. gr. 1·019, the resistance was 7·7 ohms, with 2·3 amperes. In each case the resistance was measured by observing the current and the volts between the electrodes. The quotient gives the sum of the ohmic resistance and of the polarisation. Exploration of the vat by means of a movable electrode showed that the flow of current was very uniform.

In our earlier experiments the current and voltage were observed, the vat being full of tanning liquor up to a certain mark. The hides were then put in, displacing a certain quantity of liquor. This was removed until it stood at the same mark as before, and the resistance was again determined. The results obtained in this way, however, did not give us any very definite information as to the variation in the resistance of the hides during their conversion into leather, but were sufficient to show that the hides when just immersed did not offer any material additional resistance to the electric current. Arrhenius (B. A. Electrolysis Report, 1887, 345) has previously pointed out that the resistance of solidified gelatin is not different from that of gelatin solution.

A more careful and accurate series of observations were subsequently made on the electrolytic resistance of the tanning solution, from which the following curves were obtained:—The temperature coefficient was, as might be expected, negative. The resistance decreased ·9 ohm for a rise of 1°C. or 1·32 per cent. at 16°C., falling from 75 ohms per cubic inch at 8·6°C. to 59 ohms per cubic inch at 26°C. The liquor was a strong solution containing 4·25 per cent. of tannin, obtained from mimosa bark and gambier, such as was employed during the later stages of the tannage. The same sample was tested for the purpose of ascertaining the true ohmic resistance and the fall of volts due to polarisation with different current densities on the electrodes. The resistance of the given sample of the liquor at 8·5°C. was 82 ohms per cubic inch—11 d where d is the density in amperes per square foot of electrode. This is shown by the straight falling line in Fig. 1—

$$v = 82 - 11\,d.$$

The voltage lost at the surface of the electrode is not so simple a quantity. It tends to a minimum of 1·4 volts for a minimum current, and the two following empirical formulæ closely approximate to the observed curve—

$$\text{Volts} = 1{\cdot}4 + 45\,d^{1{\cdot}2}$$

$$\text{or} = 1{\cdot}4 + {\cdot}194\,d + 8\,d^2$$

where d is the density of current in amperes per square foot. This is shown by the rising curve on Fig. 1.

A third series of tests were made to determine the change of resistance produced by diluting the liquor with water. The curve of the results of the observations, shown in Fig. 2 by the dotted curve, which evidently bears a strong resemblance to a rectangular hyperbola, and on analysing it by plotting the relation of the pro-

Digitized by Google

duct of the resistance into the strength, with the strength (taking the normal strong liquor of 4·25 per cent. of tannin as 100) the result is a straight line, shown on the diagram, the slope of which is 63, and it cuts the axis of the abcissæ at 120. The curve is, therefore, a rectangular hyperbola, that is to say, the resistance is inversely proportional to the strength of the liquor, plus the resistance to which the curve is asymptotic, that is, the resistance of the saturated solution per cubic inch would be 63 ohms per cubic inch. The formula is, therefore, $r = \frac{120}{s} + 63$ where s is the strength of the liquor per cent., 100 being the normal solution referred to.

With the view of ascertaining whether the mechanical stirring of the liquor had any oxidising or other effect upon the liquor, a vat was filled and the frame was kept rotating as in ordinary work, but without any hides, for 24 hours. Analysis of the liquor before and after this treatment gave identical results as far as the practical

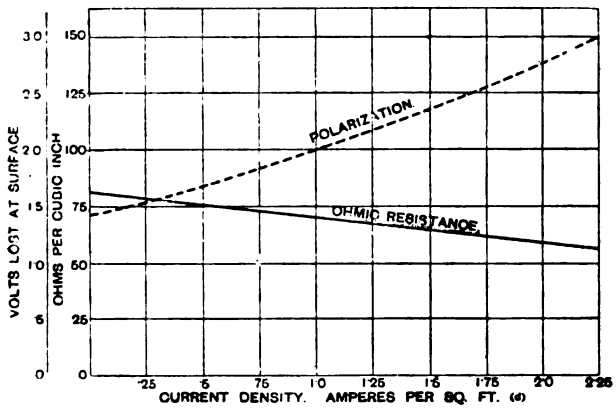

FIG. 1.—Polarisation Effect

point of the percentage of tannin is concerned, thus showing that the stirring has no effect other than that of continually bringing fresh liquor to act on the surface of the hides. A similar experiment was made to determine the effect of passing an electric current of ordinary working strength for 9 hours through the vat simultaneously with the motion of the frame. At the end of the experiment the liquor contained the same percentage of tannin. This result was to be expected, as the electrical power is remarkably small and the current density in the liquor is far below that of any ordinary electrolytic operation. Taking the mean volts and amperes of the second test already mentioned, and deducting 1·6 volts for polarisation, we have 36·8 watts expended in the liquor. It is obvious that this very small power, about $\frac{1}{20}$ of a horse power, can have but little effect on 2,000 gallons of liquor. The electrolytic effect is negligible when such weak currents are employed, since a

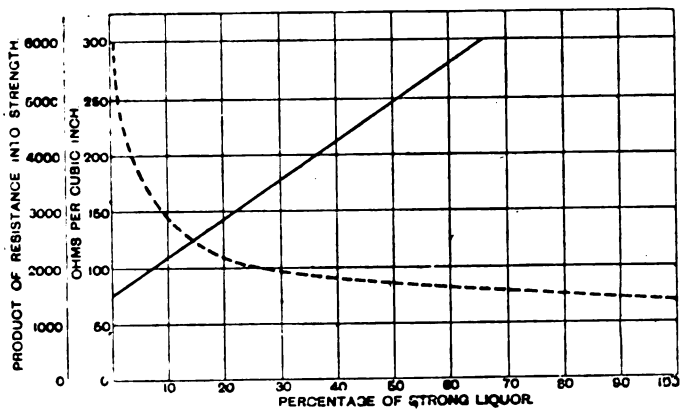

FIG. 2.—Variation of Resistance with Strength of Liquids.

current of 2 amperes will only liberate from water ·075 grm. of hydrogen and ·6 grm. of oxygen per hour, or during the whole process considerably less than 10 grms. of hydrogen would be evolved.

In our earlier chemical experiments with this process, our efforts were directed towards establishing the rate at which the tannin is taken up by the hides with and without the use of motion and an electric current. It was also of interest to determine whether the rate of tannage in the circular vats, in which the hides were suspended on a rotating frame, was similar to that obtained when a square vat was employed, and the hides suspended on a frame to which a reciprocating motion was imparted as already described. In these first experiments the rate of tannage was determined by noting the loss of tannin from the liquor after given intervals of time, and from the data so obtained calculating the average rate of loss per hour from the liquor.

The following table summarises the results obtained in three complete tannages, in which the process was discontinued at night, so that the electrical current and motion was only applied to the experimental vat for from six to eight hours per diem :—

Table I.

Experiment.	Loss of tannin per hour per 10,000 parts of liquor.	
	Day.— with motion and electricity.	Night.— without motion and electricity.
Circular vat 1, 1,600 gallons	·62	·344
Circular vat 2, 2,400 gallons	·612	·349
Reciprocating vat.....	·535	·338

The experiment in the circular vat 1 extended over a period of 26 days, during which time the machine was in motion for 167 hours, and a current of electricity applied for 98 hours to the 20 butts tanned in this experiment. The second experiment in vat 2 lasted for 33 days, during 209 hours of which the hides, 30 in number, were in motion, and a current of electricity passed for 115 hours. In the reciprocating vat 40 bellies and 20 shoulders were in the liquor for 27 days, the machine was in motion for 181 hours, and a current of electricity simultaneously applied for 82 hours. In each experiment the hides were completely tanned when they were taken out of the vat, and when finished were reported to be leather of excellent quality.

Daily temperature readings of the liquor were taken, but on no occasion was the temperature markedly different from that of the surrounding air, 15°C. being the highest reading recorded, and on some days the liquor being as low as 5°C.

The following table gives the actual experimental numbers obtained in the second of the above tannages, from which the average numbers given in Table I. for this experiment were obtained.

Table II.—*Circular Vat 2.*

A. With Electricity and Motion. Day.

Strength of liquor in parts per 10,000.		No. of Hours.	Total decrease per 10,000.	Decrease per Hour per 10,000.
Machine started.	Machine stopped			
92·8	89·4	5	3·4	·68
93·8	90·0	7	3·8	·54
84·6	81·2	5·5	3·4	·618
139·2	134·15	8	5·05	·63
127·8	123·05	8	4·75	·593

Average ·612 parts per hour per 10,000.

B. Night, at rest.

89·4	84·4	14	5·	·357
99·4	93·8	15	5·6	·373
90·0	84·6	14	5·4	·385
105·6	100·2	14	4·4	·38
133·8	129·6	14	4·2	·3
282·2	268·3	45	13·98	·304

Average ·349 parts per hour per 10,000.

The concordant nature of the above figures, as well as similar ones obtained in the other two experiments mentioned in Table I., at first led us to imagine that the hastening due to the combined action of motion and the electric current was expressed by these numbers. Further experiments, to be referred to later, however, proved to us that the rate of absorption at night, after the action of the electric current had been continued for some hours during the day, was much greater than that observed when the hides had not previously been subjected to this influence; in other words, the increased rate of absorption continued after the machine was stopped and the current was switched off. This effect may in all probability be attributed to the fact that as the hides pass through the liquor, the pores of the skins become distended and thus facilitate the passage of the liquor through the hides, which remain in this distended state for some time after they are brought to rest and the electric current cut off. When the machine is at work the hastening is further increased by the motion of the hides in the liquor augmenting the frequency of contact of tannin molecules with uncombed gelatin, and when the current is passing a further hastening is no doubt due to the increased motion of the tannin

Digitized by Google

molecules through the liquor which such current imparts to them and its disposition on the suspended hide. An endeavour was also made to trace the change taking place in the hides during the absorption of the tannin, and from the series of numbers obtained it was noticed that the percentage of water present in the well-drained hide gradually diminished as the tannage became more complete, the fleshed hide containing approximately 77 per cent. of water and the leather as taken out from the vat from 45—55 per cent. according to the part of the skin examined. A gradual increase in the specific gravity of the dried skin was noticed, 1·062 being the lowest and 1·119 the highest specific gravity obtained. Samples of the leather obtained in these three experiments were subsequently tested by the Kjeldahl process and nitrogen contents ranging from 7·35 to 6·99 were obtained. Very little is apparently known as to the nitrogen contents of finished leathers, and although Böttinger (*Ann.* 244, 229) has shown that the compound of gelatin with oak bark tannin contains 9·4 per cent. nitrogen, and oak-bark tanned leather from 9·03—9·24 per cent., he has pointed out that both of these bodies are decomposed on heating with water, yielding a soluble compound of greater nitrogen content and an insoluble body containing only 7·79 per cent. nitrogen in the former case and 6·17 in the latter.

It is obvious that if the nitrogen content of a leather can be regarded as an indication of the completeness of the change, that simultaneous determinations of the actual quantity of tannin taken out of solution by an unknown weight of hide substance and their average nitrogen content, would give data which would be of value to the tanner, and enable him to predict the weight of his finished leather, and at the same time tell him the cost of the tanning material consumed in the work. Considerable difficulty was at first experienced in obtaining samples of the hide from time to time during the tannage that would represent the average composition of the leather. By taking the precaution, however, of taking the samples from a thick hide along the median line of the back from day to day, the error due to the varying thickness of different hides was reduced to a minimum, and the samples taken were then divided into two portions, one of which was dried at 100deg., rasped, and the filings analysed, whilst a second portion was frozen, reduced to fine shavings by means of a microtome, dried, and analysed, and thus gave a check on the former value. As these are probably the first experiments in which a thick sole leather has been produced in a time sufficiently short as to render it possible to trace the gradual diminution in the percentage of nitrogen in the hide with its absorption of tannin from the ooze, we give a table showing the results obtained in a recent experiment.

Thirty specially selected green hides were marked and weighed, limed in the usual way for six days, unhaired and fleshed, but not scudded, washed and coloured in a weak liquor for two days. Their total weight was 2,322lb., of which the horns, &c., weighed 104lb., giving a net weight of 2,218lb. used. The wet fleshed hides when introduced into the vat weighed 1,673lb., and after the tannage was completed on the twenty-second day, the wet leather taken out weighed 2,040lb. The leather has since been finished, and the weight in the dry and finished state was 986lb. The hair sold weighed 714lb. and the flesh 569lb. The following table gives the composition of the leather at different stages of the tannage and the amount of tannin disappearing from the solution.

Table III.

Date.	N. per cent.	Weight of tannin absorbed in lbs.
Fleshed hides :		
February 26th	16·5	...
February 28th	14·43	103·3
March 2nd	12·44	258·4
March 4th	10·56	400 3
March 9th	8·95	656·4
March 12th	...	760·0
March 20th	7·50	775·2

It will be noticed that the absorption after March 12th was very slow, and that the total gain in weight estimated from the tannin absorbed during the following eight days only amounted to 15lb., or about ½lb. per hide. This slight increase in the weight, unless it markedly affects the quality of the leather, cannot possibly compensate for the extra time and power spent after the fourteenth day. In this experiment the 775lb. of tannin consumed were obtained from mimosa bark and gambier, and for estimating the cost we may assume that 625lb. were obtained from the bark, and 150lb. from the latter. A 35 per cent. bark at £16. 10s. per ton would furnish 625lb. of tannin for £12. 9s., and a 50 per cent. gambier at £34 per ton would furnish 150lb. for £4·55, making a total cost for the tannin materials consumed in tannin the 30 hides, £17·45. Other materials would, of course, work out to a different cost, and if valonia or oak bark had been employed the cost of tannage would be considerably less.

It will be seen from the above figures that a very large amount of tannin was absorbed during the experiment which was not present in the finished leather obtained. We believe that this result is due to the large portion of the tannin consumed being deposited on the surface of the semi-permeable membrane, and subsequently being removed when the leather is washed and during the finishing process. The difference between the amount found in the finished leather and the amount lost by the liquor during the tannage can, of course, be utilised for further work. Ostwald (*Zeits. Phys. Chem.* 6, 71) and Tammann (*Zeits. Phys. Chem.* 6, 237) have recently drawn attention to the deposit of copper in this way from a copper solution on the surface of a semi-permeable membrane of copper ferro-cyanide, and it would seem probable that after the gelatin tannin compound is formed the deposition of tannin continues, but on the surface only of the leather. If the experiment had been stopped earlier, the quantity of tannin absorbed would have been less, and the amount removed from the surface in the finishing process also less.

Böttinger's experiments, already alluded to, point to a direct condensation of the gelatin and tannin taking place in the conversion of hide into leather, but so far as we are aware, there have hitherto been no direct experiments that this absorption took place gradually, and that there was a definite relation between the tannin lost by the liquid and the nitrogen content of the hide.

From analyses of the fleshed hide and finished leather, the decrease in the nitrogen value and increase in the oxygen per cent. has been repeatedly pointed out, but by those who held that no definite compound was produced, this change was attributed to the direct oxidation of the hide substance and loss of nitrogen as ammonia. The above experiments go far to establish that when tannin is employed the conversion of the hide into leather is due to a combination or condensation of the gelatin and tannin. We have not been able to ascertain what is the maximum amount of tannin which a given weight of hide will chemically absorb, but many of the samples of leather prepared by the ordinary process contain less tannin than the above. It is obvious that, provided the quality of the leather is equally good, the tanner, instead of aiming at the maximum yield of weight, should strive at the minimum yield, when tannin is worth more per pound than fleshed hide, and conversely when the economic conditions are reversed. The limits for a good leather appear to be approximately 40—60 per cent. hide substance, in union with 60—40 per cent. "tannin."

(To be continued.)

ON THE CHEMISTRY OF ACCUMULATORS.*

BY MATHIAS CANTOR.

The question as to the part played by hydrogen at the negative plate of a secondary cell is still unsettled. Although Gladstone and Tribe, as well as Frankland, found that lead or lead sponge cannot take up any appreciable quantity of hydrogen, Streinitz is of an exactly opposite opinion, and regards the amount of gas occluded as considerable, and its action as of great importance. Others, Drzewiecki and Schoop, for instance, conclude that a combination occurs between the lead and hydrogen. The author undertook a quantitative investigation into the various chemical processes occurring during charging and discharging, and he believes that by this means it is possible to arrive at a clear understanding of the matter.

Since the escaping gases, hydrogen and oxygen, can only be analysed quantitatively in the electrolyte, and not on the electrodes (without destroying them), an indirect method was adopted for the analysis of the latter. For one electrode a metal was used which undergoes no noticeable chemical change, so that any variation in the electrolyte depended only on the second electrode. As the positive electrode a plate of platinum was placed in a specially adapted glass vessel, the negative being formed of an E.P.S. plate, containing two or three sets of four meshes. The electrolyte used was a 28 per cent. solution of sulphuric acid. In the circuit, which was supplied by eight Meidinger cells, were also included a resistance box, a galvanometer, and a Hoffmann voltameter. Consequently, at corresponding electrodes in the voltameter and the secondary cell, equal volumes of oxygen and hydrogen were produced in the same time. Since the negative electrode consisted of a lead grid filled with lead oxide and lead sulphate, these three substances could enter into the chemical processes that occurred. At the low current strength employed (6 to 12 milliamperes) it was proved, from measurements of the volumes of the gases produced and analysis of the electrolyte, that the only change that took

* "Exner's Rep.," Vol. 27.

Digitized by Google

place in the electrolyte was an alteration in its degree of concentration, which agrees with the results obtained by H. Aron and Frankland.

Before charging, the electrolyte contained hydrogen only in the form of water, whilst afterwards it existed partly as gas, partly as water, and, perhaps, also, in one form or the other, combined with the cathode. The total quantity of hydrogen must remain unaltered after charging, so that the amount of combined hydrogen at the cathode must be equal to the difference between the amount existing at first in the electrolyte as water and that existing in it in the same form after charging together with the quantity of gas produced. Experiments with several plates gave values for this difference, which were all found to lie below the probable error that might be expected, and they could therefore be neglected. It appears, therefore, that the negative plate cannot take up any appreciable quantity of hydrogen either by occlusion or in the form of a lead hydride.

From a comparison with the voltameter it was found that the whole of the hydrogen that might have been expected did not appear in the accumulator; the remainder in the "active" state was used in reducing lead oxide and lead sulphate, probably in the first instance the $PbSO_4$ to H_2SO_4 and Pb, since an increase in the amount of SO_3 in the solution was observed. The proportion between the "active" hydrogen and that that appears electrolytically, seems to bear some relation to the capacity of the plate. It does not, as Gladstone and Tribe conclude, increase as the current strength diminishes, but it is highly probable that for every plate a current density exists for which this proportion becomes a maximum.

Although Streinitz wishes to explain the evolution of gas at the cathode of a charged cell by the giving off of occluded hydrogen, and not through the decomposition of the sulphuric acid, it must be remembered that, on the one hand, J. Thomson asserts that lead at high temperatures decomposes water, and, on the other, that several metals, when in a finely divided and freshly reduced state, have properties which ordinarily belong to them only at high temperatures. The author describes experiments which demonstrate the possibility of such a decomposition of the water.

The result of his experiments on the chemical processes occurring at the negative plate during charging is as follows:—The lead oxide existing on the plate is transformed to the sulphate. The electrolytic hydrogen reduces the sulphate and forms sulphuric acid. The freshly reduced lead decomposes sulphuric acid again and liberates hydrogen, at the same time forming a sulphate again. The charging can be continued until a stationary position between the two reciprocal actions is reached.

UNDERGROUND TELEGRAPH WORK IN GERMANY.

A recent issue of *La Lumière Électrique* contains a brief account of the difficulties encountered in laying the Saxon section of the Munich-Dresden underground telegraph line.

To complete the network of subterranean telegraph lines in Germany it was decided last year to run a cable from Munich to Dresden, Munich being already connected in this manner with Stuttgart, and Stuttgart with Carlsruhe. The preliminary surveys having been made, work on the line began at the Dresden end on August 27, 1890. The cable employed contains seven ·7mm. copper conductors, each insulated with gutta-percha to a minimum diameter of 6mm. The conductors were further separated by thick layers of jute. The core had a total diameter of 23mm., and was sheathed with twenty 3·75mm. galvanised iron wires, wound spirally so as to make one complete turn per 32 or 35 cms. Over the iron armour was laid a coating of asphalt, then more jute yarn, and finally a second coating of asphalt. The cable was supplied in 1,000 metre lengths. All joints were enclosed in galvanised iron sleeves. Where passing through water and marshy land the cable was further protected from mechanical injury by a movable galvanised iron pipe composed of double sleeves 35cms. long.

The preliminary surveys led one to anticipate that the task of laying the cable would prove exceptionally laborious; but the reality exceeded all expectations. Hard rock, such as porphory, gneiss, diorite, quartz, and amphibole was met with. The pick made no impression on these rocks, and it was found necessary to blast for a distance of about 11½ kilometres, some five quintals (one ton) of dynamite being employed for this purpose.

Another circumstance retarded the progress of the work. Some eight more or less important towns had to be crossed, having extensive systems of gas, water, and sewer pipes. As the Imperial Telegraphs Department makes a point of having these cables as far as possible underneath all these pipes, it was out of the question in these towns to make use of the special laying waggon. It was, therefore, necessary to drag the cable through by hand, and 67 kilometres out of a total of 177½ kilometres were laid in this manner. The operation of dragging through occupied considerable time, especially in frequented places. Moreover, while it only required three workmen to *uncoil* the cable, at least fifty were required to drag it, a workman being stationed at every ten metres, and closer where there were curves. The work also necessitated the employment of men of endurance, the men having often to remain for hours together in water and in cramped positions. Poles, who are very suitable for this kind of labour, were employed.

The Bavarian frontier was reached on December 7th, and on April 6th work was commenced on the Munich portion.

THE DISTRIBUTION OF STEAM FROM THE CENTRAL STATION.*

BY F. H. PRENTISS.

The history of commercial electric lighting covers hardly a decade. The same is true of the sale of steam from underground pipes radiating from a central station. The pioneer work has been done, and the electric lighting companies are therefore in a position to reap the advantage of the experience gained, and to begin their work where the steam companies have left off. The joining of two enterprises together, such as electric lighting and the distribution of steam from central stations, has both its advantages and its defects. In a combined plant the general expenses of management, superintendence, and so forth, need not greatly exceed the cost for the same items in a single plant alone. An obvious disadvantage is the increased back pressure put upon the engines. The prejudicial effect of this back pressure is a subject which will well repay a little study. If this increase of back pressure is only that required for circulation of the steam for heating purposes, the increased consumption per useful horse power per hour will not be greatly augmented in consequence, provided the pipes are sufficiently large and properly run. The heating of residences by steam supplied from our Fifty-eight-street station is often effected with steam at a pressure of one or two pounds. And it is well known that there are several systems in use where exhaust steam is applied for heating in a manner so as to make it possible to produce a vacuum in the heating coils. In order to illustrate this point, I will present some calculations based upon a back pressure of 17lb. absolute, with an initial pressure of 92lb. absolute. We will call this case No. 1. For case No. 2 let us take the back pressure at 30lb. absolute and the initial pressure at 105lb. absolute. In case No. 3 let the back pressure be 105lb. absolute and initial pressure 180lb. absolute.

An engine working under conditions No. 3 would require 60lb. of water per H.P.H. In a similar manner, between the limits of pressure 90lb. (105lb. absolute) and 15lb. (30lb. absolute) there would be required 26lb. per I.H.P.H. This covers the case of an engine exhausting into low-pressure street mains. An engine exhausting into the atmosphere with 2lb. back pressure (17lb. absolute) and receiving steam at 77lb. (92lb. absolute), would require 19·7lb. of water per H.P.H. In actual practice the losses due to clearance, wire-drawing, incomplete expansion, cylinder condensation, &c., would have to be added to the amounts above given. For this we may add 10lb.

Take a concrete case. The engine was an automatic cut-off type, having been built for ordinary duty and not especially designed or altered for work of this unusual character. The engine was directly belted to a 750-light alternating current Westinghouse dynamo, which supplied current to about 600 incandescent lamps in the Lenox Lyceum. The building was wired throughout on the Edison three-wire plan, and the converters were arranged two in series, with a middle wire to suit these conditions. The plant was supplied with electric meters and the various station instruments, and represented, therefore, on a small scale, a central electric lighting station. The exhaust pipe of this engine was directly connected with our street mains, where an average steam pressure of about 55lb. was always maintained. The steam from the street mains was used in part for operating elevators in apartment houses and for running engines, and in part for heating. If we follow the steam in its course through the electric light engine, thence through the elevator, engines and pumps, and other engines along the line of the underground steam mains, and thence to the radiators where condensation takes place, it will be evident that an economy is attained similar to that in a compound condensing engine, the electric light engines playing the part of the high-pressure cylinder, the other engines playing the part of the low-pressure cylinder, and the radiators taking the place of the condenser. This engine was operated under these conditions three or four evenings a week for about a year, affording a perfectly steady and satisfactory light from the incandescent lamps. The running

* Abstract of a Paper read before the National Electric Light Association at Providence, R.I., February, 1891.

Digitized by Google

of the engine was not attended with any special difficulties, and gave no more care and occasioned no more trouble than if exhausting into the atmosphere. On several occasions the exhaust of the engine was shut off from the street mains and turned into the atmosphere, the initial pressure being reduced at the same time to correspond. At other times the reverse of this change was effected and the exhaust turned from the atmosphere into the street mains without in either case producing a noteworthy fluctuation in the light from the incandescent lamps.

In order to make it clear beyond dispute that the business of a district steam company can be added to that of an electric lighting company without prejudice to the latter, two points only need be established: First, the possibility of utilising the exhaust of electric light engines without detriment to the light and without introducing any serious complications or expense in the management of the station; second, the certainty of an extra revenue, the net profits of which will equal or exceed the profits from the lighting plant for equal amounts of money invested.

I need, I think, only refer to the practical working of the combined system at the Fifty-eighth-street station of the New York Steam Company, where the back pressure of the engine was 55lb. (with no inconvenience and with no extra expense, save an almost indeterminate increased consumption of fuel) to prove that with a back pressure of only 15lb. a practical mechanical success is assured. Of course, to get the same power from the engines, it would be necessary, unless previously running with a light load, to increase the initial pressure 15lb., or to the same extent that the back pressure is increased. The effect of this, as I have shown, will be merely to pass a little more steam through the engine per horse-power, which ordinarily would be a bad practice and a waste of fuel, but when distributed and sold for heating purposes has nearly the value of live steam taken direct from the boiler. There would be times, of course, when the demand for heating would be slight, and when, therefore, it would be more economical to use a free exhaust, or, where there were several engines, to have only a portion of them deliver their exhaust into the street mains. The experiments of the New York Steam Company, previously cited, showed that the engines could easily be shifted from one exhaust pressure to the other without detriment to the light, and therefore be easily possible to secure at all times the maximum of economy which a combined system would permit. So far as profits and dividends are concerned a very considerable saving would follow by the mere union of the two interests, without even taking into account the value of the exhaust steam. Since, however, so much is dependent upon local conditions it is impossible to give figures which would apply to anything more than a hypothetical case. The amount of heat lost by radiation from the pipes of the New York Steam Company showed the loss to be about 3 per cent. of the carrying capacity of the pipes.

The average price received for steam from the aggregate of consumers, large and small, is somewhat more than double the cost of producing the steam at the boiler house. This average price is one willingly paid by the consumer, owing to the saving in cost of labour and to the many conveniences and advantages to be derived from having steam on tap, like gas and water. Since the cost of steam amounts to 50 per cent. of gross receipts, it is evident that if one-half of the steam sold for heating can be obtained from engine exhaust the saving effected in this way alone will amount to enough to pay a 10 per cent dividend.

In this Paper I have attempted to show the complete practical and commercial feasibility of combining a system of steam distribution from a central station with an electric light plant in a manner to utilise the exhaust.

THE TELEPHONE.

The following letter appeared in *The Times* of yesterday:—

SIR: The Duke of Marlborough claims to have made a special study of the telephone for many years, and his letter shows that he understands the subject better than many who attempt to instruct the public regarding it. May I be allowed, in virtue of a similar claim, to say a word or two in reply?

The licences, as originally granted by the Post Office, were not "all-England" licences, inasmuch as the areas of operation were limited to towns. No inter-town trunk lines were permitted. Such lines could only be leased by the companies from the Post Office, and at exorbitant rates. So high were these rates that, although the companies were enterprising enough to comply in certain cases with the Post Office terms, the result in every case was heavy loss. After years of discussion the restriction was removed, but meanwhile the development of trunk-line communication—one of the most valuable of telephonic facilities—was practically blocked.

Nor were the only reservations those which the Duke of Marlborough mentioned. In addition (not to mention minor points), no company was to be allowed to run any line over any route which the Department might require in the future to use, no message was to be written down, no railway-line route over which the Department might have control was to be used, no post-office was to be connected up so that telegrams might be telephoned for transmission (even now this privilege is only accorded upon terms which are prohibitory), access to telegraph offices in order to establish call-offices for the public was denied, &c. In addition, a telephonic exchange service by the Post Office was announced, every post-office in the United Kingdom being placarded with notices that the Department was about to establish exchanges wherever required. In short, the licence was a maimed and distorted parody of what such a document should have been, and had (and has now even more strongly) all the appearance of a concession wrung from the Department in the fear that the verdict they had obtained might probably be reversed on appeal. The telephone interest in those days was too weak to carry the case higher, and accepted the inevitable with the best grace it could. It remains open to-day to any one to assert the principle that the Telegraph Acts never could have been intended to confer upon the Department an exclusive property in an invention totally novel in its principle and application, and not even dreamt of when the Acts were passed. The swaddling-clothes in which the business was enveloped by the Department, the apathy of the public, which for years all but ignored the utility of the invention, and the unredeemed promise of the Post Office to provide exchanges, all combined to render the earlier efforts of the companies costly and their progress slow.

To come, however, to the present state of the case, the Duke of Marlborough says that there is only a "small development" going on "in some of the large provincial towns of England," and that "practically no development of the telephone for social or business purposes exists." May I be allowed to say that this is an entirely erroneous view? In Scotland, for instance, which was the original field of the National Company's operations, every town of any importance is now in communication with all the rest. Recently, as an experiment, I myself, from Edinburgh as a centre, talked successively and successfully to every recognised business centre in Scotland, one after the other, without leaving my chair, and with only a few minutes' delay (at most) between each conversation. A similar development has gone on in the Midland counties of England and in the Western counties.

As regards the question of cost. When the National Company took over the business of the other companies, the average rate of subscription over its own system was under £12, and has since been reduced. The methods of the National Company have been now introduced over the whole of the area it absorbed, and the proof that these are appreciated is in the enormous increase in subscribers and revenue shown in its last balance-sheet, a rate of increase which, it is understood, is now being exceeded in the current year's operations.

The fact is that the whole telephone industry in this country has been prejudiced in the eyes of the public by the disgraceful mismanagement which prevailed in London until put an end to recently by the amalgamation of the companies. The effects of that muddling are still apparent. For two years the whole energies of the London staff have been devoted to rooting out the bad construction work of the United Telephone Company, and, as the Chairman of the National Company stated at the last meeting, another year must elapse before the work can be completed. Then, and only then, can the question of reduced rental be considered, because at the present moment I suppose no greater calamity could befall the Company than the accession of orders which a reduction of tariff would bring in. The work of coupling up could not, indeed, be overtaken.

A word as regards the single-wire system. It obtains simply because no other is possible. Powers to build subways do not exist, and if they did a reduction on the present tariff would be impossible at present owing to the cost of construction. Mr. Bennett's scheme is no doubt very ingenious, but the history of the Mutual Telephone Company, as illustrating the question of cost, does not lead us to suppose that his estimates under that head are not open to challenge. If the Duke of Marlborough will show how "it is demonstrable" that the whole of London can be telephoned on the twin-wire system with "a remunerative profit for a £10 a year subscription," I am certain the Directors of the National Telephone Company will be the first to thank him. Meanwhile, I think the best possible thing to be done will be to let the proposed new Company try it and give us the benefit of their experience.—I am, &c.,

F. FAITHFULL BEGG.

Bartholomew House, E.C., Aug. 31st.

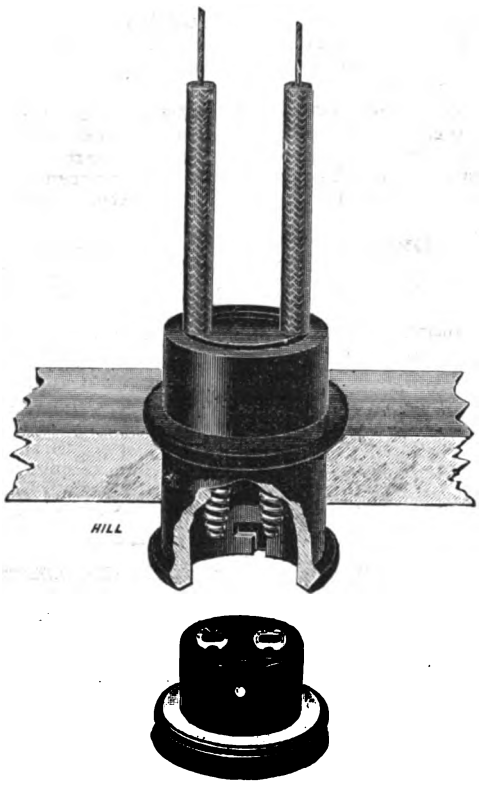
TRADE NOTES AND NOTICES.

NOW READY.—"THE ELECTRICIAN" PRIMERS (38 in all. Vol. I., 20; Vol. II., 18), in two volumes. Price per volume 2s. paper covers, 2s. 6d. cloth; post free, 2s. 2d. and 2s. 9d. respectively. Single copies, 3d.; post free, 3½d. Prospectus on application to the Publisher.

TENDER.—Tenders are invited, up to September 12th, for the supply of 40 tons of sulphate of copper to the Dirección General de Correos y Telégrafós, Madrid.

THE WEYMERSCH BATTERY.—On Friday last further demonstrations of the capabilities of this battery were given at the offices of the company owning the patent. The inventor, while not pretending in any way to rival the supply companies in point of cost, claims that the battery is especially suitable for isolated country residences. In order that there may be no bad contacts through bad electrical joints, mercury connections to some extent replace binding screws. It is claimed that the battery gives a fairly constant voltage for about 20 hours, at the end of which time the cells require to be re-charged with depolarising solution, which costs about a shilling per gallon.

NEW VITRITE CHEMICAL LAMPHOLDER.—Our illustration shows a lamp-holder which has been specially designed for use in chemical



works, starch factories, underground tunnels, and all places where sulphurous and other fumes are present. The Vitrite chemical holder entirely protects the metal lamp connections from any contact with the outer atmosphere. A special form of vitrite cap is supplied, which is sent to the lamp manufacturer, when ordering, for affixing to the lamp. A small rubber ring is placed on the cap, which enables the cap to be fitted to the holder, forming a perfectly air-tight joint. Connection is made with the spring in the body of the vitrite material itself, and enough length of insulated wire is provided with each holder to enable anyone to make a perfect insulated joint with the distributing leads of the installation, in the ordinary way. The spring connections in the interior are similar to those in use in the ordinary vitrite holder. A rim is placed near the top of the holder, so that the holder may be fitted into boards or other fixtures, if desired. Messrs. Woodhouse and Rawson United (Limited), of 88, Queen Victoria-street, E.C., are prepared to supply these holders.

CARBON WORKS FOR SALE.—Messrs. Wheatley Kirk, Price, and Goulty announce in our advertisement columns that they have for disposal by private treaty a small compact works, all the necessary plant and utensils, together with the stock of manufactured materials, office fittings, &c., as a current going concern.

ELECTRIC SHADES AND GLOBES.—We have received from Messrs. Woodall and Son, of Great Hampton-street, Birmingham, and 12, St. Andrew's-street, Holborn-circus, London, E.C., an artistic catalogue of designs in electric shades and globes. Some of these are very elegant, and should secure a large sale. The catalogue is well got up, and the more elegant designs are printed in colours. Messrs. Woodall and Son are manufacturers of all kinds of glass goods, and keep a large stock both in their London and Birmingham show rooms.

MESSRS. O. BEREND AND CO.—We have received from this firm a new price list of the electrical measuring and test instruments manufactured by Messrs. Hartmann and Braun, of Frankfort-on-the-Main, for whom Messrs. Berend and Co. are agents. The instruments comprise their well-known amperemeters, galvanometers, voltmeters, battery testers, resistance boxes, switches, pyrometers, &c. Messrs. Hartmann and Braun's instruments are all made on the interchangeable system by elaborate machine tools, each one being separately calibrated and run continuously for several weeks, and all calibration curves being preserved for reference.

GENERAL ELECTRIC COMPANY (LIMITED).—We have received from this Company an illustrated price list of their Manchester and Johnson microphones, either of which they are prepared to supply, completely fitted with battery bell or magneto-bell.

REMOVAL NOTICE.—We are requested to state that in future all communications hitherto sent to the Edison General Electric Company's address at Antwerp, Belgium, must be sent to the Edison General Electric Company, 34, Victoria Street, Westminster, S.W., where the principal offices of the European district of the American Company will be located. The warehouse at Antwerp, containing a complete stock of the Company's goods, will be continued as heretofore.

NEW FIRM.—Messrs. Mackenna, Macfarlane, and Co. inform us that they have commenced business as engineers and oil and general merchants, at 59, Southwark Bridge-road, London, S.E. Mr. Mackenna was for a considerable period with the late Mr. W. T. Henley.

DISSOLUTION OF PARTNERSHIP.—The firm of Mori and Co., carrying on business as electrical engineers at 3, Thornton's-buildings, Upperhead-row, and 40, New Briggate, Leeds, have dissolved partnership, as regards Mr. Frederick Mori. The business will be continued by Messrs. Edwin Moorhouse and R. P. Stocks.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

August 24, 1891.

14,238. J. FARQUHARSON. Acton. An improved method of insulating and laying electric light conductors under ground.

14,266. M. and A. E. HUMM. Forest Hill. Improvements in appliances for the administration of electricity to horses for curative purposes.

COMPANIES' MEETINGS & REPORTS.

Bath Electric Lighting and Engineering Company (Limited).

The statutory meeting of the shareholders of this Company was held on Saturday, at the offices, 2, Northumberland-buildings, Bath, under the presidency of Colonel Vaughton.

The CHAIRMAN explained, for the information of the shareholders, that the original Directorate of five had been increased to eight, one from the Brush Electrical Engineering Company, one from the Callendar's Company, and one a member of the firm of Messrs. Laing, Wharton, and Down, who were all large shareholders. The number of shares issued was 3,241, and their accounts had been thoroughly overhauled by Mr. Butcher, the accountant, so that they knew exactly what their position was. At present the light was only running a portion of the day and night, but it was hoped by-and-by to run it altogether; but that would depend on the number of customers. They were anxious to remove, as far as they could, every obstacle to the success of the undertaking, and so they would reduce the cost of installations to the lowest figure consistent, of course, with successful working, for all concerns must be worked at a profit. They would supply meters where required.

Mr. TITLEY, the solicitor to the Company, said the meeting was a formal one, it having to be held, under Section 49 of the Act of 1862, for the purpose of allowing the shareholders the opportunity of obtaining any information they might require, and also for declaring the number of shares taken up, which the Chairman had done. It was manifestly too early to give any account of the working of the concern, but it certainly could be said that the Company had started with exceedingly bright prospects. The present plant would permit of their working three or four times the amount of light now in hand, so that they could increase their revenue and profit without any very great additional outlay.

Major-General JERVOIS said that the Directors had given their attention to the popularising of the light, and the policy of the Company would be to make the installations as economic as possible. They had every reason to believe that the number of customers would increase, and that the advance would be sure, if slow.

A few questions having been put and answered, the proceedings terminated.

NEW COMPANIES, STATUTORY RETURNS, &c.

CALEDONIAN TELEPHONE COMPANY (LIMITED).—This Company, which was registered last week in Edinburgh, has been formed to acquire from Andrew Erskine Muirhead, Cart Forge, Glasgow, the business, stock, and plant carried on by him of supplying telephone communication; to establish a telephonic exchange or exchanges; and to carry on any business relating to telephones. The nominal capital is £50,000, in £1 shares. The first subscribers (one share each) are Walter Menzies, tube maker, Phœnix Tube Works, Glasgow; William Kenneth, shipowner, 13, George-square, Glasgow; R. Easton Aitken, C.A., 68, St. Vincent-street, Glasgow; Mark Hurll, coalmaster, 95, Bath-street, Glasgow; Robert M. S. Moore, C.E., 156, St. Vincent-street, Glasgow; James Wallace, dentist, 36, Dundas-street, Glasgow; A. Erskine Muirhead, Cart Forge, Glasgow; and William Barton, accountant, 109, St. Vincent-street, Glasgow.

G. FOWLES AND SONS (LIMITED).—This Company was registered on the 25th instant, with a capital of £5,000, in £5 shares, by E. C. Johnson, 412, Mansion House-chambers, E.C. Among its objects are the acquisition and carrying on of the business of G. Fowles and Sons, mechanical and electrical engineers, machinists, ironfounders, &c. Registered without Articles of Association.

HORTON AND SON (LIMITED).—This Company was registered on August 26, 1891, with a capital of £100,000, in £10 shares, by Jordan and Sons, 120, Chancery-lane, W.C. The objects are: To acquire and carry on the business of nut and bolt manufacturers hitherto carried on by Enoch Horton, under the name "Horton and Son," at Darlaston, Staffordshire. To carry on the business of mechanical and electrical engineers, toolmakers, metal workers, steel converters, &c. Enoch Horton, of Bescot, Walsall, is the first and only Director. Qualification of an ordinary Director (should any be appointed), 50 shares. Remuneration not specified. Office: New Alma Works, Station-street, Darlaston.

JOHN WARNER AND SONS (LIMITED).—This Company was registered on August 27, 1891, with a capital of £40,000, in £5 shares, by Messrs. Duffield and Bruty, solicitors, 6, Tokenhouse-yard, E.C. The objects are: To acquire and carry on the business of bell and brass founders, hydraulic, sanitary, mechanical, and electrical engineers, coppersmiths, braziers, &c, carried on by R. Warner, at Jewin-crescent, E.C. C. T. Richardson and A. Marriage are the first Managing Directors, and are entitled to £700 per annum and 10 per cent. of the amount available for dividend divided between them. Office: 27, Jewin-crescent, Cripplegate, E.C.

MEXICAN LANDS AND RAILWAY TRUST (LIMITED).—This Company was registered on August 25, 1891, with a capital of £100, in £1 shares (with power to increase), by Paine, Son, and Pollock, 14, St. Helen's-place E.C. It intends to acquire, take over, and work any concessions granted by the Government of Mexico, or of the United States of America, for the construction and working of any railways, telegraphs, telephones, waterworks, gas or electric lighting, and other public works. Registered without Articles of Association.

RAILWAY EQUIPMENTS SYNDICATE (LIMITED).—This Company was registered on August 31, 1891, with a capital of £10,000, in £100 shares, by the London Law and Trade Protection Association (Limited), 85, Gracechurch-street, E.C. The objects include the equipment of telegraph and telephone lines, electric works, &c. Registered without Special Articles.

W. F. MASON (LIMITED).—This Company was registered on August 29, 1891, with a capital of £30,000, in £10 shares, by C. Doubble, 14, Sergeant's-inn, Temple. The objects are: To acquire and carry on the business of an engineer (including civil, hydraulic, electrical, mechanical, sanitary, and otherwise) carried on by William F. Mason, at 504, Stockport-road, Longsight, Manchester.

WYLEYS (LIMITED).—This Company was registered on August 31, 1891, with a capital of £60,000, in £10 shares, by Waterlow and Sons (Limited), London-wall, E.C. The objects include the manufacture of, and dealing in, electrical, chemical, and scientific apparatus carried on by W. F. Wyley, at Wheatley-street, Coventry, and at 52, Moor-street, Birmingham, under the style of "Wyleys and Co." Mr. W. T. Wyley is the Chairman and Managing Director, and the office is in Wheatley-street, Coventry.

BOY MESSENGERS AND ELECTRIC CALL COMPANY (LIMITED).—By an agreement, dated May 7, 1891, between the Exchange Telegraph Company (Limited) and the above Company, the Exchange Company agree to sell and the Messenger to purchase certain electric call system instruments and apparatus, and, in full consideration therefor, 5,000 £1 shares, numbered 15,001 to 20,000 inclusive, will be allotted to the vendor Company or its nominees. An agreement of the same date between the Boy Messengers (Limited) and the above Company states that the former Company agree to sell all the lands, buildings, patents, telegraphs, and plant to the Messenger Company, and £25,000, of which £10,000 will be in cash and the remainder by the allotment of 15,000 £1 shares, will be considered full satisfaction therefor. A supplementary agreement of June 20, 1891, made between the same Companies, change the cash payment to £5,000, and 25,000 more shares will be allotted to the old Company. Office: Billiter House, Billiter-street, E.C.

COLLIER AUDIBLE TELEPHONE SYNDICATE (LIMITED).—An agreement, dated June 11, 1891, between the above Company of the first part, A. T. Collier (the vendor) of the second part, and the London and Colonial Finance Corporation, Limited (the promoter), of the third part, states that the Syndicate intend to allot 30 fully paid-up shares of £100 each, to A. T. Collier, numbered 28 to 57 inclusive, and 30 fully paid-up shares of £100 each to the London and Colonial Finance Corporation (Limited), numbered 58 to 87 inclusive. Office: 5A, Coleman-street, E.C.

INTERNATIONAL ELECTRIC SYNDICATE (LIMITED).—The office of this Company is situate at 59, Guardian-buildings, Manchester.

CITY NOTES, &c.

ALUMINIUM COMPANY (LIMITED).—At the fourth ordinary general meeting of this Company, held on Wednesday, the Chairman (Mr. G. W. Balfour, M.P.) stated that during the past twelve months the market price of aluminium had further declined in a very considerable measure, owing to the introduction of electrical processes for its manufacture, and at the present figure it was more beneficial to sell sodium direct than to employ it in the manufacture of aluminium. The Directors had accordingly turned their attention to the sodium branch of the Company's business,

Digitized by Google

and their efforts in this line had met with a great deal of success. They hoped that the increased use of sodium, already resulting from experiments which had been made, would enable the Company to avoid liquidation.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the past week were £4,739.

CITY AND SOUTH LONDON RAILWAY COMPANY.—The traffic receipts of this Company for the week ended August 30, 1891, amounted to £717.

CUBA SUBMARINE TELEGRAPH COMPANY.—The estimated traffic receipts of this Company for the month of August were £3,000, as compared with £2,913 in the corresponding month of last year, showing an increase of £87.

DIRECT SPANISH TELEGRAPH COMPANY.—The Board of this Company have decided to recommend the payment of the dividend at the rate of 10 per cent. on the Preference shares, and a dividend of 5 per cent. (free of income-tax) upon the ordinary shares, for the half-year ended 30th June last.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this Company for the month of August, 1891, amounted to £53,393, and to £52,606 in the corresponding period of 1890, an increase of £787.

EASTERN EXTENSION TELEGRAPH COMPANY.—The receipts of this Company for August amounted to £53,398, as against £52,606 in the corresponding period of last year, showing an increase of £797.

ELECTRIC TRACTION COMPANY (LIMITED).—A meeting of the shareholders of this Company (in voluntary liquidation) will be held at the offices of the General Electric Power and Traction Company (Limited) 35, New Broad-street, E.C., on September 30th, at 11, for the purpose of receiving an account of the winding-up.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended August 28th, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £3,215.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The receipts of this Company for the month of August show a decrease of £591 as compared with the corresponding period last year.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 695.—Vol. XXVII. FRIDAY, SEPTEMBER 11, 1891. Price Fourpence.

NOTES.

The minutes of the proceedings of the Board of Trade Electrical Standards Committee contain a great deal of very interesting matter, interspersed with some dreary discussions of a more or less legal character. We alluded in our last issue to one or two points, and regret that it is impossible to make an intelligible abstract of the whole, owing to the proceedings being of a conversational order, and a large part of the work discussion of verbal amendments. The reasons for many of a these amendments, however, are of considerable interest; and the Blue Book, which is to be bought for elevenpence, should be in the hands of all those who are interested in this important matter. Among the unexpected difficulties was one which, while it concerns almost every trader in the country, is probably known to only a few. The yard is the one standard of length which is paramount over all multiples and fractions of it. The chain, the foot, the inch, and many multiples of these, have been separately named as legal denominations by an Order in Council; and it is illegal to use a 37-inch rod for measuring calico, and the "blue" used for measuring beer at Cardiff, three "blues" going to a pint, is an illegal measure. Sir William Thomson pointed out that 10,000 million "denominations" of the ohm, at least, would be required if this precedent were followed.

In commenting upon the Report, our contemporary *Nature* objects to the use of the word "pressure" in connection with the volt, as it "has certainly led to very erroneous notions in the minds of the general public as to the functions of electric supply mains," and advocates "voltage." The Board of Trade had sanctioned this word before the Electrical Standards Committee was appointed, and the Committee have apparently accepted it without objection. The great thing is to avoid the term "electromotive force," and while "the volts" and "voltage" will generally suffice, some other word is often required. Why is "pressure" more erroneous than "current"? Does anything flow? The word "electricity" has very properly been dropped. We do not know that it flows or even exists; we find that it is easy to get on without it. Any ideas which the public may have are pretty much the same as they were before the Board of Trade used the word "pressure." The expression is not, as our contemporary says, more misleading than "tension," because there was a distinctly erroneous idea a few years ago of quantity currents and high-tension currents as indicating two different kinds or qualities of something that was called electricity. Electromotive force is doubly wrong, as well as pedantic, but "pressure" is a word borrowed, as is "current," from our everyday language; they do not attempt to be explanatory, and are undoubtedly of a temporary character.

The Electrical Standards Committee of the British Association have a printed form bearing the address, "Cavendish Laboratory, Cambridge," being a certificate of comparison of resistance coils sent by makers or others, with the B.A. units, which are kept there. This form states that "It has been assumed, for the purposes of comparison, that one legal ohm is equal to 1·0112 B.A. units." The word "legal," which was never justified, is erased on one of these certificates, which is now before us, and the 1·0112 is altered to 1·01358.

Now the report, after defining "the ohm," which will shortly rank with the yard and the pound, and which may, therefore, be called the Imperial Ohm, alludes to the B.A. unit as being ·9866 of the ohm; that is, the ohm is 1·01358 B.A. units. Now, the "legal" ohm referred to on the certificate was the 106 centimetre compromise, which was agreed to at Paris in 1884, but which has produced nothing but confusion, and, fortunately, has been accepted by very few electricians. But the ratio of 1·0112 to 1·01358 is not the same as 106 to 106·3, but as 106 to 106·24948, say 106·25. The certificate in question was given to Messrs. Nalder Bros., for a resistance coil which has been found to be 1·00005 ohms at 16·8°C. The following table gives the relations of the various ohms:—

	In terms of mercury standard.	In terms of B.A. unit.
B.A. unit	104·8	1
Paris Congress, 1884, or so-called legal ohm	106	1·0112
"True ohm" so called (Jamieson)	106·2	1·0131
Imperial ohm (Board of Trade)...	106·3	1·01358 (?)

The problem of preventing a spark on rupturing or cutting an electrical conductor in a coal mine is not an easy one, and the ingenious cable which is described elsewhere seems to solve it in a satisfactory manner. This invention was made, and a cable manufacturer had with difficulty been induced to carry it out, before the reading of the important Paper on Electrical Mining Machinery at the Institution of Civil Engineers, but owing to the incomplete state of the patent the authors were compelled to be silent about it, much as a

Digitized by Google

description of it would have enhanced the interest of their communication. While it will naturally be accepted with great caution, the cable can undoubtedly be tested as to its non-sparking properties with much greater ease than a coal-cutting motor; for, as in experiments which have been carried out with it, a considerable self-induction can be introduced to exaggerate the spark by putting the magnets of a dynamo in series with it, and cutting or rupturing it in the dark. We understand that, after careful and satisfactory tests, some four miles of this cable have been ordered for Lord DURHAM'S coal mines.

THE safety cable depends for its effectual action on the working of fuses and automatic cut-outs, and it is obvious that these must be arranged for the rapid interruption of the circuit. The cable was exhibited at Prof. S. P. THOMPSON'S British Association lecture on Electricity in Mining, and was arranged for showing the action of the fuse and knock-over switch on rupturing the cable. But the second device, a resistance for guarding against crushing or cutting, and consequent contact between the outer and inner conductors, was omitted; and, by one of those luckless mishaps which are apt to occur in lecture experiments, this very contact was made, and the result caused an unfavourable impression on the audience, an impression which we hope this explanation, and a perusal of the description of the cable, will remove.

THE above information, by-the-bye, we received yesterday by telephone from Harrow-road, a sufficient proof of the great improvement which has been effected of late in the service. Two or three years ago communication with the outlying parts of London was almost useless, speech being very feeble and smothered with cross-talk and other disturbances, and conversation being generally restricted to shouting, "Are you there?" and "Who are you?" while the lady at the exchange would occasionally encourage the subscribers by suggesting that they should "Speak up!"

WE commence in the present number a series of articles by Mr. G. F. C. SEARLE, of Cambridge, on "The Determination of Currents in Absolute Electro-Magnetic Measure." Our object was, in the first place, to present to our readers a description of the work of Lord RAYLEIGH in his determination of the ampere, now that this is about to define one of our two primary electrical standards. The author has, however, written a considerable amount of introductory matter dealing with those dynamic properties of the current which are utilised in making the measurements, and this will not only form an introduction to the description of Lord RAYLEIGH'S research, but will be a *résumé* of the electro-magnetic system of units and the method of applying it to practice.

Electrical Engineering Exhibition.—It is proposed to hold an Electrical Engineering Exhibition at Glasgow this winter.

Alicante.—Messrs. Siemens and Halske are equipping a central station at Alicante, in Spain. Power is to be derived from gasmotors.

The Berlin-Munich Subterranean Telegraph Line.—This line, to which we referred in our last issue, is now completed, and is expected to be at work in a few days, as soon as the necessary tests have been carried out.

Sheffield.—The Town Council have decided to apply for an electric lighting order, unless satisfactory arrangements can be made with a company.

Nomeny.—The town of Nomeny (Meurthe-et-Moselle) will shortly possess an electric light station, in which the necessary power is obtained from the adjacent river.

Budapest.—The lighting of the palace at Budapest has been entrusted to Messrs. Ganz and Co. The installation will include 8 arc lamps and about 2,700 incandescents.

Glasgow and West of England Technical College.—The 1891-2 session of this College commences on Monday, October 5. Further particulars will be found in our advertisement columns.

New Cable.—The new submarine cable, establishing direct communication between Brazil and the United States, was opened for traffic last week. This cable belongs to the Société Française des Télégraphes Sous-Marins.

Electric Traction in Russia.—According to the *Elektrotecnischer Anzeiger* it is expected that the Allgemeine Elektricitäts Gesellschaft will equip a tramway line in Kiew with their overhead wire system of electric traction.

The Chicago Exhibition.—Sir Henry Trueman Wood and Mr. James Dredge started on Saturday for Chicago, as representatives of the Royal Commission for the Chicago Exhibition, and with the object of making preliminary arrangements for the British Section there in 1893.

Electricity in Mines.—At the recent annual meeting of the National Association of Colliery Managers, at Newcastle, the President advised colliery managers to begin to accustom themselves to electricity, and to make themselves familiar with the rules relating to its measurement.

The Lauffen-Frankfort Transmission Plant.—Our Frankfort correspondent informs us that the current from Lauffen at 15,000 volts has during the past week been used daily, after transformation, for lamp lighting with complete success. The motor on Wednesday was running at full load, driving the pump for the artificial fountain.

Electric Inspector.—The City of Liverpool (City Engineer's Department), as will be seen by our advertisement columns, wants a well-trained electrical engineer to act as electric inspector. The person appointed will not be allowed to engage in private practice, and will be required to devote his whole time to the duties of his office.

Electric Lighting at Damascus.—The *Levant Herald* says that among the applications for concessions for public works now being considered by the Minister of Public Works, is one for the lighting of Damascus by electricity. An application for the building of an electric tramway in the port of Smyrna is also at present under consideration.

The Telephone in East Prussia.—Telephone lines connecting Berlin, Posen, Bromberg and Königsberg (400 miles), and Berlin, Schneidemühl, Dirschau, Danzig, Elbing and Königsberg (350 miles) are projected. Both lines will pass through Landsberg. The Landsberg—Frankfurt-on-Oder—Berlin line (100 miles) is to be opened on October 1st.

The Telephone in Kent.—Since the amalgamation of the South of England Company with the National Company, th telephone system has made great progress in Kent. A trunk line is being worked down from London, and will cross the Thames at Gravesend, and from thence will be carried from Chatham to Maidstone, whilst a branch line is being constructed to Minster.

Thunderstorms.—There has been the usual quota of thunderstorms during the past 10 days. On Saturday, the 29th ult. a severe thunderstorm broke over Willingham, in Hampshire. The lightning struck a wheat-cutting machine, shattering one of the rakes, throwing the driver and killing the two horses. In the North and along the East coast houses have been struck and cattle killed.

Physical Research Studentship.—An election to the Coutts Trotter studentship at Trinity College, Cambridge, will take place next month. Applications from candidates must be sent into the College office, addressed to the Secretary of the Coutts Trotter Studentship Committee, on or before October 15th.

Digitized by Google

The studentship is tenable for two years, and is for original research in physiology or in physics.

Brighton.—At the meeting of this Committee, held on August 24th, Mr. Shoolbred reported that he had received a communication from Messrs. Sharp and Kent, stating that they were willing to carry out the work of wiring and fitting up lamps at the generating station, for the amount mentioned in their estimate of July 30th last, viz., £189. 15s. The Committee resolved that the firm named carry out the work.

The Electrical Utilisation of Water Power.—At a recent meeting of the Société des Ingénieurs Civils reference, says *La Lumière Electrique*, was made to a hydro-electric plant now being erected at Saint-Michel for M. Adolphe Minet. Power is obtained from the falls of the Valloirette. The ultimate available power amounts to 30,000 H.P.; though some 6,000 H.P. only will at present be utilised. The works will be devoted to various electro-metallurgical purposes.

The British Association.—The meeting of the British Association stands adjourned until Wednesday, August 3rd, 1892, at Edinburgh, when the president will be Sir Archibald Geikie. In 1893 the British Association will meet in Nottingham. The following are some of the money grants made: Prof. Carey Foster, "Electrical Standards" (partly renewed), £27. 4s. 6d.; Prof. G. F. Fitzgerald, "Electrolysis," £5; Dr. Lodge, "Discharge of Electricity from Points," £50.

City and Guilds of London Institute.—The matriculation or entrance examination for the Central Institution will be held on September 21-24th; and for the Day Department of the Technical College, Finsbury, on September 29th. The new session of the Central Institution commences on September 30th. The next session of the Finsbury Technical College commences on October 6th. Further particulars will be found in our advertisement columns.

Crystal Palace Electrical Exhibition, 1892.—The Special Committee appointed by the Electrical Section of the London Chamber of Commerce to co-operate with the Directors of the Crystal Palace Company in promoting the success of the Exhibition, consists of the following gentlemen: Mr. R. E. Crompton, (Chairman), Major S. Flood Page and Mr. Emile Garcke (Vice-Chairmen), Mr. J. E. H. Gordon, Mr. G. Binswanger, and Mr. Alexander Siemens.

Canterbury.—At a recent meeting of the Town Council a letter from the Brush Company was read, in which they stated that they were willing to undertake the formation of a company to take over the Provisional Order and to pay the expenses of it, depositing 10 per cent. as security. Several members were of opinion that it would be better to refer the matter to a small committee to make terms with the Company and place them before the Board of Trade. This was agreed to.

Portsmouth.—At the last meeting of the Town Council it was finally resolved to adopt the electric lighting scheme, which will, it is estimated, involve an outlay of £60,000. At one time it was thought that the introduction of electric lighting into Portsmouth would be left to private enterprise. A company was formed, but the Town Council afterwards determined to apply for an order, and the company was dissolved. Mr. Shoolbred was consulted by the Town Council, and he recommended the adoption of the low-pressure system, supplemented by storage batteries, distribution to take place on the three-wire system. The capacity of the station will be at first 10,000 8 c.p. lights.

Glasgow.—At a recent meeting of the Town Council, the sub-committee of the Tramways Committee reported that they were of opinion that it was desirable, after the termination of the present lease (1894), that the working of the Glasgow tramways by means of horses should be discontinued as far as possible, and that mechanical traction, by means of electricity, cable, or compressed air, should be substituted. Before, however, coming to any conclusion as to the respective merits of these several systems with reference to Glasgow, the sub-committee recommended that the fullest information should be got as to their relative cost and advantages; and that it should be remitted to the sub-committee to obtain this information. The report was adopted.

The Telegraph in Norway.—The following table will give an idea of the deviations necessitated by the nature of the country in Norway when running telegraph lines:—

Places connected.	Distance as the crow flies, in kilometres.	Length of the telegraph line.
Tromsoe—Alten	170	330
Alten—Kistrand	90	150
Kistrand—Hammerfest	60	70
Kistrand—Gjesvaer	70	150
Tromsoe—Hammerfest	210	550
Hammerfest—Gjesvaer	80	170
Tromsoe—Gjesvaer	300	580

Birmingham Municipal Technical School.—The School has been established for the purpose of carrying out a liberal scheme of technical education, which has been rendered possible by the Technical Education Act of 1890. The Committee earnestly desire that the instruction given may be of practical value to all sections of the community, and have, therefore, endeavoured to provide, on broad lines, classes which shall be of service for all the local trades. As regards payment, it is the wish of the City Council that the amount of the fees should be so low as not to prevent the poorest from entering the school. Chemical, Physical, Metallurgical, Electro-Metallurgical Laboratories, and a well-equipped Machine Shop have been provided. The first session begins next Monday, and ends on Saturday, April 30, 1892. A number of scholarships admitting to the classes in each of the trade groups will be awarded on the result of the examinations to be held shortly.

The Practical Efficiency of Telegraphic Apparatus.—The following table relating to the "efficiency" of the various telegraph instruments employed by the French Post Office may be of interest. The figures are taken from an article in *La Lumière Electrique*. A message is reckoned at 20 words, and each word at 7·5 letters:—

Apparatus.	Average number of messages per hour.	Number of operators.	Average number of messages per hour per operator.
Morse	25	2	12·5
,, (duplex)	50	4	12·5
Sounder	40	2	20
,, (duplex)	80	4	20
,, (quadruplex)	160	8	20
Wheatstone	100	10	10
,, (duplex)	200	18	11
Delany (quadruplex)	160	8	20
Baudot (quadruplex)	160	10	16
Hughes	50	4	12·5

The Production of Ozokerite in the United States.—Ozokerite, or "mineral wax," belongs to the series of hydrocarbon compounds, which include marsh gas, petroleum, and paraffin, it being very similar in appearance to the latter. It is colourless to white when pure, but frequently occurs leek-green, yellow and brown. Prior to 1888 the only locality producing this mineral oil was the province of Galicia, in Austria. Mining began there in 1862, and though at first it was found exceedingly difficult to obtain sufficient capital to push the enterprise, it has increased rapidly since that date, and at present there are 35 companies engaged in the industry in the province of Galicia alone. For 26 years production was limited to this locality, but in 1888 American ozokerite began to receive the attention of the trade, and considerable work was begun upon a newly discovered vein in Utah. The mineral had been known to exist in Utah for some years, but whether in paying quantity was not satisfactorily determined until August, 1888. The production of 1888 was estimated at 65,000lb. of crude mineral. The production for 1890 probably exceeded 300,000lb. Refined ozokerite is used for nearly all the purposes to which ordinary bees'-wax is applicable. Crude ozokerite, like other hydrocarbon compounds, is used to a considerable extent as an electrical insulator.

Phosphorescence.—M. Henri Becquerel has recently studied the different manifestations of the phosphorescence of minerals under the influence of light and heat, and has communicated some observations upon the subject to the Académie des Sciences. The result of M. Becquerel's experiments up to the present time is to place the phenomenon of phosphorescence induced by heat (hitherto considered as distinct from all other phenomena of the kind) once more into the class of known and studied phosphorescence effects. One fact in particular deserves attention in connection with this subject—the conservation to an indefinite time in certain bodies of a portion of the energy which they have absorbed, and which they emit upon being heated. M. Becquerel asks by what mechanism this energy is thus maintained in its potentiality without appreciable loss. He declares himself unable for the present to answer this question; but he looks to future research for information upon the subject, which may have the most important bearing upon the state of knowledge of the mechanism of light radiation and the storing of energy in its highest and most intense forms.

Electric Lighting Statistics of the American Census.—In a recent issue the *Electrical Engineer* of New York devotes a leading article to some electrical statistic spinning from the census return on the "Social Statistics of Cities." It seems that 309 American cities, with a population of 16,335,659, have for their streets 182,671 gas lamps, 53,696 electric, and 57,480 oil. Each of the 293,847 lights costs $35.50 per annum. Gas is now used exclusively for street lighting in only 13 cities, whereas electricity is exclusively used in no fewer than 125. Another table of interest is that containing the condensed figures of cities up to 100,000 inhabitants. In 278 of these, with a population of 7,018,653, there are 35,191 electric lights, compared with 35,127 gas. The value of electric lights is brought out by the table which furnishes details as to the number of lamps to the mile of street. Thus in New York, where there are only 1,369 electric lights to 25,483 gas lamps, there are 46·92 lamps to each mile. In Buffalo, where there are 1,223 electric lights to 4,377 gas, there are only 15·05 to each mile. Denver, with 1,750 electric lights and no other lights, has only 2·31 to the mile.

Exports of Telegraphic Apparatus.—The August trade returns, so far as they refer to the exports of telegraphic wires and apparatus connected therewith, are again most satisfactory; in fact, the value of the exports last month was phenomenally large, having amounted to more than twice as much as in the corresponding month of either last year or the previous year. Our exports under this head, previously this year, have been very heavy, and the increase in August has brought up the total exports for the first eight months of this year to approximately 1¼ million sterling. In the following table we show the value of the exports for August, and for the eight months, in comparison with the corresponding figures of the two previous years:—

	1891.	1890.	1889.
First quarter...	£653,081	£324,670	£431,309
Second quarter.	331,449	397,042	145,147
Six months.....	984,530	721,712	576,456
July.....	150,754	56,575	32,909
August	112,690	55,601	45,452
Eight months...	£1,247,974	£833,888	£655,817

Standards of Electromotive Force.—The following suggestion emanates from our New York contemporary, the *Electrical World*:—"It is rather odd that electromotive force should be so unreasonably difficult to determine. No aspersions are to be cast on the Clark cell, but it is only adapted for open circuit, and has a trick of getting out of order on very small provocation. The thermopile has been from time to time proposed for the purpose of a standard, but the electromotive force of a single element is exceedingly small, and, furthermore, the working of the apparatus is anything but constant. In this exigency why would it not be well to turn to the dynamo, not as a source of electromotive force of the utmost scientific accuracy, but as one capable of giving very conveniently such a range of electromotive force as is desirable in applied work, and of being operated on closed circuit within reasonable limits and without perceptibly impairing its exactness? Of course a dynamo for such a purpose would have to be specially constructed. It would probably be best to use a comparatively small quantity of iron, of the very highest magnetic properties, as carefully annealed as the core of a transformer—the windings would be arranged with special reference to keeping their temperature steady, and the armature would have to be constructed with the same object in view. Such a machine, when run at a constant known speed, would give an electromotive force definite enough and constant enough for all practical purposes, and would furthermore possess the great advantage of giving a very perceptible current without changing the electromotive force, particularly if, as might readily be done, compound winding were applied. Changing the speed would give a beautifully easy way of obtaining any desired electromotive force. The motive power would naturally be an electromotor directly coupled to the shaft and furnished with a shunt box, for the purpose of enabling its speed to be adjusted to exactly the proper point. The cost of such apparatus would be but little more than that of a battery of standard cells, such as is required in any laboratory of considerable size, and its use would probably be found in the long run to be for all ordinary circumstances much more convenient and reliable. Considerable care would be necessary in constructing such a standard dynamo, both to insure freedom from errors through heating and the requisite constancy of the magnetic qualities, but the advantages of the plan are sufficiently numerous to warrant trying it in spite of these minor objections."

Manchester Technical School.—A new department of physics and electrical engineering will be commenced this session at the new branch of this school in Whitworth-street, where a large well-lighted warehouse is being fitted as follows:—Basement: Dynamo house, with 14 H.P. Crossley engine. Dynamos and motors, arranged specially for purposes of instruction. Secondary battery room, with a set of 27 high-discharge accumulators, arranged with switchboard for illustrating the application to instrument calibration and to electric light installations. Complete appliances for electro-chemical operations. General workshop conveniences for electrical instrument making, including electrician's power lathe. Ground floor: Electro-technical museum and advanced physical laboratory. In the former will be arranged samples of manufactures presented or lent by different electrical firms. In the latter, electrical testing instruments of the most approved construction will be provided. Also a library of works relating to general physics and electrical technology. First floor: Lecture room. Second floor: Elementary physical laboratory. The building will be lighted by electricity, the installation being fitted up with especial regard to purposes of instruction. The regular scheme of study extends over two years, though students may remain for a longer period, and is designed to give a satisfactory training in pure and applied physics, pure and applied mathematics, geometrical, freehand, and mechanical drawing, applied mechanics, steam and the steam engine, machine design, theoretical and practical chemistry, and metallurgy (the latter for second year students), and in the German language. Systematic practice is provided in the school workshops in the use of wood and metal working tools, both hand and power. The workshop course is arranged so as to give sufficient instruction in wood, brass, iron, and sheet metal-working to enable students to construct efficient electrical instruments. The mechanical drawing, especially during the second year, will have reference more especially to the design and arrangement of electrical plant. In the evening department, in addition to the usual courses of general physics, special instruction will be provided in electric lighting and power transmission, as well as telegraphy and telephony, the two latter subjects being under the charge of Mr. Taylor, of the Manchester Postal Telegraphs. After Christmas a course of six lectures on electric bells, designed chiefly for plumbers, will be given, and during the summer term lectures and laboratory work, devoted to the study of electro metallurgy and alternate currents of electricity, have been arranged.

MAGNETISM IN IRON AND OTHER METALS.*—XLIX.

BY PROF. J. A. EWING, F.R.S.

(*Continued from page 496.*)

§ 176. **The Constraint of the Molecules due to their Mutual Action as Magnets.**—The matter becomes immensely simplified if we put aside all these arbitrary postulates regarding directive force and resistance to turning, and inquire what is the character of the constraint the molecules necessarily suffer through the forces which they exert on one another in consequence of the fact that they are magnets. It appears that this constraint is sufficient to account for the observed characteristics of the process of magnetisation, that it completely explains hysteresis, and that it at least offers a clue to those complicated variations of magnetic quality which are known to be caused by the variation of such physical conditions as temperature or stress.†

In proceeding to consider the equilibrium of the molecules under their mutual magnetic forces, it is clear that we cannot confine our attention to any one molecule. For the directive force that acts on any one molecule depends on the positions of the molecules which surround it, and becomes altered when these are disturbed. We cannot investigate the equilibrium of the individual without including in the question the equilibrium of its neighbours. When an external force is applied, they, as well as it, are deflected, and the constraint they exercise on it suffers change. What must be studied is the configuration of the group as a whole, and the manner in which the group becomes distorted, broken up, and rearranged in the process of applying and removing an external magnetising force.

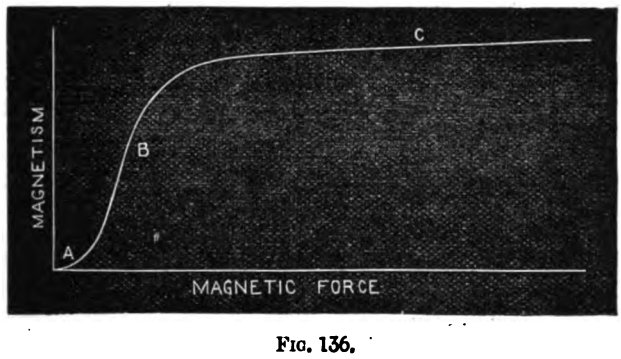

Fig. 136.

In seeking to find in the mutual constraint excited by the magnetic molecules, an explanation of the changes of susceptibility which are observed as a magnetising force as gradually applied to a piece of iron or other magnetic metal, it should be borne in mind that the magnetising process may be broadly divided into three stages (as was remarked in § 141), namely, the stages A, B, and C of the typical curve (Fig. 136).

They admit, in general, of being distinguished from one another without difficulty, though the passage from one stage to the next is never perfectly abrupt. In some cases, however, it is remarkably sharp, as in the curves of Figs. 120 and 121, which relate to nickel under torsion, and under a combination of torsion with longitudinal pull.

In the first stage the susceptibility is small, and there is almost no retentiveness. In the second stage the magnetism is acquired with great readiness, and much of it may be retained if the force be removed. In the third stage the growth of magnetism is again slow, and what is acquired in it does not contribute much to the residual magnetism. We shall see that these stages are just such as the molecular theory would lead us to anticipate.

§ 172. **Imaginary Molecular Groups.—A Single Pair.**—By way of leading up to the consideration of groups consisting of many magnetic molecules, we may begin by thinking of a group which consists of a single pair. Each member of the pair is to be conceived of as a short magnet capable of free rotation about a fixed centre. In the absence of all external magnetic force this pair of molecules will arrange themselves as in Fig. 137, with opposed poles exactly in the line joining the centres. Let an external magnetic force, H, now be applied in any direction (Fig. 138).

If H is weak the molecules will be but slightly deflected. But as H is gradually increased a stage will be reached at which the molecules part company, and will fly round into a position

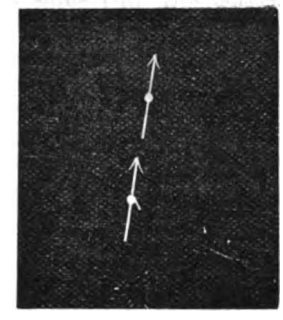

Fig. 137.

in which the direction of the magnetic axis of each is nearly parallel to H (Fig. 139).

Except in special cases perfect parallelism will be reached only when H becomes indefinitely strong.

Then as H is gradually reduced there will at first be little change in the configuration, until a stage is reached at which a sudden return to the condition of Fig. 138 occurs. This will happen at a lower value of H than that which was needed to

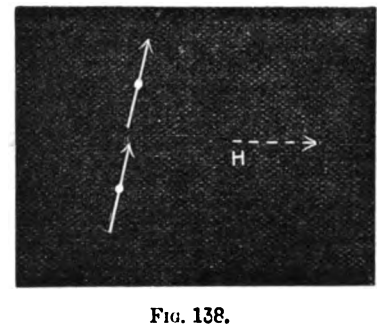

Fig. 138.

break up the group of Fig. 138; here we have, in fact, an elementary example of hysteresis. If the direction of H is chosen so that it is perpendicular to the line of centres this return will occur only when H is reduced to zero. In the more general case, illustrated by the figures, the sudden return will happen when H has a small finite value, and then the subsequent reduction of H to zero will be associated with a gradual change from the state of Fig. 138 to that of Fig. 137.

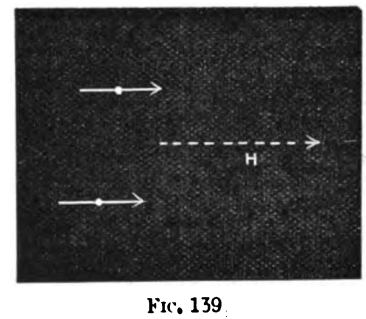

Fig. 139.

During the application of H we have three stages; there is, first, the slight deflection of the molecules (Fig. 138) which precedes what may be called the rupture of the tie that holds them in line with one another. Then there is the sudden swinging into a position of much greater deflection when that tie is broken. Finally there is the continued approach towards perfect alignment, made under strong values of H. During each

of these three stages the group is acquiring resultant magnetic polarity in the direction of H, though the magnetisation of the individual molecules is, by assumption, a constant quantity. In the first stage the process is, so to speak, perfectly elastic—that is to say, it corresponds to the elastic stage in the straining of a solid when there is no permanent set left after the removal of the straining force. If we suppose H to be removed at any part of the first stage, the molecules at once return to their primitive positions. But after the critical value of H has been passed, which separates the first stage from the second, this is not so; there is then a tendency to retain the new configuration. We shall see presently that this tendency, which is the very essence of hysteresis, becomes much more conspicuous when we have to deal with larger groups. Finally in the third stage we have again a quasi-elastic part of the process of magnetisation.

To begin with, the equilibrium of the group is, of course, stable with respect to small displacements. Any small casual disturbance, applied and removed, will leave the magnets swinging about the position of equilibrium, shown in Fig. 137. The equilibrium continues to be stable so long as the deflecting force is weak (stage 1). But as the critical point is approached, the stability becomes reduced—just at the end of stage 1 it is neutral, and any further increase of H brings about instability. The molecules then precipitate themselves into the new form (Fig. 139) in which they are once more stable so long as H continues to act.

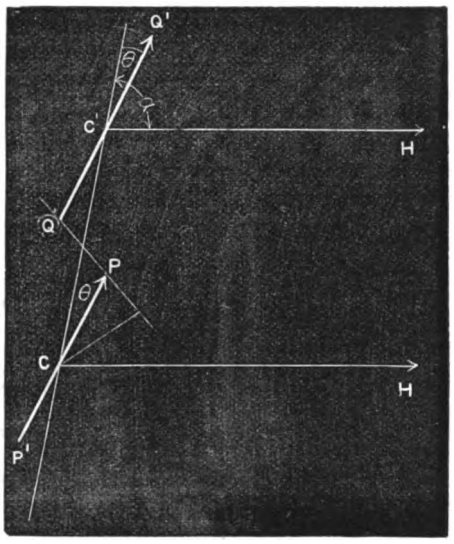

Fig. 140.

To express the matter in symbols, let us suppose that each magnet may be treated as a pair of poles of strength m, separated by a distance $2r$, which is the length of the magnetic axis. Let α (Fig. 140) be the angle which the direction of the applied deflecting force H makes with the line of centres C C', and let θ be the amount of deflection, which is the same for both magnets. It is assumed, in the first place, that H is not so strong as to produce instability.

The field H exerts a mechanical force m H on each pole, or a couple on each magnet, the distance between the parallel forces of the couple is $2r \sin(\alpha - \theta)$.

The deflecting moment which acts on each magnet is, therefore,

$$2\,\mathrm{H}\,m\,r \sin(\alpha - \theta),$$

and this is to be balanced by what we may call the restoring moment, due to the forces which the magnets exert on one another.

These forces are (1), the attraction of the poles P Q; (2), the attraction of the poles P' Q'; (3), the repulsion of the poles P' Q; and (4), the repulsion of the poles P Q'. Of these forces the moments of the third and fourth balance one another, and the moment of the second is insignificantly small compared with that of the first, provided the distance C C' is not much greater than the length of one magnet, and the deflection is not great. Under these conditions it will suffice to consider the restoring moment as due to the first force only, namely, to mutual attraction of P and Q. Its value is

$$\frac{m^2\,\mathrm{C\,N}}{\mathrm{P\,Q^2}},$$

and the condition of equilibrium is that

$$2\,\mathrm{H}\,m\,r \sin(\alpha - \theta) = \frac{m^2\,\mathrm{C\,N}}{\mathrm{P\,Q^2}}. \quad . \quad . \quad . \quad (1).$$

As θ is increased the restoring moment at first increases, but passes a maximum at a value of θ which depends on the relation of the length r, or C P to the length C C'.

When H and θ are sufficiently increased the equilibrium becomes neutral. This occurs when

$$\frac{d}{d\theta}\left\{2\,\mathrm{H}\,m\,r \sin(\alpha - \theta)\right\} = \frac{d}{d\theta}\frac{m^2\,\mathrm{C\,N}}{\mathrm{P\,Q^2}},$$

or

$$\frac{d}{d\theta}\left\{\mathrm{H} \sin(\alpha - \theta)\right\} = \frac{m}{2r}\frac{d}{d\theta}\frac{\mathrm{C\,N}}{\mathrm{P\,Q^2}} \quad . \quad . \quad (2).$$

From these two equations (1) and (2) it is possible to determine the values of H and of θ corresponding to the critical point in the deflection, at which the equilibrium of the deflected molecules become neutral. Any greater value of H will cause instability; the molecules will then swing violently round into a new position of equilibrium with their axes nearly parallel to the direction of H.

If there were a number of such pairs of magnets, all acted on by the same deflecting field, but with their lines of centres inclined at various angles to the direction of H it is clear that some would reach instability sooner than others, as H was strengthened. The first pairs to become unstable would be those which were inclined at something more than a right angle to H, so that $\alpha - \theta$ became a right angle when the value of θ corresponding to instability was reached. Other pairs would escape passing through the unstable state altogether, namely, those pairs which lay initially in directions nearly parallel to H. How nearly parallel to H they must lie initially in order to escape instability depends on the extent by which the distance between the centres exceeds $2r$.

If we suppose that this excess of distance, or clearance between the poles, as one may call it, is very small, then the state of instability in pairs which lie well across the direction of H is reached approximately when

$$\frac{d}{d\theta}\cdot\frac{\mathrm{C\,N}}{\mathrm{P\,Q^2}} = 0,$$

which happens when $\tan\phi = \frac{1}{\sqrt{2}}$, ϕ being the inclination of the line P Q to the line of centres C C'. In these circumstances the value of H which breaks up the pair is

$$\mathrm{H} = \frac{m}{12\sqrt{3}\,.\,(a-r)^2 \sin\alpha},$$

where a stands for half the distance between the centres C and C'.

This does not apply when the line of centres is nearly parallel to H. In the special case when the line of centres has the same direction as H, but the magnets point initially in the direction opposed to H, there is no stable deflection previous to the occurrence of instability. The critical point is reached in such a pair when

$$\mathrm{H} = \frac{m}{8\,(a-r)^2}.$$

The general behaviour of a crowd of groups, each consisting of two magnets, can be readily enough imagined, and still more readily examined by aid of a model. Until the first of the groups breaks up, or the field is increased, we have nothing but quasi-elastic deflection. Then the groups successively reach the critical point, so that a rapid, though not perfectly sudden, development of resultant polarity on the part of the crowd as a whole is observed. Finally, there is a slight and further increase, under the action of stronger fields, as the state of "saturation" is approached.

Again, as the field is gradually reduced many of the groups will return to their initial state. Many others, however, will

Digitized by Google

assume new forms, namely, with their poles pointing just the other way from the way they pointed at first, and the effect of these will be to contribute a resultant residual polarity which persists when H is reduced to zero. The application and removal of H will leave a majority of groups pointing, more or less, towards the direction in which the force was applied, although at first there was no preponderance in any direction.

We find, therefore, even in so simple a grouping of magnetic molecules as this—namely, a grouping in isolated pairs—many of the features which are presented in the magnetisation of iron. We find analogues of the first, the second, and to some extent the third stages, which are observed in curves of I and H, and we find evidence of hysteresis and residual magnetism. But a very much more complete reproduction of the phenomena of magnetisation becomes possible, as will be shown presently, if we suppose the molecules to be distributed either continuously or in groups consisting of a considerable number of members.

The behaviour of two-member groups would agree fairly well with what is known to happen in the first and second stages of the magnetising process in iron. It seems, however, to leave too little supplementary magnetisation to be acquired during the third stage. And a more obvious difficulty is, that though two-member groups suffice to account for the existence of some residual magnetism, they fail to explain the high retentiveness which is found in, say, soft iron, where we often find more than 90 per cent. of the induced magnetism surviving the removal of the magnetising force. To account for that, something more is needed than the constraint exercised by each member of a pair on the other member; the molecules must, in fact, form new ties after the old ones have been ruptured, and to allow of that each molecule must have more neighbours than one.

(To be continued.)

PRACTICAL POINTS RELATING TO THE ETHER.

BY S. TOLVER PRESTON.

In connection with the question of the compressibility of the ether, there seems to be much uncertainty and vagueness; and it may be of practical interest to notice some of the opinions in relation thereto. Dr. Lodge, in his interesting articles, "Modern Views of Electricity," mentions this matter; and it is with the desire to advance truth that I venture to comment on some passages in these articles, originally published in *Nature*.

In reference, doubtless, to Sir W. Thomson's theory* of matter, Dr. Lodge remarks in Article 9, *Nature*, August 23, 1888, viz.:—"We already know of a continuous incompressible fluid, filling all space, and we call it ether" (p. 389). In regard to this, I would merely lay stress on the fact (first) that the fluid, being assumed continuous, is, therefore, inferentially incompressible as a possible necessity; but this fluid surely is not the ether? For the passage above quoted might seem to some readers to imply that the *ether* was necessarily incompressible. Now, it is a well-known fact that the fluid by itself is imperceptible to the senses, and therefore, of course, cannot be ether, or what we call "matter," at all. The vortices in the fluid (vortex atoms) constitute the ether, including also matter generally—"gross matter," as it is called. So that this theory of vortex atoms has the advantage of making no distinction between the ether and ordinary matter, excepting, probably, one of dimensions of parts; and both ether and gross matter must in accord therewith be of molecular constitution. Maxwell remarks, in relation to Thomson's theory of matter, viz:—"The ether, if it is the medium of electro-magnetic phenomena, is probably molecular, at least in this sense" ("Encyc. Brit.," 1878, p. 527, &c.).

So it appears obvious that the fact of a "continuous incompressible fluid" existing does not imply that the ether is incompressible. The vortices constituting the portions of the fluid thus differentiated as molecules are what we call "matter" or "ether;" the rest appeals to us no more than empty space would do if the old atomic theory of Lucretius were true. In fact, the modern theory of matter does but little more, as it appears, than explain how atoms can be elastic and not "infinitely hard" according to the Lucretian postulate. Otherwise the modern theory leaves the ancient atomic theory much as it was; and this fact is not, perhaps, realised to the degree* it deserves. The ether atoms are not necessarily assumed in contact, of course, and, therefore, the structure (as far as imagination goes) may be conceived to any extent compressible. What degree of compressibility actually exists (if measurable) it is evidently for experiment to determine, or it is difficult to see what other conclusion is open to us.

Dr. Lodge says, further, viz, "The neighbourhood of gross matter seems also to render ether more *dense*. It is difficult to suppose that it can really condense an incompressible fluid, but it may load it or otherwise modify it so as to produce the effect of increased density. In iron this density reaches its highest known value" (p. 389). This is a practical point; but surely the vague idea of "loading" the ether is unnecessary, and it will probably be conceded that no defined conception attaches thereto. A true mechanical conception of increased *density* of ether in iron can apparently only be arrived at by conceiving the ether compressible† to some extent; and to allow this it is only needful to assume that its constituent atoms are very pliable (elastic) or not in contact. There must be room for gross matter in the ether, and it is not easy to see how matter could move freely through the ether if the constituent atoms of the latter were in contact. The subject is difficult, no doubt, and for this reason is all the more criticism necessary and desirable for elucidation and progress.

But I would just venture to put a question here on a very important and interesting point. Is it proved that the greater magnetic permeability (specific magnetic capacity) of iron is due to the greater *density* of the ether in it? According to this the ether in iron is inferred to be about 300 times denser than the ether in air. If we could prove the truth of the view (which seems highly probable on certain theoretic grounds, no doubt) that magnetic permeability is proportional only to the ether density in a substance, it would certainly simplify matters, and this theory deserves encouragement from its simplicity. But would not additional research be essential to establish this view?

Again, we may much admire the (parallel) theory that the specific inductive capacity of substances is proportional to the elasticity of the ether contained in the substances. But, although some considerations may render this theory probable, is there evidence, it may be asked, that the molecules of the bodies themselves or *their* elasticity have no part in regulating the specific inductive capacity, in addition to the influence of the ether, which unquestionably penetrates all substances? These conclusions would seem to be spoken of in the "Modern Views of Electricity" rather as established facts than as theories. It is then also set forth as an hypothesis regarding the assumed incompressible ether as follows:—"Let us suppose that it is composed of and by electromotive force, analysable into two constituents; let these constituents cling together with a certain tenacity, so that the medium shall have an electromotive elasticity, though mechanically quite fluid," &c. (p. 389). This implies, I assume, that portions of the fluid constituting compound molecules are "analysable into two constituents;" for the incompressible fluid itself can scarcely, of course, be said to be analysable into constituents.

Dr. Lodge in his first article, favouring, as he does, the idea that electricity is a substance, emits the view that "electricity behaves itself like a perfectly *incompressible* substance or fluid" (p. 533).

This fluid—electricity—is supposed to occupy cavities or cells in matter. But surely the *incompressibility* of this fluid makes it impossible to explain the "strains" of static electricity, which Dr. Lodge regards as synonymous with strains of the fluid;

* Known to be based on some mathematical investigations of Helmholtz.

* We are only treating the broadly announced mechanical aspects of the theory here. Of course, I am aware that the fluid about the vortex atom has important functions—conduces by its motion to the stability of the atom, &c., &c. But *roughly* the exterior fluid plays the part of space, (since it is not what we call "matter,") and there can be no doubt that this conception is a very useful and practical one.

† To my mind an incompressible ether is utterly inconceivable—certainly in relation to dynamical ideas.

Digitized by Google

and he admits that "the actual changes in volume necessary to the strain of these cavities are a defect in the analogy" (p. 536). But surely this difficulty is absolute or prohibitory, since it is the characteristic of incompressibility not to allow a change of volume. With the idea of meeting this objection, Dr. Lodge then speculates on a "*two-fluid*" theory of electricity; and it is not stated by what physical qualities the one fluid is to be distinguished from the other.

In Article 8 the induction of currents in moving conductors is tentatively illustrated, and the difficulty of conceiving motion through the magnetic field, owing to the *quasi* rigid system of gearing adopted to illustrate the hypothetical magnetic whirls, is freely allowed to be an obstacle in the way of conception. I mention this to show the numerous difficulties there are, and how all classes of mind should be invited to co operate to remove or lighten them. This criticism is far from implying a non-appreciation of Dr. Lodge's articles.

May it not be that the vibrations constituting light are not of a character to condense the ether, while the vibrations about a wire *are*—in fact, here the ether is enchained, as it were; there is no escape, it must condense (and, conversely, rarefy), if condensable at all, by a *radial* vibration about the wire as an axis, or by any enforced tendency thereto. On the other hand, when a body moves through the ether, it can do so without (sensibly, at least) condensing it, because the ether can escape round the sides of the body. No escape, however, when the ether vibrates radially or axially about a wire *which is a closed circuit*. If it were not closed (not a circuit), the ether could, perhaps, conceivably avoid condensation by escaping over the ends. But there are no ends in a circuit. Hence the *rationale* of a circuit, or possibly one function of it. This point is gone into in additional aspects in a former article published in *The Electrician* of August 14th, entitled "Rough Ideas of the Mechanism of the Electric Circuit."

In reference to the constitution of matter, it may be well to keep in mind that we are independent substantially of theories of the nature of matter generally. We have to look to experimental fact, which proves (1) definitely that molecules exist, (2) that the molecules are from *some* cause elastic, or else the conservation of energy could not be true. To show by some theory of the nature of matter, why or *how* molecules are elastic may be (as we may admit) very interesting,* but only having a secondary influence in the industrial applications of science and general theorising relating thereto.

ON THE DAMPING OF ELECTRICAL WAVES AND THE MEASUREMENT OF STATIONARY HERTZIAN VIBRATIONS ALONG WIRES.†

BY PROF. D. E. JONES.

An account was given of preliminary experiments made at Bonn (at the suggestion of Prof. Hertz) on electric waves in wires. The first object was to find a simple method of measuring the disturbance at different points of a wire (or pair of wires), along which are sent waves which interfere, after reflection, at the ends. It was found that measurements could be made by inserting a very small thermo-junction in the circuit at different points, and noting the deflection of a low-resistance galvanometer connected up to it. The method is delicate enough to detect and measure exceedingly small currents, such as those produced by telephones.

The method was next applied to measure disturbances along a pair of wires about 130 metres long. One end of each wire was connected to a (secondary) plate 40cm. in diameter. In the first set of experiments the other (far) ends of the wires were left free. The vibrator was of the usual type, provided with plates of the same size as those on the near ends of the wires and facing them. The wave-length of the disturbance along the wires was about 4·3 metres. The following results were obtained:—

I. The disturbance was zero at the end (0), rising to a maximum (51) at 2·2m. There was no further absolute minimum, *i.e.*, the disturbance did not fall to zero at any point. At about 4·6m. there was a minimum deflection of 11, at 6·7m. a maximum of 46, at 9m. a minimum of 13, at 11m. a maximum of 23, and so on. Thus the waves tail off rapidly. There were two complete strongly marked waves and indications of a third, after which the disturbance tended to become steady along the wire.

II. When the far ends of the wire were joined similar results were obtained, excepting that the positions of maxima and minima were interchanged, the disturbance being, *e.g.*, a maximum at the ends. The results indicate that only a small number of waves are sent out by the vibrator, and that these are rapidly damped. In both the above experiments the primary and secondary plates were 30cm. apart.

III. (Ends joined.) On bringing the secondary and primary plates nearer together the damping became more and more rapid, as if the secondary more quickly absorbed the energy radiated out by the primary. When the plates were 5cm. apart only one wave could be detected.

The above method has the advantage of requiring only the simplest apparatus. The only other published method which has been used for similar purposes is the bolometric method of Dr. Rubens, but Mr. Bjerknes has obtained similar results to those of the author with an electrometer instead of a thermo-junction.

In order to find whether the junction produced any disturbance, loops of wire were inserted at 17m. from the far end; but loops up to a metre long did not appear seriously to affect the positions of the maxima and minima.

MAGNETIC EXPERIMENTS MADE IN CONNECTION WITH THE DETERMINATION OF THE RATE OF PROPAGATION OF MAGNETISATION IN IRON.*

BY F. T. TROUTON.

The object of the experiments was to find whether magnetisation was propagated through iron with a finite speed, and reasons were adduced in the Paper for supposing the speed to be comparatively slow—more like that of sound than that of light.

The first experiment was made with an iron bar carrying at its ends oppositely-wound spirals, through which the same alternating current was passed. Between these was moved (coiled round the bar) a third exploring coil E (Fig. 1), connected to a

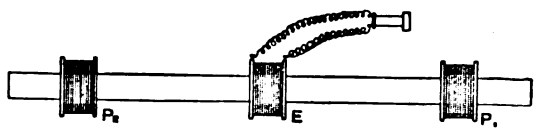

FIG. 1.

telephone. Faint indications of places of minimum intensity were obtained with the bar.

It soon became evident that if any interference-phenomena really existed, they could more simply be obtained by using an iron ring (*see* Fig. 2) with a *single* primary P coil on it. The rings were of various sizes, from 8ft. to 47ft. in circumference, and were made of iron wire—about No. 30—some four miles of it. Nodes and internodes were found in the half of the ring remote from the alternating coil. It was easily ascertained that these were not the nodes looked for, because they did not depend on the rate of alternation. The distance between the

* A true theory of the nature of matter may also, doubtless, have deductive consequences capable of being put to an experimental test, and such a theory, if true, may conceivably be some aid to theoretic thought; but certainly facts numbered (1) and (2) above are the chief practical points for us of real value in research.

nodes was 10-18 inches. A ballistic galvanometer gave no indication of nodes, but always gave deflections in the same direction. The results were the same when an ordinary alternator, a rotating commutator, or an organ-pipe and microphone was used. There were four or five nodes in a 10ft. ring (about 2,000 turns of wire).

In the discussion which followed, Dr. Lodge and Dr. Larmor both expressed an opinion that the results obtained were due to mechanical vibrations exerted by magnetism, or to differences

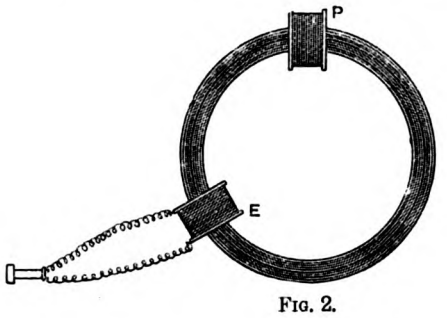

FIG. 2.

in annealing. This might explain the fact that the nodes were only obtained when the primary coil was in certain positions. But Prof. Rücker pointed out that, inasmuch as the ring was of coiled wire (not bar), an original magnetisation of the ring in the first experiment was a more probable explanation.

ON THE MAGNETIC FIELD IN THE NEIGHBOURHOOD OF THE SOUTH LONDON ELECTRICAL RAILWAY.*

BY PROFS. AYRTON AND RÜCKER, FF.R.S.

In the spring of the present year we were both interested in the question as to how far the work of a physical laboratory would be affected by the neighbourhood of an electrical railway.

The South London Electrical Railway runs from Stockwell to the City. It is constructed under the public road at a depth of 60 or 70ft. below the surface. The up and down lines are carried in separate tunnels and enclosed in large iron tubes. The current is conveyed to the trains by an insulated rail, and the circuit is completed through the rails on which the trains run, which probably are or were themselves in communication with the iron tubes and thus with the earth.†

Our observations were made at a house (No. 122) in Kennington Park-road, under which the railway runs, in two rooms, at points distant about 60ft. and 200ft. from the middle of the road respectively.

The instruments used were (1) a rough magnetometer, consisting of needles attached to a mirror suspended by a silk thread about three inches long; and (2) an ordinary Elliott's square pattern mirror galvanometer which was used as a magnetometer.

All observations were made when the period of vibration of the instrument used was about 10 sec. To compare the magnetic disturbances with those due to mere mechanical vibrations, the magnets were removed from another similar galvanometer, and replaced by copper rods of about the same mass. The mirror was then suspended by a bifilar which gave a period of about 10 sec. This was only intended to detect the effects of shaking on the galvanometer, and it may be sufficient to say that it proved conclusively that, at Kennington Park-road, the tremors due to the traffic might be almost neglected as sources of disturbance when compared with the magnetic effects of the railway.

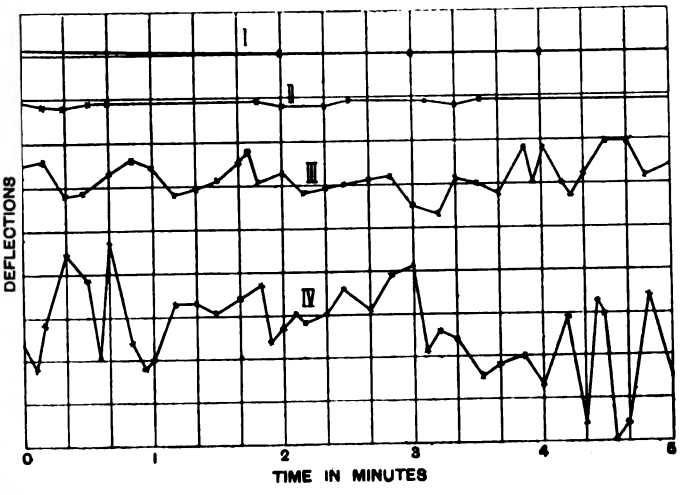
The latter were continuous and very great. On one occasion, when the line was blocked, the instruments were at rest. The oscillations began again at or within a few seconds of the time when a train which had been detained in the neighbouring station left it. This coincidence was most satisfactorily established, as some of our party were noting the times of the arrival and departure of the trains, while others were also noting the instants at which the largest disturbances of the instruments occurred.

The passage of a train caused a very sudden disturbance of the needle, especially in the room nearest the line; but the amplitude of these vibrations, though greater, was often not much greater than that of those which were continually occurring at other times.

At 60 feet from the middle of the road the larger deflections produced on a scale one metre distant from the instruments were about ±20 mm. At the more distant position, about 200 feet from the road they were about two and a-half times less.

As the instruments were about 10 feet above the roadway, and probably about 70 feet above the line, the distances from the line at the two stations were roughly $\sqrt{60^2+70^2}$ and $\sqrt{200^2+70^2}$, or 92 and 212 feet respectively. The ratio of these numbers is 2·3, and as the ratio of the disturbances at the two stations was about 2·5, it is evident that they diminish very slowly as the distance increases. The law of the inverse distance was apparently approximately fulfilled.

To show the effects of the railway we publish the comparative diagrams in curves I. to IV.



Curves showing Magnetic Disturbances caused by the operation of the City and South London Railway.

Readings of an Elliott's galvanometer arranged as above described were taken every 10 seconds in (1) a laboratory of the Royal College of Science, about 150ft. west of the middle of Exhibition-road; (2) another laboratory about 70ft. east of the same road; (3) a room at Kennington Park-road about 200ft. from the middle of the road; (4) a room at Kennington Park-road 60ft. from the middle of the road.

Curves I. to IV. show the results at each place, and the ordinates being the actual deflections observed.

The irregularities in Curve II. were no doubt due to a dynamo which was working at some distance. Curves III. and IV. show the effects of the railway and prove conclusively that ordinary students' work would be impossible in its neighbourhood. To emphasize the fact that the standard of sensitiveness adopted was very moderate we may mention that one of the instruments arranged as for the experiments was compared with a small magnetometer constructed by Prof. Boys, F.R.S. The latter instrument was found to be 160 times more sensitive than that employed in the observations just described.

A Lightning Conductor in 1783.—According to *La Lumière Electrique* a curious discovery has recently been made in the shape of a speech by Robespierre, occupying 100 printed pages, in defence of the Sieur de Vissery, who was appealing in 1783 against a judgment delivered by the Sheriffs of Saint-Omer ordering the destruction of a lightning conductor erected by him. The appeal was, we are told, successful.

* Paper read before the British Association, in Section A, Cardiff, August, 1891.

† We believe that some alterations have been made since the date of our experiments.

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

Advertisement Rates, &c., forwarded on application as above.

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday. Renewals of expiring advertisement orders and alterations to standing advertisements should be in Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday.*

SMALL PREPAID ADVERTISEMENTS *accepted up to 4 p.m. Thursday.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, 1891, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with well-written Biographical Notices of leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1891 should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Prospectuses free.

ELECTRICAL BOOKS AND PUBLICATIONS

All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad*

"THE ELECTRICIAN" *Series at present consists of—*

THE ALTERNATE CURRENT TRANSFORMER IN THEORY AND PRACTICE. By Dr. J. A. FLEMING. Vol. I. Price 7s. 6d., post free.

COMPETING TELEPHONE COMPANIES.

Although never approving of the system of license under which the Telephone Companies have been working, we have always held that the arrangement had one supreme merit—it prevented competition. Competing telephone systems in one and the same town appeared to us, on many grounds, to be intolerable, and, for obvious reasons, incapable of being worked to public advantage. The mere granting of a license seems to convey a virtual, if not strictly legal, monopoly, the acceptance of a fee from one party implying that it will not be accepted from any other party for the same privilege. Probably the licensing system was accepted in the first instance on some general understanding of that kind, an understanding amounting to this, at least, that so long as the privilege was exercised in good faith, the holder need have no fear of its being interfered with Besides this, the peculiar character of the business rendered competition impossible, except in the extreme case of a licensee grossly neglecting to carry out the object for which he obtained the license. A fairly complete telephonic system cannot be invaded by a rival system without detriment to both; and as no telephone system is of much account unless it is complete—that is to say, covers all the ground, and responds to all requirements as they arise—it follows that there is no room for a second, and if allowed to begin, its operations will only serve to impair the usefulness of the system in possession without supplying its deficiencies. Add to these reasons the intense disgust provoked by the doings of one Telephone Company in the matter of overhead wires, and we feel sure that few people ever dreamed of another Company being allowed to set its foot in the streets of London.

If, however, we are to credit the Duke of MARLBOROUGH, all these confident predictions are to be knocked on the head, for it is said that a new Company, possessed of a license from the POSTMASTER-GENERAL, is about to commence business in the Metropolis, and is preparing a Bill for Parliament next Session "with the object of establishing a complete twin-wire tele-"phone service for the whole of London on the basis of a £10 "a year rental." As the consent of Parliament is not required either for a "twin-wire" service or a "£10" rental

Digitized by Google

we are led to infer that the Company will seek powers which the existing London Company does not possess. From further letters of the noble Duke we conjecture that what will be sought is the power to break up streets for the purpose of laying down underground wires. All we need say as to this is that if the old Company does not check the move by seeking similar powers for themselves, it will be their own fault if they suffer a little sharp competition. Mr. FAITHFULL BEGG, whose letter to *The Times* we printed last week, is at great pains to throw all the shortcomings of the telephone upon the Post Office; but as regards the one place where these shortcomings are most conspicuous—indeed, the only place where grievous complaints have arisen—namely, in the Metropolis, he confesses that gross mismanagement, errors of construction, want of foresight, and bad workmanship, are the cause of all the mischief. As to the overhead wires and the consequent evils of circuitous routes and disturbing currents, he dismisses the subject with the calm assertion that "powers to build subways do not exist." We do not remember that they have ever been vigorously demanded, although from the very first the United Telephone Company have been constantly urged to make provision against the time when their housetop wires would become a public nuisance and an impracticable burden to themselves. Notwithstanding these warnings, the hand-to-mouth system with which the business began was persisted in until the task of rearrangement and redistribution has become too gigantic to contemplate, and the cost of placing the wires underground too heavy to be borne. A new Company, warned by this painful example of shortsightedness, would naturally desire to have its main wires, and plenty of them, in undisturbed security underground; and we hope that the powers to do so may be obtained if only to convince Mr. BEGG that if they do not exist already it is nobody's fault but the Company whose interests he is now trying to defend against a threatened competitor.

The financial prospects of such competitor may be safely left to the two parties concerned. The figures adduced in support of the new venture by Mr. CAMPBELL SWINTON in a letter to *The Times*, which we print in another column, will give Mr. BEGG some trouble, we suspect; but there is plenty of time between now and next Session of Parliament to have the question of cost and earnings thoroughly threshed out. Long before then, probably, the Duke of MARLBOROUGH and his friends will have realised what is the extent of the task they are undertaking. It is nothing less than that of supplanting, and one may say extirpating, the enormous telephone system with which this great Metropolitan area is at present served. For nothing short of that will avail. The division of this vast region into topographical sections, as described by Mr. BENNETT in his British Association Paper last month, is undoubtedly the right thing to do, and the absence of such systematic subdivision has been a grave defect of the existing arrangement; but it should be clearly understood that not until each of these sections is complete in itself, and connected with every other section, can they be opened for business at all. Further, that customers will have to be induced to come in before any business can be done; and before customers at one end can be attracted, customers at the other end will have to be drawn in, with whom the other customers wish to speak. Twin wires and half rates are seductive baits; but they would be esteemed dear at any price if the service were limited or less comprehensive than it is at present. In short, if the new Company are prepared to embrace all London in a network of telephone wires, of superior capacity and cheaper in price; if, when this is completed—not until then—they will say to the National Telephone Company, "Stand and deliver!" and to its customers, "Come over to this shop!"—if this is what the promoters intend doing, well, they are a very courageous set of men. Falling short of this ideal, the opposition might make things rather unpleasant for the London Company; and this would no doubt please the Duke of MARLBOROUGH, who, besides being enamoured of the new system, says very unfriendly things about the old. But shareholders invest their money with the idea of earning profit, not of vexing an opponent; and we suppose that the noble Duke is not alone going to finance this twin-wire, underground, ten-pound, London telephone system.

In all seriousness, we should very much like to learn on what conditions the POSTMASTER-GENERAL was induced in 1884 to admit a competing Company within the Metropolitan limits. So just and reasonable a man would never have taken such a step without great provocation, or the strongest conviction that this was the only way open to him of bringing the telephone system into something like order and efficiency, and within the reach of everybody fairly entitled to use it. From a further letter of the Duke of MARLBOROUGH, which we print this week, it seems that the New Company's license is an "All England" one; but that it was pointedly aimed at the capital City. If that is the case it may have been thought even then that the old Company had had a long enough innings, and ample time to provide against contingent competition. But be this as it may, the course which would have been preferred by the public was that of a frank and direct opposition directed by the Post Office itself, on the justifiable plea that as the license was not exercised to the satisfaction of the Metropolitan public, the Government would perform the work itself, giving the old Company the choice of severe competition, or sale at a fair price. The moment has passed, we fear, for this; but surely it is not too late to avert a species of competition which cannot fail to be disastrous to all the interests concerned. The plan of Mr. BENNETT, the devices of Mr. MANN, and the aspirations of the Duke of MARLBOROUGH are all excellent things in themselves, and we hope to see them introduced successfully even into London; but it is very late in the day to start these reforms, and those who are responsible for neglecting them so long should at any rate save us from the chaotic consequences of any ill-advised or precipitate introduction of them now.

OBITUARY.

LOUIS JOHN CROSSLEY.

We have to record with great regret the death of Mr. Louis John Crossley, which occurred at Halifax on August 30th. Although one of the earliest members of the Society of Telegraph Engineers, fellow of the Royal Meteorological Society, an inventor of very considerable success, and regarded in the North as a high authority on electrical and mechanical engineering, yet, on account of his retiring disposition and modesty, he was seldom to be seen in scientific gatherings other than those which he so ably assisted in his own town and the neighbourhood. Mr. Crossley was the only son of the late Mr. John Crossley, of Manor Heath, Halifax, and grandson of the founder of the enormous carpet-making industry at the Dean Clough Mills, the largest carpet works in the world. Born in 1842 he began to work at Dean Clough at the age of 17, and acquired an intimate knowledge of textile machinery engines, and the use of steam. He soon became thoroughly acquainted with the construction of engines and boilers, and ultimately this department came under his personal supervision. From time to time he introduced improvements, was ever on the alert for inventions; and there is no doubt that the excellent character of the machinery for

Digitized by Google

which Dean Clough has been famous for many years has been largely due to the skill and judgment displayed by Mr. Crossley.

His early acquaintance with electrical science is proved by his having delivered, at the age of 18, a lecture on the electric telegraph, when he showed a number of experiments, messages being sent to the works and offices, a time ball, and electric light from a battery being exhibited. The development of this early and practical acquaintance with telegraphy is to be found to-day in the very complete equipment of the Dean Clough Mills, where there are about 110 telephone and telegraph circuits and a well-fitted exchange, to which private wires from the post-office and neighbouring towns are connected. A feature in the entrance hall of his house at Moorside was a complete set of telegraph apparatus, and a telephone exchange in connection with Dean Clough Mills and the local company. He took a keen interest in meteorology, and expressed a hope that it might soon become one of the exact sciences. One of his earliest inventions was the Crossley Recording Anemometer, and the last time we saw him, during the distressing mental illness which commenced five years ago, he seemed to go back with more pleasure to the numerous meteorological instruments which were conspicuous in his garden, on the roof, and connected to the elaborate recording instrument in the hall, than to his electrical laboratory and workshop. Had it not been for the numerous duties which he undertook, and under the burden of which he broke down, he might have made the Moorside Laboratory famous as the scene of valuable research, for it was fitted with nearly every appliance that could be desired for electrical measurement, and was supplemented by a chemical laboratory, a well-furnished workshop, engine-room, dynamos, motors, and a battery-room. On the roof is a search light, provided with graduated circles; and, close at hand, a table with the bearings of numerous houses in the neighbourhood, taken during the day by a theodolite, and thus he used to turn the beam into the windows of his friends' houses at night. In his garden was laid a miniature electric tramway, worked by the dynamo in his house. It was on this line that Mr. Holroyd Smith made his first experiments in electric traction.

In 1864 he was busy with telegraphy and patented a telegraph insulator, and in the following year, in conjunction with M. Breguet, he patented an improved form of A B C telegraph, of which many thousands were sold.

Mr. Crossley exhibited the electric light in Halifax in 1875, borrowing the large Gramme machine which had been used for showing the signal light on the Clock Tower at Westminster, and shortly afterwards built a dynamo for lighting his works. A 6-light Brush was added, and in 1878 a Siemens machine, and when modern dynamo making was emerging from the old rule-of-thumb work, he took an eager interest in every improvement, and spent great pains in perfecting the electric lighting at Dean Clough Mills, his own house, and the Lancashire and Yorkshire Railway station at Manchester.

"The announcement of Prof. Graham Bell's invention of the telephone," says the *Halifax Courier*, "took everyone by surprise. Mr. Crossley, always on the alert, secured the first telephone that came to this country, and had it fixed to the wires existing at Dean Clough in place of the Crossley-Breguet instruments which were then in use. As in the case of the other inventions and discoveries, he was early at work lecturing in Halifax, Brighouse, Huddersfield, and other places, explaining and illustrating this latest development of electrical science. Finding that the telephone lacked that efficiency which was required to make it useful for commercial purposes, Mr. Crossley set himself to improve it, and ultimately brought out and patented the 'Crossley Transmitter,' by means of which the message delivered was more audibly carried to its destination. One remembers well the early stages in this development, how experiments were made in Square Church and other places, and the delight one experienced on a certain Sunday evening when, going over to Bradford, one heard there the sonorous tones of Dr. Mellor announcing the hymns and preaching in his own church, eight miles away; and when, also, the singing of the congregation could be heard with equal distinctness. The invention proved very remunerative. It was so completely satisfactory that the United Telephone Company, who held the Bell, Edison, and other leading patents, made overtures to Mr. Crossley, and ultimately gave him £20,000 for his patent."

Besides inventions connected with spinning, oiling, and carding wool, printing blocks, &c., he invented an electric engine indicator, and was associated in the invention of a system of train lighting and dynamo brush holders. His most widespread invention is the enamelled water-gauge glass for boilers, and a curious outcome of this is a glow lamp, with a bulb blown from this kind of glass, one side being opal, the other clear. The effect is extremely good, but the state of lamp patents has prevented its popular use. A man of unusual energy and capable of concentrating himself thoroughly on one thing at a time, his early death was due to incessant work, much of it being of a voluntary character. He was, at the same time, Justice of the Peace both for the county and the borough, a director of the Lancashire and Yorkshire Railway, President of the Halifax Literary and Philosophical Society, member of the Chamber of Commerce, officer of more than one political association, Colonel of the 2nd West York Volunteers, director of the huge Dean Clough Works, and president and founder of its Choral Society. He was a skilful organist, and had a good knowledge of organ construction, and often fulfilled the duties of organist at his church.

Until five years ago he had, to all appearance, a long life before him, but one after another of his public duties was given up. He went round the world in the hope that the sea voyage would restore him, particularly as he was an ardent yachtsman. His death was quiet, and occurred after an attack which left him unconscious. His loss is keenly felt in West Yorkshire, where he was esteemed as a most genial and sympathetic man, approachable by everybody, and known by all his workpeople as "Louis John." He was wont to declare himself to be only an amateur in science and engineering, and regarded these studies as a hobby; but he has left his mark in the North, as much for his scientific work as for his other pursuits. He leaves eight children, one of whom is studying engineering.

THE DETERMINATION OF CURRENTS IN ABSOLUTE ELECTRO-MAGNETIC MEASURE.

BY G. F. C. SEARLE, M.A.

§1. In this series of articles it is proposed to give an account of some determinations of the quantitative chemical effects produced when an electric current flows through an electrolyte. This subject is of interest at the present time, owing to the action of the Board of Trade Committee in this matter. The Committee has agreed to the following resolution: "That an unvarying current which, when passed through a solution of nitrate of silver in water, in accordance with the specification* attached to this report, deposits silver at the rate of 0·001118 of a gramme per second may be taken as a current of one ampere." One of the most important researches on the subject of the relation of the ampere to the amount of silver which it deposits per second is that of Lord Rayleigh and Mrs. H. Sidgwick on the Electro chemical Equivalent of Silver (*Phil. Trans.*, Royal Soc., 1884, p. 411), and it is to this research that we shall chiefly confine our attention. The methods of determining the amount of silver deposited are easily understood, but it is much more difficult to obtain a clear idea of the methods and principles employed in the determination of the current in terms of the fundamental units of length, mass, and time; and, consequently, in the minds of many people this part of the subject is surrounded by a good deal of difficulty. In the hope of making the subject of the measurement of currents in absolute electro-magnetic measure a little clearer, some preliminary consideration, from an elementary point of view, will be given to some of those dynamical properties of an electric current upon which the measurements are made to depend.

§2. First, as to the system of fundamental units employed. These are the Centimetre, the Gramme, and the Second. In all strictly scientific work, the "Centimetre" is taken to be the one-hundredth part of the distance at 0°C., between two marks

* See *The Electrician*, July 24, 1891 p. 325.

Digitized by Google

engraved on a platinum bar preserved at Paris and known as the "Mètre des Archives." The "Gramme" is taken to be the one-thousandth part of the mass of a piece of platinum preserved at Paris and known as the "Kilogramme des Archives." The "Second" is the mean solar second. This depends upon the rate of rotation of the earth upon its own axis and upon its rate of rotation round the sun. Both of these rates are being altered very slowly by the action of tidal friction, but the change is too small to be detected. For the present the earth will have to continue to be our timekeeper, since we have not yet been able to make a practical clock out of a vibrating sodium molecule whose period of vibration we might suppose would remain absolutely unchanged. The Board of Trade Committee is considering the resolution:—"That by the terms centimetre and gramme are meant the standards of those denominations deposited with the Board of Trade" (*The Electrician*, Feb. 13, 1891). The Board of Trade standards are, of course, known very accurately with reference to the Paris standards, and for all commercial purposes no fault can be found with the resolution. But it must be remembered that the knowledge of the values of the Board of Trade standards in terms of the Paris standards is derived from experiment, and is therefore affected by the inevitable errors of experiment. And it does seem to be a great pity, from a scientific point of view, to have two standards of both length and mass. Thus, on the one hand, we shall have the "Board of Trade centimetre" and the "Board of Trade gramme," and on the other, the "Mètre des Archives" and the "Kilogramme des Archives." It is, however, only in work of the very highest accuracy that it will be necessary to specify to which pair of standards the measurements are referred.

§ 3. Having now settled our fundamental units we proceed to deal with the derived units. We elect to work upon a system of derived units which introduces the smallest possible number of numerical factors into our equations, and, having made this decision, we have no longer a free choice in the matter of the derived units. Thus, a force might be measured in terms of some arbitary unit, such as the force required to produce a definite extension of a Board of Trade standard spring balance, or the force exerted by the earth upon some standard lump of matter at some standard locality. Experiments on dynamics would then show us that we could write down the important relation $P = k m f$, where P is the force, measured in "Board of Trade units," which, acting on a body whose mass is m grammes, produces in it an acceleration of f centimetres per second per second, and k is a numerical factor depending upon the Board of Trade unit of force and only discoverable by experiment. If the equation is to be made as simple as possible, the Board of Trade unit of force must be abandoned, and the unit of force must be defined in the following way: "The unit of force, the Dyne, is that force which, acting upon a mass of one gramme, produces in it per second a velocity in its own direction of one centimetre per second." By experiments with pendulums, the weight of a gramme at any given spot may be calculated in dynes. It is found to be *about* 981 dynes. On account of the variation of gravity, if the results are to be of greater accuracy than ·5 per cent., the locality at which the determination is made must be specified. The unit of work is the Erg, and is the work done when a dyne displaces its "point of application" through one centimetre in the direction of the force.

§ 4 The above example illustrates the manner in which the choice of electric and magnetic units is limited. We shall now go on to develop the electro-magnetic system of units, always keeping before us the principle that the units are to be so chosen that the equations of the subject may be as simple as possible.

Unit Magnetic Pole.—It is found that two magnetic poles of the same signs and of strengths m and m', measured in terms of some standard pole, when placed at a distance r centimetres apart, repel one another with a force $\alpha \frac{m m'}{r^2}$ dynes, when α is a numerical factor depending upon our choice of standard pole. If we wish to make $\alpha = 1$, and so simplify the equation as much as possible, we must define a unit pole in the following way: "A unit magnetic pole is such that when placed at a distance of one centimetre from an equal and similar pole it repels the second pole with a force of one dyne." By a north* pole we mean the pole which points to the north, and we consider this as the positive pole. It is, of course, impossible to make experiments with isolated magnetic poles, since every magnet has two equal and opposite poles; but the experiments of Gauss upon *magnets* proved that they behaved as if the forces between their poles obeyed the law stated above.

§ 5. **Magnetic Moment.**—When we deal with a magnet as a whole, it is often sufficient to know the product of the strength of either pole and the length of the magnet. This product is called the magnetic moment of the magnet, and completely defines the magnitude of its action at any point whose distance from the magnet is great compared with the length of the magnet when we know the angle between the magnet and the line from its centre to the distant point. Thus the action at distant points and also, as we shall see below, the couple

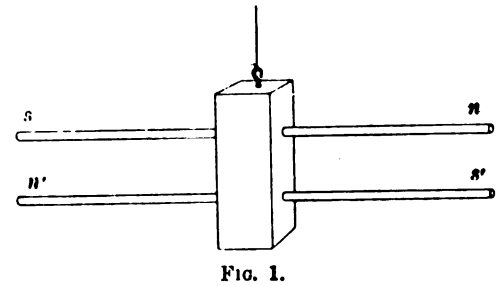

Fig. 1.

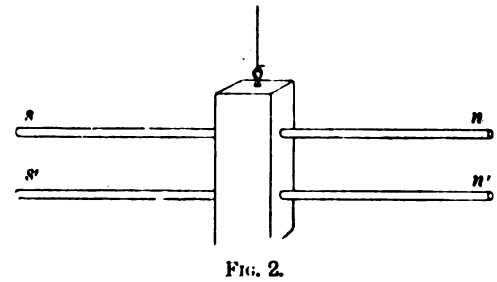

Fig. 2.

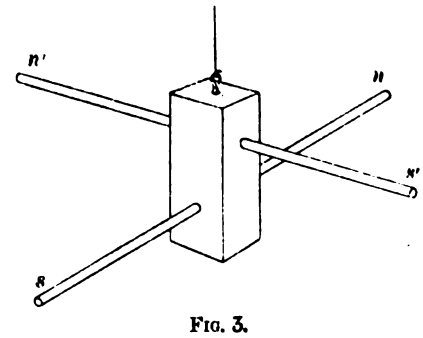

Fig. 3.

experienced by the magnet when placed in a uniform magnetic field, is completely known when we know both the numerical magnitude of the magnetic moment of the magnet and also the direction of the axis of the magnet, *i.e.*, the direction of the magnetic moment. Thus we are led to see that the magnetic moment of a magnet is a vector quantity, and we are then at liberty to apply all the laws of resolving and compounding just as we do to forces in the study of statics. The direction of the magnetic moment is the direction from the south to the north pole of the magnet. The method of resolving magnetic moments is often most useful in attacking problems on the action of small magnets. The following experiment, devised by the writer for the class at the Cavendish Laboratory, affords an example of the composition of magnetic moments. A small block suspended by a fine fibre supports two small magnets, $n s$, $n' s'$. Holes are bored in the block so that the magnets can be placed either parallel, as in Figs. 1 and 2, or at right angles to each other, as in Fig. 3.

* Sir William Thomson, following Dr. Gilbert of Colchester, would call this a true south pole, it being of the same sign as that magnetic pole of the earth which is situates in the Antarctic regions.

Digitized by Google

Each magnet is made of a half knitting needle. The moment of inertia of the system about the axis of suspension, of course, remains the same in all three cases. Let H be the horizontal strength of the earth's magnetic field, m, m' the magnetic moments of the two magnets and M_1, M_2, M_3, T_1, T_2, T_3 the resultant magnetic moments, and the times of vibration in the three cases. Then it follows at once by the parallelogram law that $M_1 = m - m'$ $M_2 = m + m'$ $M_3 = \sqrt{m^2 + m'^2}$.

Let K be the moment of inertia of the system, then, as we shall explain later, the times of swing will be given by

$$T_1 = 2\pi\sqrt{\frac{K}{M_1 H}} \quad T_2 = 2\pi\sqrt{\frac{K}{M_2 H}} \quad T_3 = 2\pi\sqrt{\frac{K}{M_3 H}},$$

whence, $$\frac{M_2}{M_1} = \frac{T_1^2}{T_2^2},$$

and therefore, $$\frac{m}{m'} = \frac{T_1^2 + T_2^2}{T_1^2 - T_2^2}.$$

Now, in case (3), the resultant magnetic moment must be along the magnetic meridian when the system is at rest. Mark upon a sheet of paper, placed close beneath

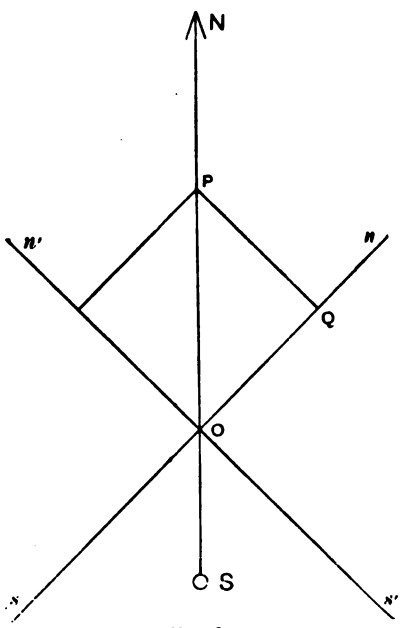

Fig. 4.

the system, the direction of the meridian N S and of the magnets in case (3). Draw P Q (Fig. 4) perpendicular to n s, then if the parallelogram law holds good, $\frac{OQ}{QP} = \frac{m}{m'}$, and therefore, $\frac{OQ}{QP} = \frac{T_1^2 + T_2^2}{T_1^2 - T_2^2}$. Experiment shows that this relation is fulfilled, and that the parallelogram law gives the correct *direction* for the resultant magnetic moment. By observing the value of T_3, we can test the correctness of the *magnitude* of the resultant given by the parallelogram law. For by this law $M_3^2 = m^2 + m'^2$, and, therefore, $2M_3 = 2(m^2 + m'^2) = (m + m')^2 + (m - m')^2 = M_1^2 + M_2^2$,

whence, $$\frac{2}{T_3^4} = \frac{1}{T_1^4} + \frac{1}{T_2^4}.$$

Experiment shows that this relation also is fulfilled, and, therefore, that the parallelogram law gives the correct magnitude for the resultant magnetic moment. We have shown that the magnetic moment of a magnet is a vector quantity, and, accordingly, if we find it useful to do so, shall not hesitate to apply the parallelogram law.

§ 6. **Magnetic Field.**—Any region of space at any point of which a magnetic pole experiences any force (depending upon its being a magnetic pole) is called a magnetic field. The strength of a magnetic field, or the magnetic force at any point, is measured by the mechanical force in dynes which a unit north pole experiences when placed at the point under consideration. The direction of the magnetic field is the direction of the force experienced by the pole. We see that the strength of a magnetic field is a vector. If H is the strength of the field and m the strength of a pole, then the force experienced by the pole is m H dynes. Hence the strength of the field or the magnetic force at a distance r from a pole of strength m is $\frac{m}{r^2}$, for the force experienced by a unit pole at that distance is $\frac{m \times 1}{r_2}$ dynes. The direction of the magnetic force is along the radius drawn from m.

We will now find the couple experienced by a magnet when placed in a uniform magnetic field. Let H be the strength of the field, M the magnetic moment of the magnet, m the strength of each pole, $2l$ the length of the magnet, θ the angle between the direction of H and the direction of M. Each pole experiences a force m H dynes in a direction parallel to that of H. The two forces acting in opposite directions produce a couple whose moment is m H × (perpendicular distance between the two forces), or m H·$2l$ sin θ. But $2ml = M$ by the definition of magnetic moment, and, therefore, the couple = M H sin θ. The axis about which the couple acts is at right angles both to the axis of the magnet and to the direction of the magnetic field.

Note.—The axis of a couple is always to be drawn in such a direction that the direction of the axis and the direction of the rotation which the couple tends to produce are related in the same way as the motion of translation and the rotation of a right-handed screw when working in a fixed nut.

In the present case, since the magnetic force and the axis of the magnet are both in the plane of the paper, the direction of the axis of the couple is outwards from the paper.

If M is placed at right angles to H then the couple becomes simply M H. Thus we can measure the strength of the field at

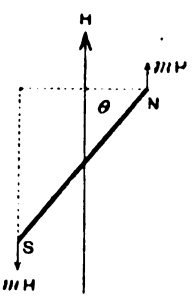

Fig. 5.

any point by the maximum couple which a small magnet of unit magnetic moment experiences when placed at the point. This is a more *real* method than that of finding the force acting on an isolated unit pole. Again, if the angle between M and H is very small we may write θ in place of sin θ, and then the couple = M H θ. Let K be the moment of inertia of the magnet, then the angular acceleration which this couple produces in the magnet is $= -\frac{M H \theta}{K}$ in the direction in which θ increases. By the principles of simple harmonic motion we see that the magnet will vibrate and that the time of swing will be $T = 2\pi\sqrt{\frac{M H}{K}}$. This expression enables us to find M when we know H, and *vice versa*.

§ 7. **Lines of Force.**—The conception of lines of force is due mainly to Faraday, and is of very great assistance to us in aiding us to form mental pictures of electro-dynamic phenomena. Taking any point of the magnetic field as a starting point, draw a curve such that at each point of the curve the magnetic force is in the direction of the tangent to the curve. This curve is called a line of force. A small magnet free to turn always places itself along the direction of the magnetic force, and, therefore, if placed with its centre at any point of the field will indicate the direction of the tangent of the line of force through that point. Iron filings serve the same purpose, since they become

Digitized by Google

magnetised in the direction of their length and then place themselves along the lines of force. Valuable information as to the state of the magnetic field can often be obtained by the use of iron filings. If we draw a large number of lines of force in the field we can employ them to indicate not only the direction but also the strength of the magnetic field at each point. In order to show how the lines, when properly drawn, can indicate the strength of the field we must employ an important proposition due to Prof. Sir G. G. Stokes. We shall have to make use of solid angles here, and also later on when we deal with electric currents, so that a definition of a solid angle is necessary.

§ 8. **Solid Angles.**—The solid angle subtended by any surface at a given point is measured in the following manner:—Let a radius from the given point travel round the boundary of the surface. Describe about the given point a sphere of one centimetre radius. As the moving line travels round the boundary of the surface it will trace out a curve on the surface of the sphere. The area of this curve in square centimetres is the measure of the solid angle subtended by the surface. If the point is completely surrounded by the surface the solid angle is the same as that subtended by the surface of a sphere at its centre. Since the surface of a sphere of radius r centimetres is $4\pi r^2$ square cm., the surface of a sphere of one centimetre radius is 4π square cm. Accordingly 4π is the measure of the solid angle subtended by any closed surface at any point within it. It might be thought that the solid angle in this case would be zero, but one can easily see that this is not the case by considering the growth of the surface from a very small patch up to the surface completely surrounding the point. The solid angle subtended by an infinite plane at any point near it is clearly the same as that subtended by a hemisphere at its centre, *i.e.*, 2π.

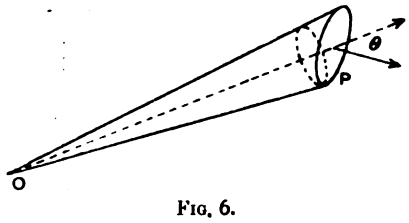

Fig. 6.

If the point is *outside* the closed surface, then, by considering the change in the solid angle as the surface grows from a small patch into the complete closed surface, we see that the solid angle must be considered zero.

We will now find the solid angle subtended by a small plane area at any point. Let O (Fig. 6) be the point, P the small surface whose area is a, and let $OP = r$. Let a radius from O go round the boundary of P, thus describing a slender cone whose solid angle is ω. Let the normal to P make an angle θ with the radius O P. Through P draw a section of the cone at right angles to O P; the area of this section is $a \cos\theta$ since the angle of the cone is exceedingly small. But the surfaces of spheres included in equal solid angles are as the squares of their radii. Hence the area on the sphere centre O and radius 1 centimetre is $\frac{a\cos\theta}{r^2}$ square cm. Accordingly, $\frac{a\cos\theta}{r^2}$ is the solid angle subtended by the area a at O.

(To be continued.)

SAFETY MINING CABLE.

The use of properly protected electric motors has become now a recognised means of transmitting power even in fiery mines; but many colliery managers still object to the introduction of electricity into their collieries owing to the possibility that exists that the cable may be broken by falls of roof or stone, or by the tubs leaving the rails and tearing down the cable, and thus setting fire to the timbers or firing the pit. With a view to removing altogether this danger, Messrs. W. T. Goolden, Woodfield Works, Harrow-road, who for some years have made electric machinery a speciality, are introducing a "safety mining cable" invented by Mr. Ll. B. Atkinson.

The diagrams and figures with the following explanation show the principles on which the cable is constructed. In Fig. 1, A A are the two poles, say, of the generating dynamo, and B B are the two poles of the motor or lamps. These are connected each by two wires, a main conductor, L, and a sub-

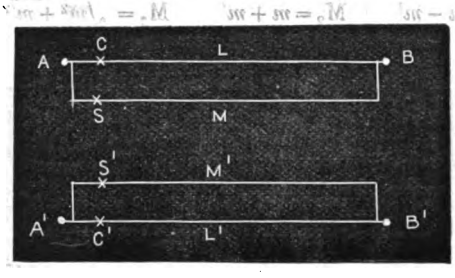

Fig. 1.

sidiary conductor, M. These wires will, of course, carry current simply in proportion to their areas, being of the same length. In each main and each subsidiary conductor are arranged cut-outs proportioned to the carrying capacity of each wire. Suppose the main conductor, L, be broken, provided that the subsidiary conductor, M, is not broken, no spark will result at breaking, as the circuit is still closed; but the whole current

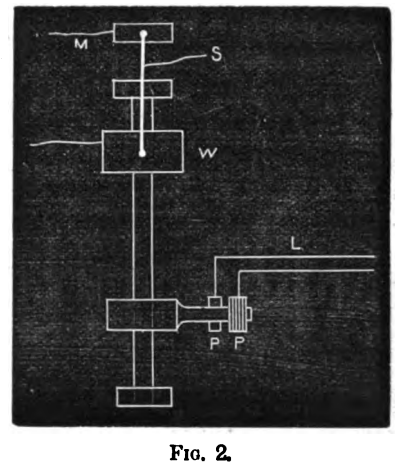

Fig. 2.

now traverses the subsidiary conductor, and the fuse at once melts. This fuse allows a weight to fall (*see* Fig. 2), where W is the weight and P P the switch, and thus instantly disconnects the whole circuit.

The practical form of cable to carry this into effect is shown at Fig. 3. A close-wound spiral of tinned copper wire, several wires being for preference arranged in parallel, is braided over,

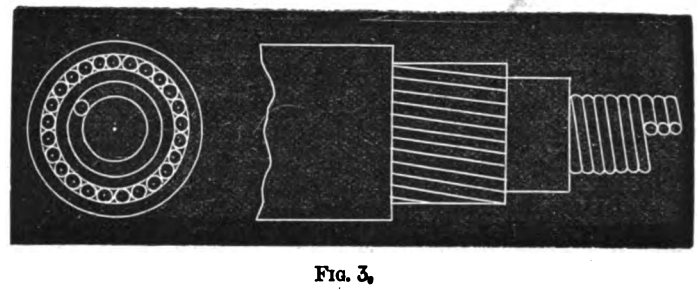

Fig. 3.

but not heavily insulated. Over this is laid a stranded conductor of the required area, and this in turn properly insulated in the usual manner. If the cable is torn down from the roof, or broken in any way in tension, this inner conductor extends to an indefinite extent, for as it gets drawn out the diameter of the spiral decreases, and hence it becomes quite loose in its tube. The outer conductor being broken, the spiral conductor carries the whole current for an instant till the fuse breaks,

Digitized by Google

when the whole conductor is disconnected from the supply. Fig. 4 shows the cable thus broken and extended.

It sometimes, however, happens that a cable may be cut in two by a falling rock, or even by a sharp instrument like a knife or axe. By a small addition to the arrangements already provided, this also leads to an instant disconnection of the circuit before it finally breaks, and hence without spark at the point of rupture. Fig. 5 is arranged similar to Fig. 1, except that at the further end of the cable from the generator is a resistance, R, in the circuit of the subsidiary conductor. The effect of this

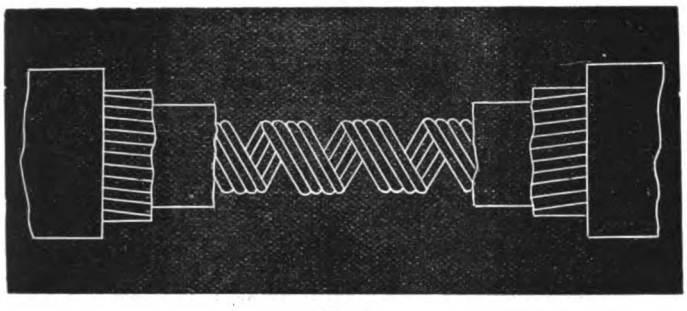

Fig. 4.

is that the ends of the cable being at the same potential, the fall of potential along the subsidiary conductor is less than along the main conductor, and that, therefore, a difference of potential exists between them. If, therefore, the cable is crushed by falling stone—or if the cable be cut by a metallic instrument effecting the same result—while the inner and outer conductors are in contact, there is an immediate increase of current in the subsidiary conductor, thus melting its fuse and disconnecting the cable as before. This cable, therefore, really acts by transferring the electrical rupture of the cable to some point, such as the switch-board at the top of the pit where it is unimportant, thus making its use safe under all circumstances.

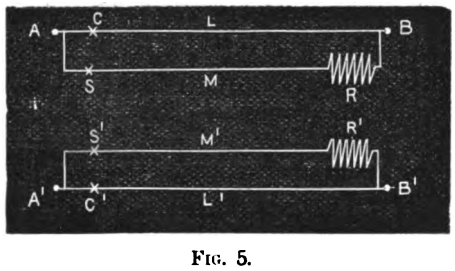

Fig. 5.

Apart from colliery work, the use of this cable would be desirable for overhead high-tension wires, as, if broken, the broken ends would not be left in the road with the current on, and thus would not be left a source of danger to persons and animals in the street.

INSTRUMENT MAKING FOR STUDENTS.—IV.

THE MIRROR GALVANOMETER.

There is, perhaps, no electrical instrument so useful, so delicate, and so accurate, as a good mirror galvanometer. It may be less convenient than other kinds as regards portability, but when once properly set up in a good position it can be used for a great variety of tests. The instrument now to be described, though, perhaps, not too beautiful from an instrument maker's point of view, is easily made, and is capable of a very fair degree of sensitiveness.

The instrument is built upon an L-shaped support of wood *a a'* (Figs. 1 & 2), mahogany being the best wood to use. The upright piece is 5¼in. high, and the horizontal base is 5in. long; both pieces are 4in. wide and ¾in. in thickness. The two pieces are held together by 2in. No. 10 round-headed brass screws *b b*, the heads of these screws and of a shorter screw, *b'*, of the same size form the legs on which the instrument rests, levelling screws being unnecessary. In the middle of the upright part of the stand there is a taper hole, 1¼in. in diameter at the front of the instrument, and $1\frac{5}{16}$in. at its small end. The centre of this hole should be 2⅛in. from the top. This taper hole is closed at the small end by a pane of glass, 1¼in. square, which is let in flush with the surface of the stand. A piece of thin brass tube, *d*, 1in. diameter outside and $2\frac{1}{16}$in. long, is mounted on a brass plate, *e e*, being fitted and soldered into a hole cut therein. The dimensions of the brass plate are $2\frac{1}{2} \times 1\frac{1}{2} \times \frac{1}{16}$; it is screwed on to the upright by means of the screws *f*, and coincides with the taper hole. This brass plate serves to keep the glass plate, *c*, in position. The screws, *f*, should be ½in. No. 8 countersunk brass screws. A second brass tube, *g*,

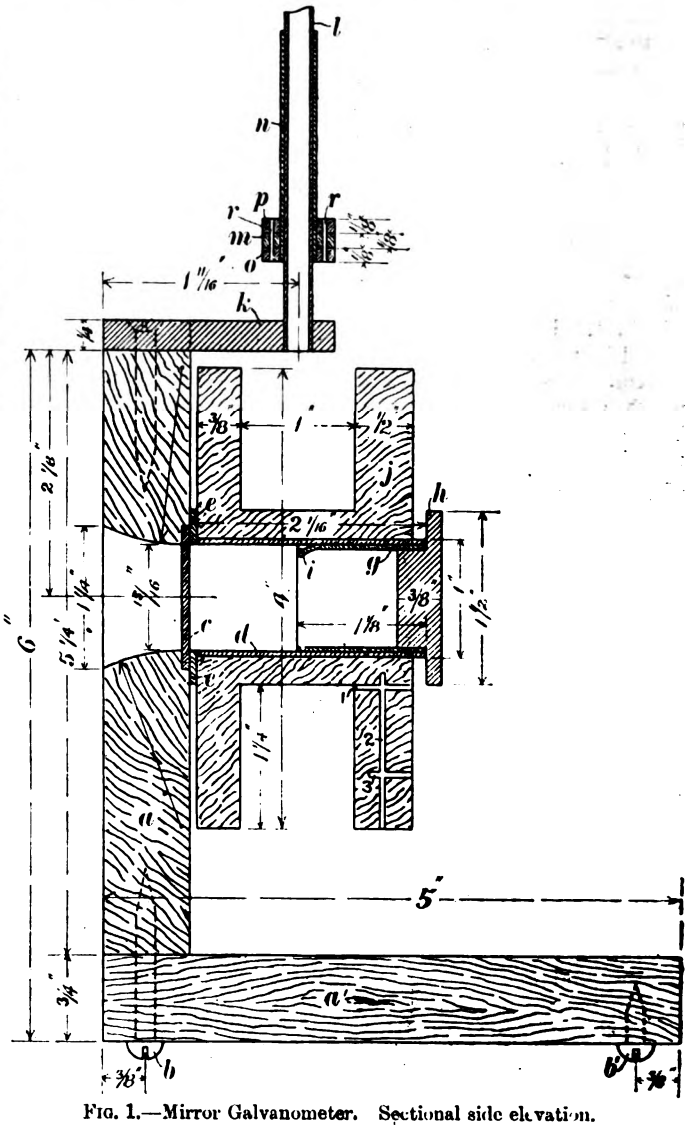

Fig. 1.—Mirror Galvanometer. Sectional side elevation.

slides smoothly (but not loosely) into *d*. It is 1⅛in. long, and one end is filled up by the brass plug *h*, which is soldered into it. This plug has a flange which should be milled. On the inner edge of the tube *g* are two saw cuts, ⅜in. deep and about $\frac{1}{16}$in. apart; the brass tongue formed between them is bent slightly inwards, as shown at *i*. The needle system is suspended from this tongue.

The bobbin, *j*, on which the coils are wound, is made of box wood, and is 4in. in diameter, and slides over the tube *d*; the front or inner flange is ⅜in. wide; the back flange, on which the terminals are fixed, is ½in. wide; and the space between, in which the wire is wound, is 1in. wide and 1¼in. deep. If the coil is to be of fine wire, the first layer should be of No. 22 S.W.G., the outer end of which is passed through the wood of the bobbin to the terminal, as follows:—First make a hook at the end of a piece of fine steel wire, and push it down to the bottom of hole No. 1 (Fig. 1) in the thick flange of *j*, then pass about 3in. of the No. 22 wire through hole No. 1, and pull

Digitized by Google

it (by means of the steel wire hook) through hole 2 as far as the edge of the flange. Then (by means of the hook) again pull it through hole No. 3, which should be drilled close to the screw of the terminal. The outer end of the coil should be passed through a hole drilled close to the screw of the other terminal. These terminals are of the same sort as those on the two instruments last described (see *The Electrician*, June 26th, July 31st). They are tapped into the boxwood, and clamped by screwing down the lower nut on the outside. The screws should not, of course, pass quite through the wood. It will be seen that the instrument may have any number of coils of different resistances, &c., as long as the dimensions of the bobbin are as shown in the drawing.

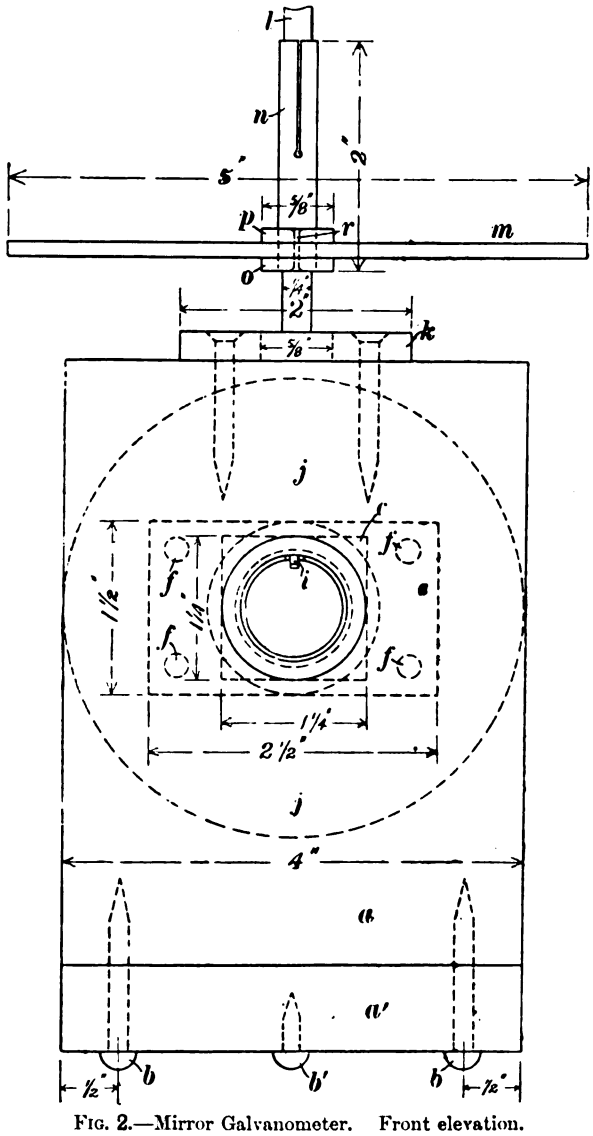

FIG. 2.—Mirror Galvanometer. Front elevation.

A T-shaped piece of brass, *k*, is screwed to the top of the upright, and at the end of the shank, with its centre exactly over the centre of the coil, is a hole into which a piece of brass tube, *l*, 7in. long and ¼in. in diameter, is soldered. This supports the directing magnet, *m*, which is mounted on a piece of tube, *n*, 2in. long, and of sufficiently large bore to slide easily upon *l*. Two brass washers, *o* and *p*, are ⅛in. thick and ⅝in. in diameter. The lower one, *o*, is soldered to the tube, *n*, and the magnet, *m*, and the upper washer, *p*, are slipped on, and the two washers and the magnet are fixed together by means of the rivets, *r*. The tube, *n* should have a narrow saw-cut an inch or so long on opposite sides of it, so that its ends may be slightly closed up, and thus grip the tube *l* in at any point in its length. Fig. 3 shows the needle system, which consists of a thin disc of mica or paper, *s*, having a diameter about $\frac{1}{32}$in. less than the inner bore of the tube *g*. From one edge a slot is cut to the centre, about ⅛in. wide, a short tongue, *t*, being left at the end of this slot, to which the suspending fibre is fastened. A small mirror, *u*, of silvered microscope glass is cemented on to one side of the mica disc, and on the other four bits of hardened and magnetised watch spring, about ¼in. long and $\frac{1}{16}$in. wide, are fastened, The corners of the mica disc must be cut

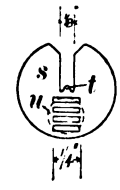

FIG. 3.—Mirror Galvanometer. Needle system.

away to allow the disc to swing freely past the tongue from which it is hung. One end of the suspending fibre is fastened to the tongue *t*, by means of sealing wax or shellac, and the other end is similarly fastened to the tongue *i* (Figs. 1 and 2)

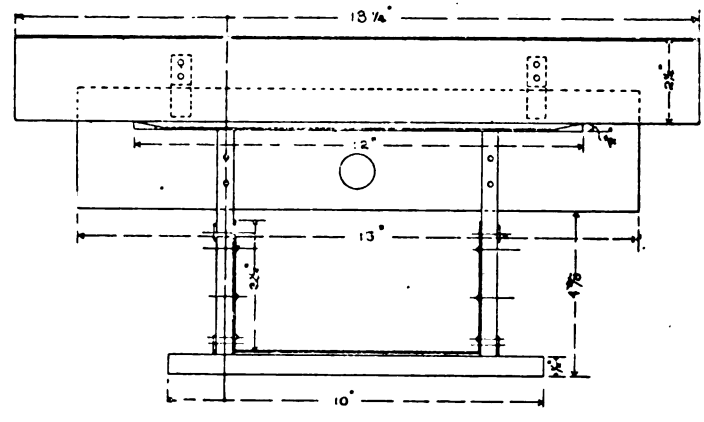

FIG. 4.—Mirror Galvanometer. Lampstand and Scale. Front elevation.

in such a manner that when the tube is held level, *i* being at the top of the vertical diameter, the disc *s* hangs exactly at its centre, and swings freely. The coil may then be placed on *d*, as shewn, and the tube *g* slid into position, the only

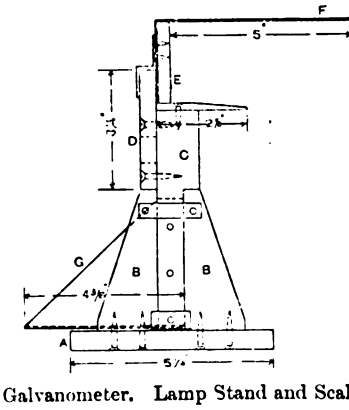

FIG. 5.—Mirror Galvanometer. Lamp Stand and Scale. End elevation.

levelling necessary being the turning of *g* round its axis until the needle system swings freely. Figs. 4 and 5 show respectively a front elevation, an end elevation, and a section of the lamp stand and scale.

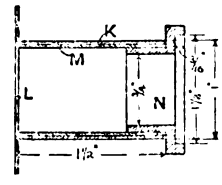

FIG. 6.—Mirror Galvanometer. Collimating Tube.

Upon a base board of mahogany A, 10in. by 5in. by 2½in., are fixed two pair of triangular uprights B B (Fig. 5), a space ¾in. wide being left between each pair in which move the two slides C C. These slides are joined at the back by the cross piece D, in the

Digitized by Google

centre of which is fixed the collimating tube (shown in Fig. 6). The scale of the instrument, which may be divided into millimetres or any other convenient division, is drawn on paper and fixed to the scale board E. A tin screen F is fixed to the back of this scale board and extends about 5in. beyond it. This extension is bent over at right angles, and serves to shade the scale from light reflected from the walls and ceiling of the room; its under side should be painted a dead black. On the back of the scale board are also two lugs of brass, by means of which it is hung on to the cross piece D. Another screen, 2½in. wide and about 1ft. long, is placed across the top of the slides and serves to cut off light reflected upwards from the table upon which the apparatus is placed. Screwed to the inside of the slides is a tin stirrup G, on which the lamp is placed (a small paraffin lamp with a wide flat wick will be found sufficient). The slides are kept in position between the triangular uprights B B by cross pieces of brass screwed to their lower ends; they are further prevented from being pulled out from between these uprights by two other cross pieces fixed to the top of the latter. The lamp and scale, &c., may be raised or lowered until the spot of light from the mirror falls on the scale; the slides should be sufficiently friction tight to remain in this position of their own accord without further clamping. The collimating tube (Fig. 6) consists of a brass tube K, 1in. outside diameter, having at one end a flange (a rectangular flange is the more easily made). The tube K passes through a hole in the cross piece D, to the back of which the flange is screwed. Another tube M slides smoothly into the first. Both tubes should be about 1½in. long. At the outer end of the tube M, is a boxwood cell N, having a hole through its centre ¾in. in diameter, this hole terminates in front in a recess 1⅛in. in diameter and $\frac{3}{16}$in. deep, to be occupied by a lens of about 5½in. focal length, this may be cemented neatly into position with black sealing-wax, a piece of fine wire is placed across the cell in front of the lens. The cell N is fixed to the tube M by means of a couple of brass wire pins.

Should any trouble be caused by the vibrations of the room in which the galvanometer is set up (a most likely thing to happen), the instrument should be placed upon a three-legged wooden stand; this stand should be weighted with a heavy lead weight, and its feet should rest not directly on the floor, but upon cushions of india rubber ½in. thick. Unnecessary light upon the scale may be avoided by painting the walls near it a dead black or covering them with black calico.

THE FRANKFORT EXHIBITION.—X.

(FROM OUR SPECIAL CORRESPONDENT.)

The firm of Kummer and Co., of Dresden, have thought it worth while to exhibit rather extensively, and their exhibit should gain them a reputation in countries outside Germany. The particular branch of electric lighting to which they devote most attention is ship lighting, and they have carried out many navy contracts. They make both engines and dynamos. We give below some illustrations of the apparatus manufactured by this firm :—

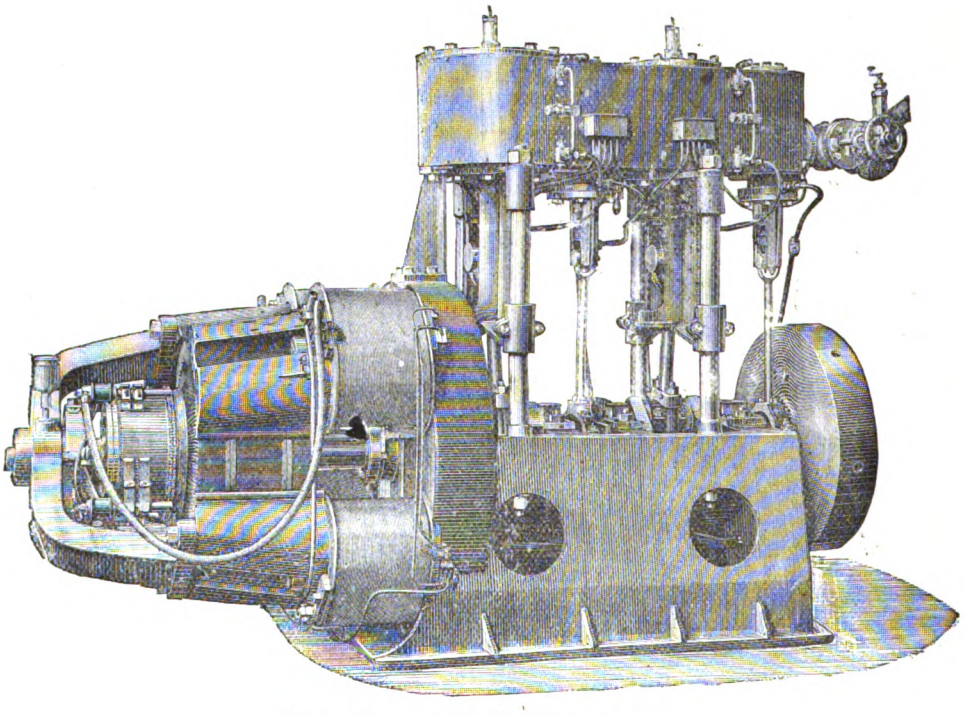

Fig. 1.—Kummer 54 H.P. Steam Dynamo.

Fig. 1 shows the largest machine they have at the Exhibition. It is intended to deliver 40 kilowatt when running at 450 revolutions, and is used chiefly for accumulator charging; it is one of the few compound machines used for this purpose at the Exhibition. The disadvantages of the dynamo seem to be its not very compact form, and the stray field which there must necessarily be when the magnets are arranged as shown. It has, however, found much favour on board ship. The magnets, and the frame supporting them, are cast in one piece with the bed plate of the engine, and the armature spindle is simply a continuation of the engine shaft. The dynamo has a good broad collector with its strips rather wide, and there is no perceptible sparking. The diameters of the high and low pressure cylinders of the compound engine used to drive the dynamo are respectively of 9½ and 15 inches. The piston stroke is a little more than 8¾ inches.

The latest type of dynamo turned out by this firm is shown in Figs. 2 and 3. It is a very compact and solidly built machine, and one likely to stand wear and tear. At a speed of 775 revolutions, one of these machines will give 13·4 kilowatts. A compound wound machine of this type is running as a motor in the Machinery Hall.

To provide for cases in which it is desired to prevent the possibility of more than one dynamo being switched on to one circuit, Messrs. Kummer and Co. manufacture a practical apparatus, of which the illustration Fig. 4 gives an idea.

Digitized by Google

It consists of a number of vertical and horizontal brass strips mounted on a stout wooden base. The three horizontal brass pieces shown in the illustration are joined up to the + poles of the three dynamos with which this particular apparatus is used in the Exhibition, while the vertical cross pieces are joined each with the positive end of one of the circuits to be fed. Both the horizontal and the vertical conductors have holes bored in them in such a way that any vertical conductor can be joined, by means of a special key, with any of the horizontal conductors. To prevent the possibility of the bar being connected with another horizontal conductor, a sliding piece is arranged on the top of it, provided with holes in such a manner that when the connecting key is once introduced to join the bar with one of the horizontal conductors all the other holes are barred.

The contact key is cylindrical at the lower and conical at the upper end. The cylindrical part is cut down the middle parallel to the axis, and a hole is bored right through the key.

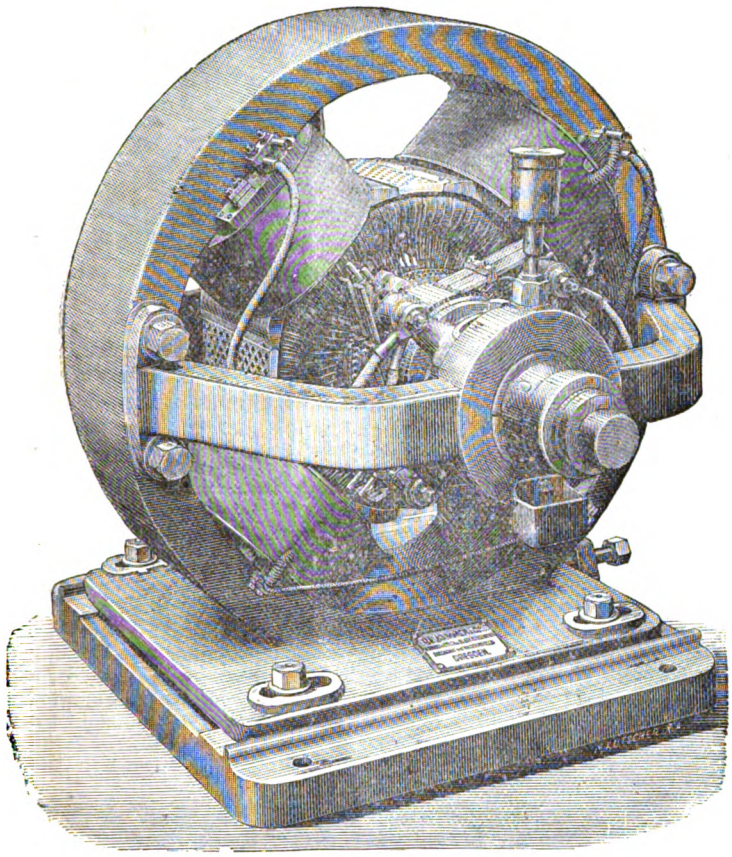

FIG. 2.—Kummer Four-Pole 19 H.P. Dynamo.

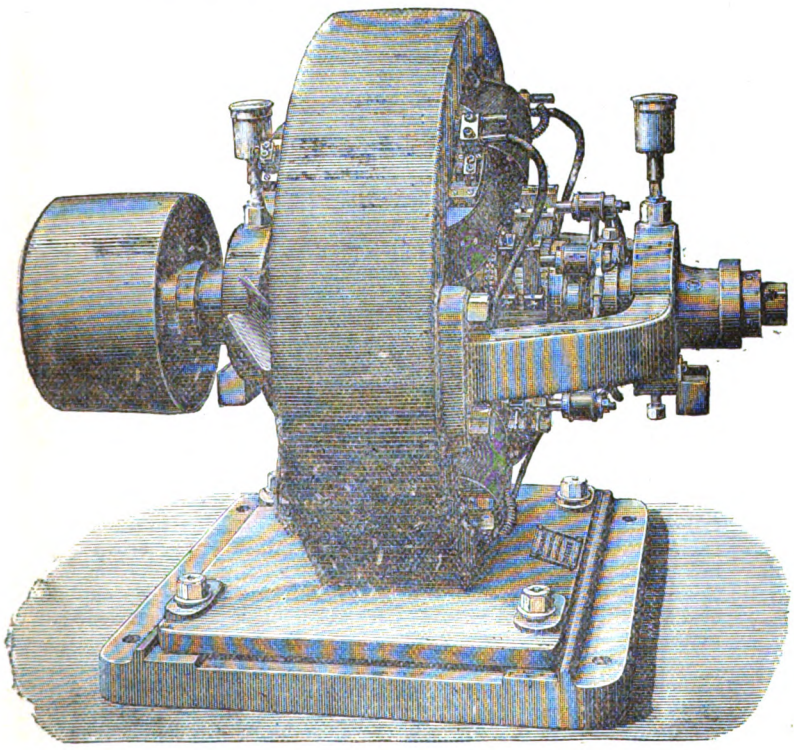

FIG. 3.—Kummer Four-Pole 19 H.P. Dynamo.

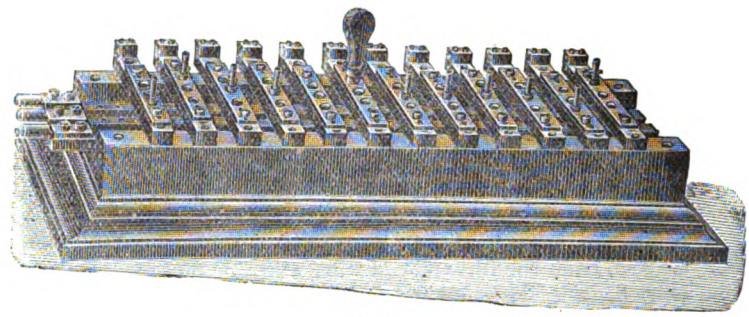

FIG. 4.

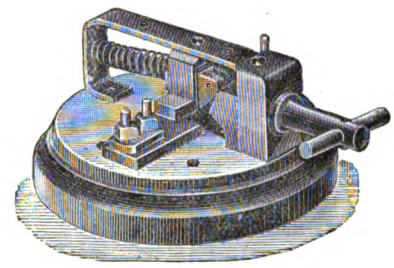

FIG. 5.

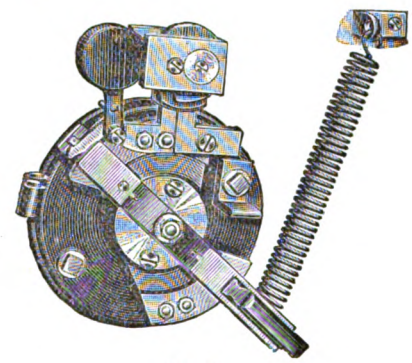

FIG. 6.

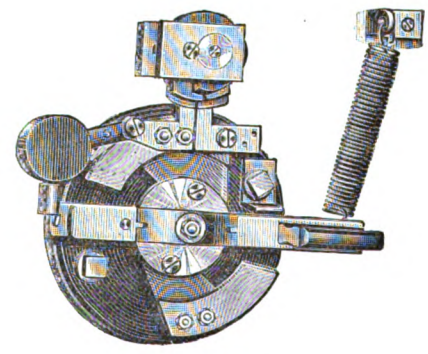

FIG. 7.

Digitized by Google

The boring runs upwards to a pointed cone, with a screw-thread cut in it, into which fits a corresponding conical screw piece, at the top of which is the key handle, which fits on as in the case of an ordinary tap with removable key. To make contact the sliding bar is lifted and the key inserted, a turn to the left makes good contact with the vertical piece, and a turn to the right screws up the interior conical screw, thus pressing out the two divided parts of the lower part of the key, and forming a good contact with the lower or horizontal conductor.

Each of the circuits is provided with an instantaneous cut-out switch, such as is shown in Fig. 5. The "make" and "brake" are very rapid.

An automatic cut-out made by Messrs. Kummer and Co. is shown in Figs. 6 and 7. The base is of cast iron, and two insulated contact pieces are arranged on opposite sides of it, the connection being made by a cross rod moveable round the pivot. As seen from the illustration, when the apparatus is in circuit (Fig. 6), a spring tends to break the circuit and snap the lower part of the cross lever upwards. This is, however, prevented by a catch held in position by the iron clapper. To regulate the action of this clapper, and ensure its falling and liberating the cross lever when the current has reached the prescribed value, the following method is employed:—The upper terminal is lengthened out into a spiral with three turns, and provided with pole pieces, thus making an electro-magnet, arranged in such a way that its attraction just fails to keep up the iron clapper when the current reaches the prescribed value below which it is decided not to go.

THE ARCAS SYSTEM OF ELECTRO-PLATING.

Existing methods of covering corrodible metals with a protective coating leave much to be desired. Two reasons may be assigned for this: the first, that the adhesion of the protective film is imperfect; the second, that the film itself is attackable to some extent. Gold properly deposited electrolytically forms a fairly satisfactory coating, but its cost is against it; platinum until lately could not be deposited in a bright coherent state, and the success claimed for a process much discussed some little time ago was far from complete; more recently still investigations by an American chemist have led to a more rational method being devised, and the practicability of the process may be now safely conceded. At the best, however, platinum is unlikely to find a very extended application as a protective coating. Its price and its porosity are serious obstacles to its use for many purposes. The former limitation forces itself upon the notice of the least observant, but the latter is too often overlooked by those who might reasonably be expected to realise its importance. When it is remembered that it has been proved that zinc oxide may be reduced by the gases penetrating a platinum crucible heated by a gas flame, and that in the best analytical practice a porcelain tube is preferred to platinum in the determination of carbon in steel, in spite of the obvious convenience of the latter and its adoption by some chemists of repute, it will be understood that a mere film, such as all plating from the nature of the case inevitably is, cannot be expected to protect the surface to which it is applied effectively, and unless it be effective it might as well be abandoned altogether.

There remain, therefore, silver and nickel. The former adheres well to most metals, and is not porous; the latter adheres badly to iron and steel, for which it is, perhaps, most largely used, and fails to protect them adequately; a glance at the "bright parts" of a modern cycle, after a few months' wear, will confirm this statement.

In view of these facts it can readily be understood that there is a considerable field for a method of plating which shall be non-porous, not readily tarnishable, and moderately cheap. The London Metallurgical Company claim to have introduced a process of the kind, which was recently inspected by a representative of ours. The coating deposited is an alloy of silver, but it is noticeable that the great tendency of that metal to become black by the formation of sulphide of silver from contact with the sulphurous gases present in a town atmosphere is not possessed by the alloy. The new method, which is known as "Arcas" plating, costs about the same as ordinary electro-plating, and is applicable to all the purposes for which silver and nickel are now used. On account of the foreign patents for the process being still incomplete, we cannot yet publish details of the anodes and electrolyte used, and the methods of deposition. Testimonials from numerous users go to show that the plating has unusual powers of resisting atmospheric influences, articles protected by its means showing almost no deterioration after prolonged exposure. The claims made for the possession by the alloy of the qualities mentioned above will, of course, have to be made good by independent expert testimony, upon the production of which it may be conceded that a distinct addition to our manufacturing resources has been made.

THE TRANSMISSION OF SIGNALS ON UNDERGROUND CABLES.*

In a Paper read by Herr A. Franke before the Elektrotechnischer Verein (Berlin) there is some interesting information as to the way in which an electric current is propagated on underground cables, &c. These cables possess both electrostatic capacity and self-induction; and knowing the values of these two quantities, we could attack some of the problems by mathematics, but it is better to have recourse to direct experiment. In this abstract we shall not occupy ourselves with the manner in which the experiments were carried out, but only with the results obtained. The principle employed was that of a Morse key, connected either to a circuit possessing a given capacity and self-induction, or to a cable.† The method allowed of the measurement of the current at exceedingly brief intervals of time. These intervals were brief enough to enable one to estimate the one-ten thousandth of a second.

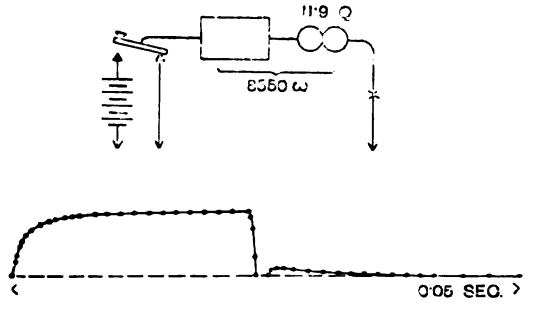

FIG. 1.—Resistance and Self-induction.

In Fig. 1 we have a circuit of a total resistance of 8,550 ohms, and self-induction 11·9 quadrants. The curve is that which is obtained when the battery is connected to it, and when this connection is broken. The time included between the arrows is the total duration of the phenomenon. The initial curve is an exponential curve, the exponent being the ratio of the resistance to the coefficient of self-induction. The curve obtained deviates a little from the theoretical curve. It rises more rapidly, bends over more decidedly, and approaches its final value more slowly than theory would indicate. When the battery circuit is broken the current falls to zero in ·0004 second, the conductor circuit was closed through the back-stop ·005 second later; the current at first rose slightly, and then fell slowly to zero. This current could only be due to the induction of the electro-magnet, which shows that the magnetism does not disappear at the same time as the current, which phenomenon is undoubtedly caused by undulatory currents, and these explain also why the exponential curve does not coincide with that deduced mathematically.

The curves in Fig. 2 refer to a case where there was only resistance and capacity and no self-induction. The conductor consisted of two rheostats, the resistances of which were respectively 1,710 and 6,840 ohms, the capacity being one microfarad. Curve I., showing the growth of the current, is an exponential one, as in the previous case, the exponent now being the ratio of the resistance to the capacity. This curve agrees exactly with the theoretical curve. When there is no capacity the current is everywhere the same, while here there is a difference between the current behind (Curve I.) and that in front of the condenser (Curve II.). At the first instant the condenser absorbs an appreciable quantity of electricity, and

* From *La Lumière Electrique*.

† For description of apparatus, see *The Electrician*, Vol. XXVI., p. 459.

Digitized by Google

the potential falls to zero. The initial value of the current in front of the condenser only depends on the resistance which there may be in front of it; it is greater than that of the steady current. The current falls according to an exponential, and attains its steady value at the same time as the current on the far side of the condenser. As soon as contact is made with the backstop, the condenser suddenly discharges. The two currents (I. and II.) approach zero, taking an exponential curve.

When it is a case of a circuit possessing both capacity and self-induction, we see that these two properties act in opposition. We obtain under certain circumstances electric oscillations, the duration of which depends on the square root of the product of these two values. Oscillations of this kind were frequently observed, and their duration varied between wide limits. The curve in Fig. 3 shows the result obtained by discharging a 1 microfarad condenser through the

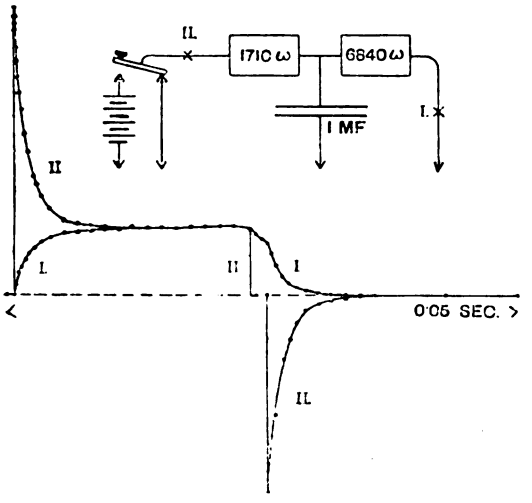

Fig. 2.—Resistance and Capacity.

coils of the electro-magnets of a Morse instrument. The resistance was 563 ohms, the self-induction 11·9 quadrants, the duration of the oscillation ·025 second. It is to be seen clearly by the figure that the curve cuts the axis five times.

Under favourable conditions one can obtain oscillations on charging a condenser. To show this the large resistance of 18,900 ohms was interposed between the key and the condenser (see Fig. 4), a resistance of 750 ohms, equal to that of the battery, being connected to the back stop. In order to reproduce as closely as possible the same conditions on charge and discharge, means were taken to avoid breaking the circuit on passing from one stop to the other. It was then observed that the current passed its normal value, oscillated about it, and disappeared in the same oscillatory manner. The slight differences between the theoretical curve and the experimental curve are again due to the magnetism of the iron.

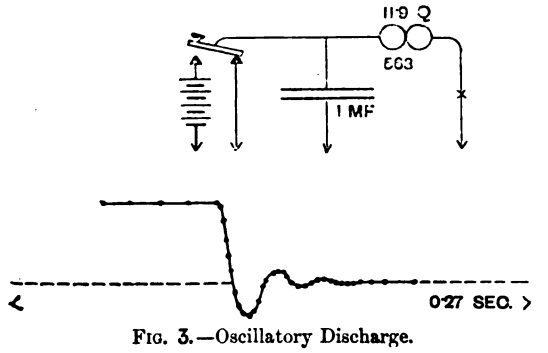

Fig. 3.—Oscillatory Discharge.

The conditions become more complicated when it is a question of telegraph circuits, where the capacity is spread along the whole length of the line instead of being concentrated at a given point, and where the current varies from one point to another. Self-induction and the insulation of the line come in, and instead of obtaining simple easily calculable curves we then obtain complicated curves. Nevertheless, it is easy to see that these curves should agree in certain characteristic features with those already considered. It is evident that measurements on these sort of circuits cannot be so accurately carried out as on artificial lines. The induction of neighbouring wires especially may have a considerable disturbing effect. The curve in Fig. 5 relates to the cable connecting Berlin to Perleberg, 276 kilometres long. To avoid as much as possible the effects of induction the two ends of an artificial cable were added, which brought up the total length to about 500 kilometres. The total capacity of the conductor was 112 microfarads, the total resistance 3,800 ohms.

Fig. 4.—Oscillatory Charge and Discharge.

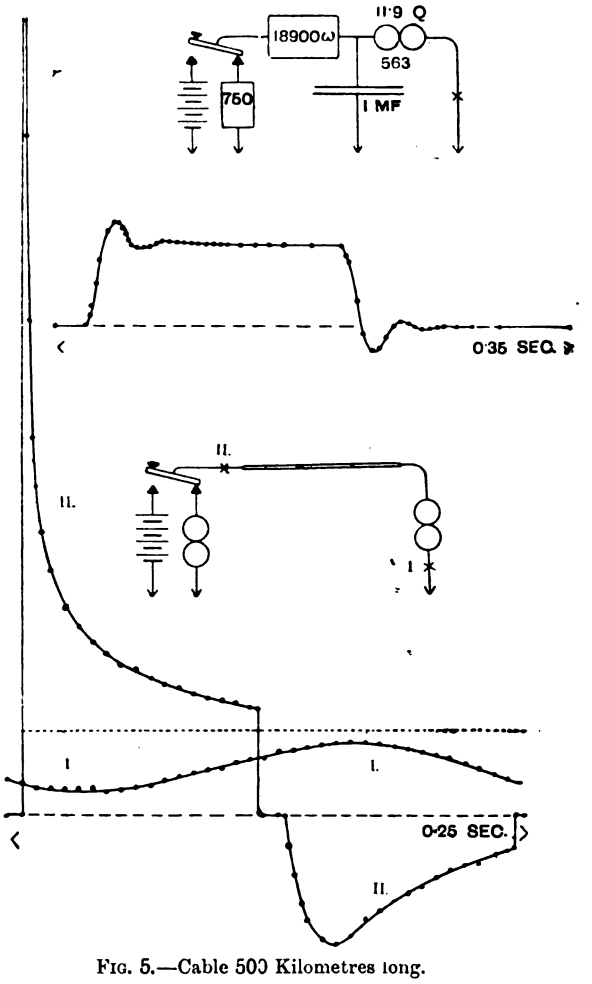

Fig. 5.—Cable 500 Kilometres long.

The current at the near end of the line denoted by Curve II. exhibits a high initial value, reduced by one half in the figure. The first point observed was also the highest, showing that the current reached its maximum value in less than ·0001 second. This value

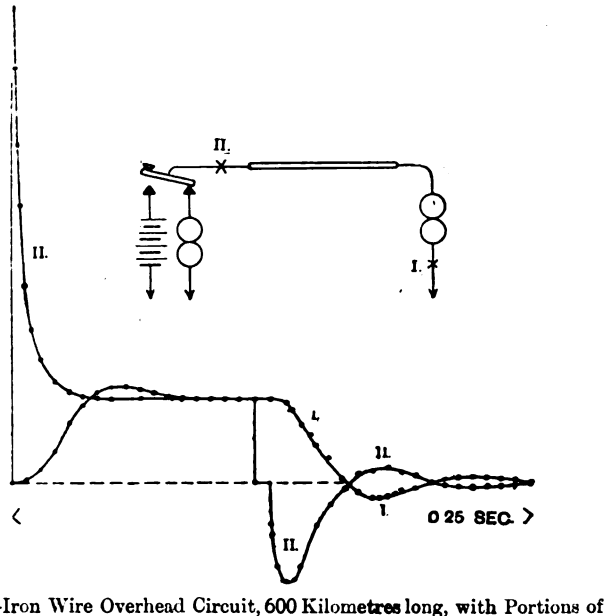

Fig. 6.—Iron Wire Overhead Circuit, 600 Kilometres long, with Portions of Cable.

is fifteen times that of the steady current indicated in the figure by a dotted line. This shows that there was considerable capacity behind the key, and that the initial value of the current only depends on the battery resistance. We thus see how important it is to use low

Digitized by Google

resistance batteries in cable work. The charging wave diminishes first quickly, then more slowly, and at the end of one-eighth of a second the steady value is still not attained. The curve next shows the breaking of the battery circuit, and then the discharge through the back stop. Here there is no peak, because the self-induction of the Morse apparatus opposed any sudden increase of current. The current at the far end of the line vanishes sinusoidally (Curve I.), and never attains either the stationary value or zero. It is to be observed that this wave only attains its maximum value long after contact has been made with the back stop.

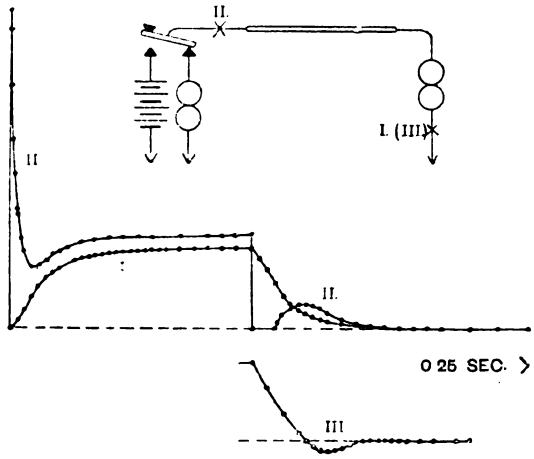

FIG. 7.—600 Kilometres of Overhead Bronze Wire.

The curve in Fig. 6 was taken on an overhead line running from Berlin to Hanover and back, a distance of 600 kilometres. The conductor was of iron wire, but in the towns there were cables which brought up the capacity to 11 microfarads, the resistance being 7,500 ohms. As at the beginning of the line there were a few kilometres of cable, the top of the curve is, as was previously the case, very high. On the diagram only a portion of this initial period is shown. The charge is, however, quickly terminated, and curve II. (Fig. 6) soon attains a steady value. We have here to do

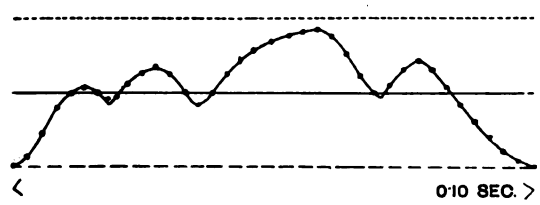

FIG. 8.—Bronze Conductor : 600 *f's* per minute.

with a high resistance circuit, at the end of which, close to the Morse apparatus, are a few kilometres of cable ; and these, as we have pointed out above, are the necessary conditions for obtaining an oscillatory *charge* at the far end of the conductor. Curve I. (Fig. 6), in fact, exhibits these oscillations. The oscillatory discharge which is observable on either side of the condenser, is symmetrical ; it is strongly damped, the duration of the oscillation being ·083 second.

It was not possible to investigate an iron overhead line of any length, since in every town there are portions of cable ; but long

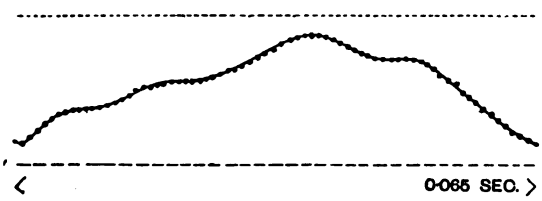

FIG. 9.—Bronze Conductor : 924 *f's* per minute.

overhead lines were obtained by utilising bronze wire telephone circuits. Tests were carried out on a line running from Berlin to Hamburg and back. This line was 600 kilometres long, but its resistance was only 1,700 ohms, and its capacity about 2 microfarads ; it was impossible, owing to external influences, to obtain the exact value of the capacity. In spite, however, of this low capacity, spread over the entire length of the line, we see (Fig. 7) that the point corresponding to the charge is still fairly high. When the line is charged, which in this case is soon completed, no more electricity can be pumped in at one end than flows away at the other (as is seen by Curve I.) ; and as, owing to the self-induction of the receiving apparatus, the steady value is not yet attained, the current at the near end at first falls below its steady value, after which the two curves (I. and II.) rise together. The constant difference between Curves I. and II. is due to a defect in the insulation of the line. On lifting the key the conductor discharges fairly rapidly (see Curve I.), and on closing on the back-stop there is no oscillation (Curve II.). The current at the extreme end of the line disappears in the manner depicted in Curve III., from which we see that when the key is midway between the stops it is possible to obtain an oscillatory discharge even with aerial conductors.

These curves show that when dealing with cables self-induction is negligible compared with capacity ; that in the case of a mixed circuit, consisting principally of aerial conductors, self-induction gives rise to oscillations ; but that its influence is most marked in the case of purely aerial conductors.

It may now be asked what happens when, instead of a single current, it is a question of several currents quickly following one another, such, for instance, as telegraphic signals ; the conductor then remains more or less charged. To investigate the matter, a rapid succession of *f's* (— — — —) was sent to line, and the current at the distant end was analysed.

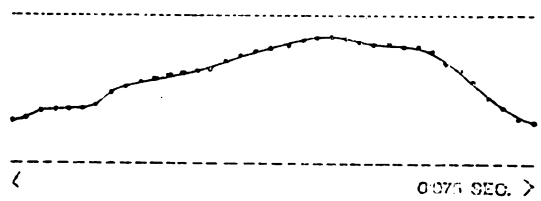

FIG. 10.—Mixed Circuit : 800 *f's* per minute.

At the highest possible speed attainable by hand (60 to 80 *f's* per minute) each signal arrived individually at the receiving end. It was only when a speed of 600 a minute was attained that curves such as those shown in Fig. 8 were recorded. Under these conditions we neither get the steady value of the current, nor a complete discharge, but only maxima and minima. But this does not (with a suitable apparatus available) prevent the interpretation of the signals received. The phenomenon, well known to telegraphists, of the shortening of the first dot of a signal is very observable.

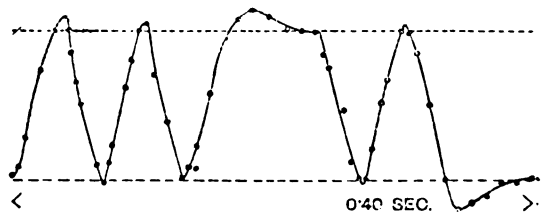

FIG. 11.—Mixed Circuit : 150 *f's* per minute.

Under these conditions, and for the lines in question, the above is the limiting speed of transmission. If the speed is still further increased and attains 924 *f's* per minute, the curve, Fig. 9, is obtained, in which it is no longer possible to distinguish the dots. It would be impossible to communicate telegraphically under these conditions.

With iron conductors and pieces of cable the unfavourable curve shown in Fig. 10 is obtained at only 800 *f's* per minute. The disturbing influence of high resistance and capacity is plainly discernible.

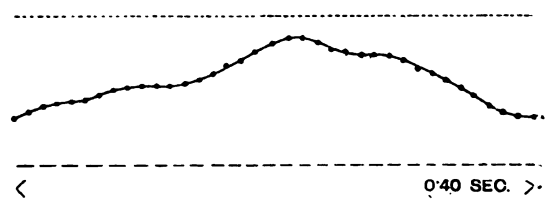

FIG. 12.—Cable : 150 *f's* per minute.

Curve Fig. 11 refers to a mixed circuit, and shows that with 150 *f's* per minute transmission is still perfect. The current it will be observed rises at times above its steady value. So long as it is not a question of high speed transmission, cabled conductors at the extremities of a circuit are rather advantageous than otherwise.

M. Jacquin * has shown mathematically that a condenser and a resistance introduced behind the receiving apparatus act favourably

* *La Lumière Électrique*, Vol. XXXIV. p. 32.

Digitized by Google

on the transmission; but that the capacity of the conductor and the self-induction of the receiving apparatus also produce this result is a fact which has not hitherto been pointed out.

It is found on comparing the results obtained on cables, that with speeds for which overhead conductors give perfect transmission, a curve, such as that in Fig. 12, is obtained, which no longer permits one to distinguish the signals—a fact which demonstrates in a striking manner the superiority of overhead circuits. To lessen this defect, M. Godfroy* has proposed to put at the beginning of the conductor and behind the key an inductive coil connected to earth. Curve, Fig. 13, shows the result of doing so. The signals are much clearer.

For similar conductors possessing resistance and capacity the current curves become the same when the speed of the signals is inversely proportional to the product of the resistance into the capacity. This fact has often been made use of in connection with mixed circuits. The preceding curves show what degree of accuracy is attained by this law.

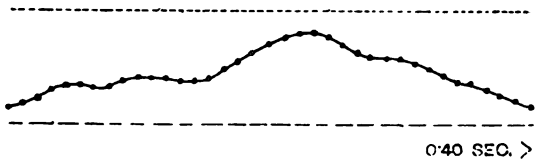

Fig. 13.—Cable: provided with the Godfroy device; 150 *f's* per minute.

The following table gives, in the third column, the values of $K \times R$ for the different conductors, K being in farads and R in ohms. The fourth column gives the speed of signalling v, and the fifth column the product of these two quantities. It is to be observed that the product in question is sensibly the same for cables and mixed circuits. For bronze wire circuits it would be necessary to increase the speed of transmission in the ratio of 1 to 16 to obtain the same product. If this product were the only thing one had to concern oneself with, the same current curve could be obtained with 15,000 *f's* per minute. But with a bronze conductor, self-induction intervenes in a preponderating manner. The last column gives the value of $\frac{L}{R}$ for the different conductors, and would give the current curves if there were no capacity. As it is not easy to measure the self-induction of long conductors, and as it is only a question here of giving a general idea of the phenomenon, the self-induction of the apparatus, 12 quadrants, has alone been taken into account.

Table.

Conductor.	R	K	KR	v	KRv	$\frac{L}{R}$
Cable	4,800	112×10^{-6}	·54	150	8·1	·0025
Mixed circuit	8,500	11×10^{-6}	·093	800	7·5	·0014
Bronze wire...	2,600	2×10^{-6}	·0052	934	4·8	·0046

The deductions that we may draw from these investigations is that for mixed circuits the speed of transmission depends on the product of resistance and capacity, but only on the condition that self induction by resistance is negligible in comparison to this product.

TANNING BY THE AID OF ELECTRICITY.†

BY DR. S. RIDEAL AND A. P. TROTTER.

(*Continued from page 507.*)

At present it is customary to judge of the quality of the leather from its appearance and colour; a hide is, however, frequently struck through when it has only absorbed a comparatively small quantity of tannin, and the colour of the finished leather varies considerably with the kind of tanning materials employed.

lish the qualitative fact that the combined action of the motion and the electric current considerably hastened the rate of tannage. It was of interest, however, to ascertain, if possible, what was the average rate obtained when the hides were slowly rotated in the pit and when no current was passed through the liquor.

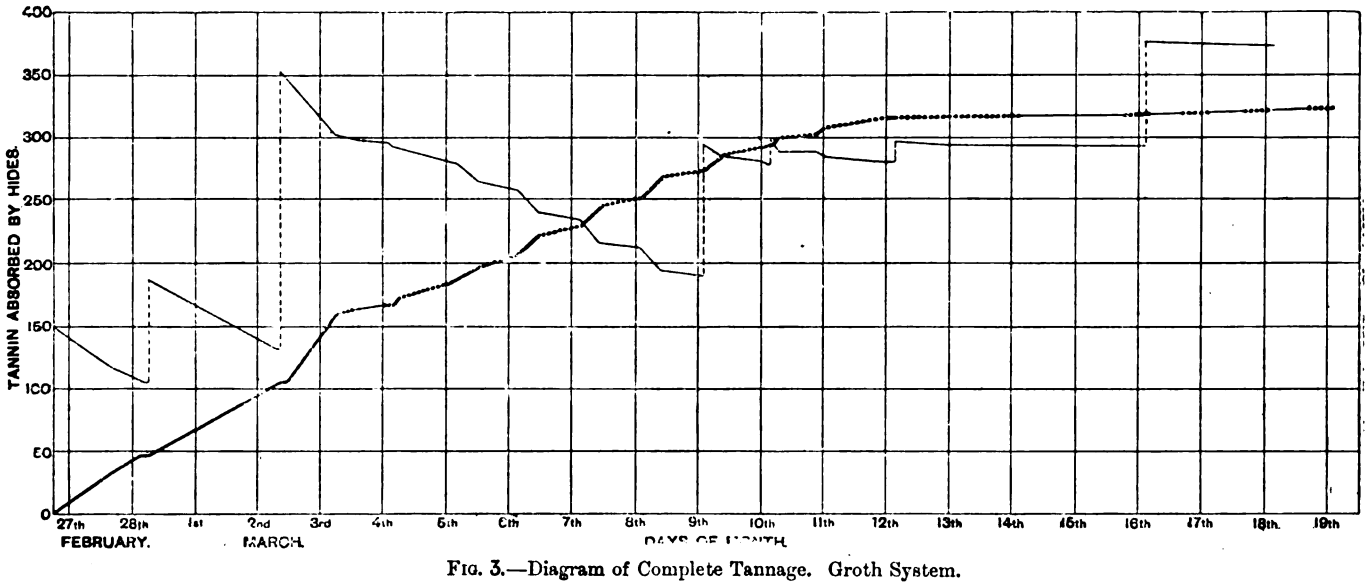

Fig. 3.—Diagram of Complete Tannage. Groth System.

Rest ——— Motion ..... Motion and Electricity ———

In Fig. 3 the daily absorption of tannin from the liquor in the above experimental tannage by this process is shown, in which it will be seen that the rate of absorption, as already shown in Table III., gradually diminishes as the hide becomes saturated with the tannin, and finally the rate becomes so small that the ordinary permanganate valuation of the liquor is useless for estimating the change.

In Fig. 4 the daily readings for a similar experiment are plotted out and show analogous results. The readings were, however, discontinued on the eleventh day, although the quantity of tannin absorbed by the hides used in this experiment was not sufficient to completely tan them. They were subsequently finished in another vat. From the foregoing results, we have sufficient data to estab-

A comparative experiment was made to establish this point, the results of which are given in the accompanying diagram (Fig. 5). Two circular vats were employed, A and B, containing 1,600 and 2,400 gallons of liquor respectively, made up to approximately the same strength. A batch of hides which had previously been limed, unhaired, and fleshed under the same conditions, was divided into two portions, whose weights were in the ratio of the volumes of the liquor in the two vats, so that the loss of tannin per unit volume of the liquor is equal to the absorption of tannin per unit weight of hide in each vat. The liquor in both vats was analysed at the commencement of the experiment (Feb. 14th, 4 p.m.), and the hides remained suspended in the liquor, without any motion or electric current being applied to them, for 44 hours. Samples of the two liquors were analysed, and the rate of absorption in each vat deduced and found, as might be expected, to be practically

* See *The Electrician*, July 17, p. 303.

† From the *Journal* of the Society of Chemical Industry, No. 5, Vol. X.

Digitized by Google

identical. The subsequent treatment of the hides in the two vats was so arranged that the hides in vat 1 should be subject to the joint influence of motion and electric current, whilst those in vat 2 were under the influence of motion alone. The experiment was then repeated for a longer time, and after an interval of rest the conditions were reversed, the hides in vat 1 being subjected to motion alone, and those in vat 2 to the joint action of motion and electric current.

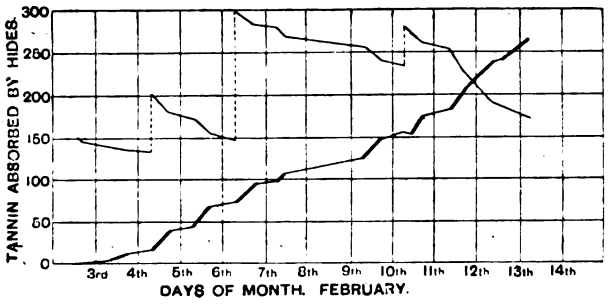

FIG. 4.—Diagram of Complete Tannage.

Rest —— – Motion and Electricity ——

The results are plotted together in Fig. 5, where the upper curves show the gradual loss of tannin from the liquor and the lower curves calculated from them, to show the quantity absorbed by the hides (as during these experiments the liquors were not strengthened, the lower curves are the images of the upper). From the slope of the lines the relative rates can be obtained.

The following table summarises the above results ;—

Comparison of the Rates of Tanning.

Kind of tanning.	Total loss in parts per 10,000.	Total time in hours.	Rate.
Ordinary tannage	12·8	88	·145
Rest after motion and electric current	15·3	56	·273
Rest after motion alone	15·7	56	·280
Motion after electric current	8·6	24	·36
Motion alone	18·8	38	·49
Motion and electric current	53·6	38	1·42
Electric current after motion	59	24	2·47

Thus, while the initial rate in vat 1 was ·163 parts per 10,000 per hour, and ·104 parts per 10,000 per hour in vat 2, when a current of electricity and motion was applied to vat 1, and motion only to vat 2, the rate of loss in vat 1 rose to 2·43 parts per 10,000, and in

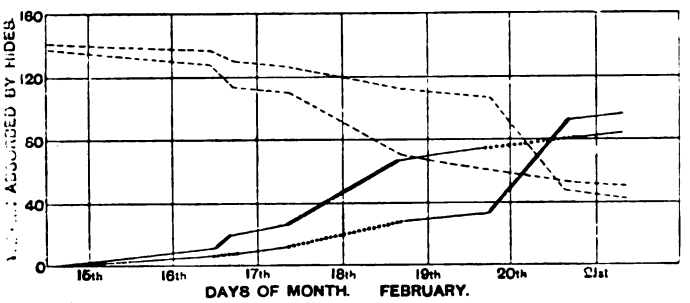

FIG. 5.—Diagram of Comparative Tannages.

Loss of tannin from liquor - ····· Motion ·····

Rest – – – Electricity and motion ——

vat 2 to ·63 parts per 10,000. After an interval of rest, vat 1 showed a rate of 1·36 parts per 10,000, and vat 2 a rate of ·52 parts per 10,000. It is to be noted, however, that the apparent falling off in the rate in vat 1 may be due not only to the gradual diminution as the tanning proceeds as already referred to, but to the electric current during the night of this experiment being smaller than during the day, or possibly interrupted for some time, as no electrician was controlling the experiment during the night in question. After an interval of rest the conditions were reversed, motion being alone used in vat 1, and motion and a current of electricity simultaneously in vat 2. The rates of loss were then found to be ·36 parts per 10,000 per hour in vat 1 and 2·46 parts per 10,000 per hour in vat 2, thus confirming the previous figures and proving that the vats or proportions of liquor and hide employed in each were not affecting the comparison.

The average values thus obtained are in the proportion of—

Ordinary tanning.	With motion.	With motion and electricity.
·133	·503	2·08

or the rate of tanning under the combined influence of electricity and motion is four times faster than the rate when motion alone is employed, and 16 times faster than when neither are used.

We have not tried the effect of a current of electricity on the hides when at rest, although no doubt the tanning rate would be similar to that obtained when motion is employed, as the hides when at rest would not be uniformly influenced by the flow of the current through the vat, and the leather produced would therefore be unequally tanned. It ought also to be noticed that these rates were obtained with the motion of the kind produced by the first kind of machine, and that no doubt other rates of tanning would be observed under the influence of other kinds of motion, and if no provisions were adopted for preventing the hides from being in contact with another, it is safe to assume that the rate would be considerably less, as the circulation of the liquor to every part of the hide would be prevented.

Theoretical Conclusions.—The original suggestion of Grothius in 1805, with its chain of molecules and bonds, its pairing and unpairing, formed a very fair working hypothesis, and has been gradually developed and elaborated until we are to-day confronted with a very serious complication of theories. Helmholtz has suggested that there is no tearing apart of the molecules, but that work must be done in separating an atom from its electrical charge, or in removing electricity from an atom of high specific attraction, and giving it to another lower in the scale. Clausius considered that the molecules are always changing partners, that dissociation, in fact, is always present to some extent, and that the effect of the electromotive force is to give direction to movements which are already going on. Arrhenius considers that dissociation is complete in very dilute solutions, but Traube maintains that such a view upsets our conceptions of chemical affinity, and makes the convenient assumptions as to the nascent state impossible, and flatly contradicts the theory of hydration. The idea of a nascent state has been to a large extent given up by chemists, but the ions undoubtedly are occasionally liberated in a form in which, although they do not readily combine with the other matters in solution, and are in a self-combined state, *e.g.*, ozone, they are in a very energetic condition. From *à priori* considerations, as we have observed, this nascent state or the resulting facilities for combination which arise from the cause whatever it is called, might be expected to facilitate the operation of tanning in the same way that it affects the operations of bleaching and treatment of sewage. But although the tannins are molecules of some complexity there are no grounds for supposing that dissociated molecules react with the gelatin of the hides, and we have no proof whatever that any such dissociation takes place in the tanning process. Turning to the question of dialysis and osmosis, we find dialysis to be a form of diffusion to which electrolysis has been compared by Wiedmann, who showed that the conductivity of an electrolyte may be considered as depending on the coefficient of diffusion of the components through each other. Dialysis is a selective diffusion, and is undoubtedly facilitated by the passage of an electric current, and it is easy to see that such an action must be extremely advantageous in the slow process of tanning, which is probably retarded enormously by the superficial coagulation which takes place almost at the moment of first contact of the green hide with the tanning liquor.

Theories of dialysis are at present incomplete, but Van t'Hoff's law of osmotic pressure and our knowledge of the migration of ions indicate the direction from which a satisfactory theory of the process may be looked for.

In the meantime, the facts which have been established are of a very different order, so widely different indeed that hypotheses of osmosis and observations of the migration of ions are alike useless. Dr. Oliver Lodge's experiments with dilute H_2SO_4 give a velocity of about $\frac{1}{35}$cm. per sec. for H, and $\frac{1}{800}$cm. per sec. for SO_4. With jelly and a slope of potential of 1 volt per cm. the velocity of Ba was $\frac{1}{3000}$cm. per sec, and Cl and Br $\frac{1}{4150}$cm. per sec. But with a slope of one-tenth of this, *i.e.*, about 1 volt. per cm., the rate of progress of tanning is only about ·025cm. in 100 hours, or $\frac{1}{13000000}$ cm. per sec., or $7\frac{1}{2}$ inches per annum.

It thus seems necessary to attribute part of the hastening effect to the direct action of the electric current upon the suspended hide.

Helmholtz and Ostwald have given considerable attention to the resistance of electrolytes, and it is pointed out that the degree of dissociation can be determined from the conductivity. Arrhenius concludes that the resistance is greater as the ions are more complex, and the tannin molecules are considerably more complex

Digitized by Google

than any compounds that have yet formed the subject of careful experimental work. Not only have we a complex solution, but it is admitted that with weak currents secondary actions are likely to take place at the electrodes, and it is only with strong currents that the real ions are liberated. The fact that the rate of absorption of tannin distinctly diminishes with even four amperes shows that if any chemical action be involved it is probably some secondary action of considerable complexity, and that, therefore, there is no need for attempting to explain the process by an electrolytic breaking down of the tannin molecules.

Although it is difficult to advance any definite theory as to the effect of the passage of the electrieal current upon the process of tanning, the increased rate is obviously due to the current hastening the chemical union between the bodies which are in a condition to combine. It is well known that chemical combinations which only take place at elevated temperatures, can be induced to occur at ordinary temperatures, when an alternating current is passed through the mixture of the two bodies. Amines combine with aldehydes in this way, and Meritens (Eng. Pat. 16,947, 1889) has proposed to bring about etherification, and so effect the quick ageing of spirits by the help of an alternating current.

Dr. S. Ehrmann, of Vienna, has also recently shown that a moist skin absorbs salts very rapidly from their solution when an electric current passes, and Wagner has also proposed to administer cocaine by a similar process of cataphoric medication. In Ehrmann's experiments, in which a current of 10—20 milliamperes was passed from zinc electrodes through a solution of methylene blue, in two cups in which the hands of the observer are immersed, blue spots appeared on the back of the hand in the anode vessel and none on the other hand in the other vessel. The absorption was most marked where the hair and fatty glands are situated, and thus throws light on the fact that in tanning the process is most rapid on those parts of the skin, and that the electric current has no doubt a distending effect upon the pores of the skin, as indicated by our earlier experiments. Lithium chloride is similarly absorbed by endosmosis through the skin, and Edison has shown that gouty secretions in the fingers are speedily dissipated by the prolonged action of currents of 20 milliamperes. H. N. Lawrence and Dr. Harries have obtained similar results (Soc. Arts, March 11, 1891). We believe that the hastening of the tanning process is of a similar character, and we draw attention to these experiments as analogous, if not confirmatory of the explanation of the process which we tentatively advance in this Paper.

We have to thank Mr. Bawden, one of our assistants, and Mr. Fox Bourne for help in carrying out part of the experimental work of this Paper.

THE LONDON TELEPHONE SERVICE.

The following letter, which appeared in *The Times* of Tuesday, will be read with interest :—

TO THE EDITOR OF THE TIMES.

SIR,—Having for some years been much interested in telephonic matters, and having devoted not a little time to the consideration of the subject, may I be permitted to say a few words in reply to Mr. Faithfull Begg's letter and in support of the Duke of Marlborough's contentions ?

Mr. Begg would apparently have us believe that the present inefficient condition of telephony in this country is due almost entirely to obstruction on the part of the Post Office, and that the costliness of telephonic communication in the metropolis, though to some extent due to past mismanagement, is for the greater part unavoidable. He apparently admits that the two-wire system is preferable, but defends the existing single-wire arrangement by declaring that without powers to build subways no other is possible.

With reference to this latter question, I venture to dispute his assumption. There may be difficulties in working the double-wire system above ground, but that these are by no means insuperable is evidenced by the Post Office exchange at Cardiff and by the Mutual exchange at Manchester, in both of which the double-wire system is exclusively employed, and where overhead wires are also used.

But to come to the most important question of all—namely, that of cost—Mr. Begg seems entirely to deny the Duke of Marlborough's statement that London can be telephoned with a £10 subscription at a profit. It appears to me that this assertion of the Duke of Marlborough's is demonstrable from the accounts of the National Telephone Company itself, but to show this I must be pardoned if I have for a few moments to touch on the past history of London telephony.

When about two years ago an amalgamation took place of the various telephone companies, the existing National Company bought up the business of the United Telephone Company, which up to that date had run all the metropolitan telephone exchanges. The capital of the latter company prior to the amalgamation stood at some £500,000, about one half of which sum represented the expenditure on plant, the remainder having been paid away chiefly for patents. These patents, or, at any rate, all of them that are of importance, have now expired, so that, assuming that the money expended on plant was well laid out, about £250,000 is the present value of what the National Company purchased.

For this, however, they paid no less than £1,250,000. It is this latter figure that stands as the value of the London exchange system in the existing companies' books, and it is this latter figure that requires a £20 rate of subscription in order that a dividend may be earned.

If we retain the £250,000, which is the most that can be taken as representing the value of the plant, and write off the remaining £1,000,000, which now represents nothing at all, and with which a new company would not be burdened, let us see what is the result.

The National Company have at present some 6,000 subscribers to their London exchanges, which, at the existing rental of £20, gives a yearly gross revenue of £120,000. The Company's last dividend was at the rate of 7 per cent. per annum, so that this £120,000 is apparently sufficient to cover all working and other expenses, and to pay a dividend at the above rate on the £1,250,000 capital. Reduce this capital, as mentioned above, by writing off the £1,000,000 that represents nothing, and a rental of £8. 6s. 8d., producing a revenue of £50,000 per annum, would still pay all expenses and give 7 per cent. on the £250,000 that may be taken as the cost of the plant.

Mr. Begg says that the Directors of the National Telephone Company would be glad to know how London could be telephoned at a remunerative profit with a £10 rental. If he means a remunerative profit on an inflated capital like that of the National Telephone Company, the feat is impossible; but that it can be done by a new company, starting fair, and spending its money judiciously, is, I think, proved by the above figures, taken from the published accounts of the National Telephone Company itself.—I am, Sir, your obedient servant, A. A. CAMPBELL SWINTON.

66, Victoria-street, Westminster, September 5th.

SCANDINAVIAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

COPENHAGEN, *September* 7, 1891.

In Stockholm, the works in connection with the new central station are rapidly progressing, and the laying down of the electric light cables and the telephone cables of the State telegraphs is being simultaneously proceeded with, both being encased in underground concrete covering. The former have an aggregate length of 45 kilometres, with a sectional area of 260 millimetres for the main lines and 16·25 in the branch lines. The system is constructed for 10,000 simultaneously-burning lamps. The larger cables consist of a number of copper wires, placed in the centre, round which is the insulation, then a lead jacket, then more insulation, and, outside all, an iron sheath protected by asphalt or some similar substance. The cables are laid in the ground without any further protection. The work is being carried out by Siemens and Halske, of Berlin. In another part of the town the firm of Messrs. Crompton and Co. is installing an experimental main, 385 metres long, on their well-known air-insulation principle.

The Copenhagen central station is also approaching completion ; the brickwork is practically ready, and the six boilers, three Babcock and Wilcox and three Steinmüllers, are in place. The engines, which have been delivered by the Burmeister and Wain Shipbuilding and Engineering Company, Copenhagen, are also being delivered. The cables in the streets are mostly laid, and the house work is also well in hand. The site round the buildings will be dug out to a depth of 10ft., and the accumulators will be placed there. The dynamos from Siemens and Halske are ready, and only wait for the installation of the engines.

CORRESPONDENCE.

THE LONDON TELEPHONE SERVICE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR,—In reply to your letter to me of September 1st requesting further information on the subject of my letter to *The Times* of August 20th, I have much pleasure in sending you the following information. The Company which is about to commence its operations by offering the telephone to everybody in London on the twin-wire system and with the Mann exchanges is the "New Telephone Company (Limited)." This Company was formed in 1884 by several gentlemen interested in bringing about an efficient telephone service in London. The Company obtained a licence from the then Postmaster-General similar in every way to previous licences. They proposed, however, to use a telephone which it was believed would not infringe patents owned by others. In this belief the New Telephone Company was mistaken and the Directors found themselves unable to continue the business of the Company during the existence of patents held by the United Telephone Company (Limited), and they therefore determined to place the Company in liquidation. However, the patents in question having expired it was resolved to take the Company out of liquidation, and the debts of the concern having been paid in full this was accordingly done. A strong Board is in process of formation, and

Digitized by Google

the Solicitors to the Company have been instructed to apply to Parliament next Session for powers to run underground mains where necessary, so as to enable the telephoning of large towns such as London, &c., to be established on the plan of central and sub-exchanges upon the lines indicated by Mr. Bennett in his Cardiff Paper. In order to telephone a town such as London, the first step is to divide its entire area into sub-stations. These sub-stations are to be connected direct with subscribers, say 500 to 1,000 at each sub-exchange. From these sub-exchanges to the central exchanges it is sufficient to run a much smaller number of trunks, say 25 or 50, according to the business done on this sub-exchange. In the City we should require many. In Kensington very few mains, not more than a few subscribers ever wishing to speak at one time. Now, the whole of this system, both of central and sub-exchange, will be on twin wires, and the exchanges will be on the Mann system, so that there will be no delays in getting switched on to anyone throughout the whole of the 23 square miles of the London district. £10 a year will be the terms of subscription for talking all over this area.

The New Telephone Company are not only going to begin in London, but they intend to commence operations in other large towns of England on the same plan, with the object of connecting all these towns up with one another, and thus establish long lines of through communication right through England, on the twin-wire plan. For a £10 a year subscription you will be able to do all your business and perform your social engagements by conversation from your own writing tables, with a little pegging through connection in your clerk's office or in your basement to the exchange, so that you will not be worried by the telephone bell, but will only admit your being at home if you choose. You will have through communication with other towns, your country places, your friends who live in those country towns, and if you happen to be out of doors and wish to communicate with anyone, your own house for instance, you will find call stations all over London where you will go in and call up who you like for a small fee.

It is now six years ago since I set up nearly sixty telephones about this house and property. I have two central exchanges interconnected, and I talk all over the place from any room to anywhere habitually. A small ten-year old boy runs the basement exchange of 48 different ways, and I may say that the telephone is hardly ever out of use during the day. This system is twin wire, and I therefore knew long ago what the advantage implied. The electric light mains which run alongside these twins have no effect whatever on the instruments. I placed all these facts before Mr. Brand when he was Chairman of the United Telephone Company, which I believe has amalgamated with another Company, the National, that still continues its business on a single-wire plan, with only two central exchanges for the 23 square miles area of London, the terms of subscription being either £20 or £16 a year, according as you consent to tie yourself up with a term of years agreement. Now, in order to establish a twin-wire system you have got to divide your area into squares like a chess-board and commence in each of these areas at the same time. The central stations for London that will be connected with these sub-stations by other mains would be from three to five for all London. The system is fully set forth in Mr. Bennett's paper. The National Telephone Company, in order to arrive at such a system as the New Telephone Company are going to inaugurate, will have to make very extensive changes, which would practically mean a total reorganisation of their whole system. In fact, Mr. Bennett said at Cardiff that it would be practically impossible for them to convert their present system without putting in entirely new plant.

Now, the only thing that renders this healthy competition possible is the expiry of the great telephone patents, which have been worked with a draconian severity against inoffensive persons beyond any experience of former patents. This is now all over, and anyone may put a telephone in his house to-day without anxiety, either for his amusement or to replace bells and speaking tubes, or what not. What we may not do, however, is "start a business of letting out telephones for intercommunication, and taking rent for same." This would be infringing the Postmaster's rights, and this can only be done therefore by companies or persons who hold a right from the Postmaster to do this. Now the New Telephone Company have one of these admirable "All England licences," of which there exist very few. They have about 20 years unexpired on this licence, quite time enough to build up a very fine industry. The amalgamated Telephone Companies, which call themselves "The National," have a capital of about three millions sterling. What the Government would have had to pay for exercising the purchase clause with regard to this three million of stock no one at the General Post Office had the very smallest idea! With our present experience, however, a capital of this amount is not necessary to telephone the whole country; and Mr. Bennett's estimate of from twenty to thirty pounds per head expenditure for every subscriber added, on a twin-wire plan of sub and central exchange, is probably about the proper cost of erection, including everything. Maintenance is a considerable item, but I am confident from very careful investigation of the business, that at £10 a year per subscriber a very handsome profit can be earned for the shareholders. The New Telephone Company will, therefore, take its fresh start after having been freed from its past difficulties, under most promising auspices. Every penny of capital that will be subscribed will go to the erection of twin wire plant and modern exchanges, which are the result of all the laborious experience which has been earned by precursors in this field, and which the New Telephone Company was unabie to make use of till this year. The cost of putting down this system is perfectly well known to our Electricians, and we shall commence to secure sub-exchange stations and erect exchange centres all over London very shortly. Our wish is, however, before we go to the cost of swinging these hideous large trunk connections across streets and negotiating the way-leaves, to bring the whole matter of underground connections once more before Parliament in the telephone interest. Another encouraging feature in the enterprise is that the telephone has hardly taken any start in London outside the City. I find it quite impossible to communicate ever between the City and West End. This will give the New Telephone Company great advantages. It is impossible to develope a telephone system so as to extend it to all residents in a town unless the central and sub-exchange is first carefully devised, as the fixing of these exchanges stereotypes the system for good. The New Telephone Company will have no difficulty in this respect, as the present overhead system that exists depends on two isolated exchanges at Cannon-street and Regent-street. The new telephone system will not interfere with the existing system, but will take its radiation points at situations which have no bearing on the National plant. Whether the present amalgamated companies will approve of the strong competition we are about to put them to I do not know. They have three millions sterling of capital on which they have to pay dividend. The value of their patents is gone, and it would seem that the whole of their overhead system will have to be re-devised from end to end. The New Telephone Company will therefore have this advantage, that it has not got to carry this gigantic dead-weight of capital, and that it will probably be able to reduce its price far below what the existing Company can, and that it also will be able to develop with extreme rapidity so soon as it commences its operations in earnest. I have no doubt whatever that this New Telephone Company must grow to be one of the most important concerns of this country, little inferior to the Government telegraph in its development, in the course of the next few years.

If anyone who has occupied himself with electrical science will think out, not only what the telephone does, but the number of uses and substitutions for other purposes that the telephone is fitted for, he will perceive that his almost unstudied instrument is a greater invention than the telegraph itself, and that the day will come when Morse codes and Wheatstone transmitters will be superseded, and that the human voice will either be its own record for telegraphic purposes in the future, or some form of recorder of the sound waves will be constructed, such as the phonograph, which will provide a written record of those electrical waves produced by

Digitized by Google

the human voice. The telegraph instrument will then be as antiquated a machine, in England, anyway, as the older semaphore, and the New Telephone Company will have reaped its harvest by having placed itself in the van of this development.—I am, Sir, &c., MARLBOROUGH.

Blenheim Palace, September 7, 1891.

SUBMULTIPLES OF THE OHM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR,—With regard to the means at the disposal of Prof. V. Jones for determining the value of small resistances, and Mr. Preece's remarks upon the same, mentioned amongst "Notes" in your last issue, permit me to state that Messrs. Crompton and Co. have made and supplied such submultiples of the ohm for the measurement of heavy currents for several years past.—I am, Sir, &c., WM. C. FISHER.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

RESULTS OF TENDERS.—The following is the list of tenders received for lighting the new Ladywell Sanatorium, Salford, by electricity, for which Messrs. Maxwell and Tuke and E. and F. Hewitt are joint architects :—

R. A. Scott	£2,543
Siemens Bros. and Co.	2,200
C. Mellier	2,167
Fowler, Lancaster, and Co.	2,125
J. C. Howell	2,100
Drake and Gorham	2,080
Anderson and Munro	2,034
Sharp and Kent	1,975
W. Leake	1,912
Paterson and Cooper	1,900
General Electric Power and Traction Company	1,847
Swinburne and Co.	1,841
E. Scott and Mountain	1,790
City Electric Light Company	1,765
Barclay and Sons	1,665
Charlesworth, Hall, and Co.	1,655
India Rubber, Gutta Percha, & Telegraph Works Company	1,640
Roper's Engineering Company	1,640
Holmes and Co.	1,630
Mather and Platt	1,627
Edmundsons (Limited)	1,591
Electric Installation and Maintenance Company	1,575
C. A. Parsons and Co.	1,570
West End Electric Company	1,546
Gülcher (New) Electric Light and Power Company	1,535
J. D. F. Andrews and Co.	1,516
J. Pearce	1,450
Mercier, Corlett, and Co.	1,445
Brush Electrical Engineering Company	1,431
General Electric Company	1,425
H. A. Clegg	1,368
R. and H. Dobson	1,352
Alterion Company (Limited)	1,345
C. E. B. Pritchett	1,320
Manchester Edison-Swan Company (with extra powerful dynamo) (accepted)	1,312
W. Rowbottom and Co.	1,020

MORRIS BROTHERS (LIMITED).—This firm have just brought out a combined ammeter and voltmeter, which is mainly intended to measure the electromotive force and current of batteries, but may be used for other purposes, such as measuring the E.M.F. and the amount of current passing through accumulators while charging or discharging the amount of current taken or used by an incandescent lamp or lamps, &c. Each instrument is calibrated separately; they are well made and will stand rough usage.

MESSRS. HUGHES AND HILL.—Mr. Edgar Hughes and Mr. Claude W. Hill have commenced the business of consulting electrical engineers, under the above title, at 5, Parsonage, Manchester, and are prepared to advise on all kinds of electrical installations.

ELECTRICAL POWER STORAGE COMPANY (LIMITED).—We have received a very neatly got up catalogue giving particulars and prices of this Company's various types of accumulator, cell-tester, automatic apparatus, &c.

MESSRS. W. H. WILLCOX AND CO.—This firm, who about two years ago purchased the goodwill of W. Goodwin and Co., leather band makers, Primrose-street, Bishopsgate, and have since carried on the business there under the old name, notify that the works are now removed to 34 and 36, Southwark-street, London, S.E., where the business will in future be carried on under their own name.

RAILWAY ELECTRICAL CONTRACTORS (LIMITED).—A meeting of the shareholders of this Company (in voluntary liquidation) will be held at the offices, 1 and 2, Great Winchester-street, E.C., on October 23, at 3 p.m., to receive an account of the winding up.

DISSOLUTION OF PARTNERSHIP.—Messrs. J. Adams and Co., electric light engineers, of 37, Kensington High-street, have dissolved partnership.

SALE BY AUCTION.—Messrs. J. M. Klenck and Co. announce in our advertisement columns that they will sell by auction, at the Mart, Tokenhouse yard, E.C., on Thursday next, the 17th inst., the goodwill, plant, machinery, &c., of the electrical business carried on by Messrs. D. Judson and Sons (Limited), at the Atlas Works, Ewer-street, Southwark-street.

NEW COMPANIES, STATUTORY RETURNS, &c.

ALEX. WILSON AND COMPANY (LIMITED).—This Company was registered on September 4, 1891, with a capital of £20,000, in £1 shares, by Ashurst, Morris, Crisp and Co., 17, Throgmorton Avenue, E.C. The objects are :—To carry into effect an agreement with A. Wilson, and to carry on the business of mechanical, electrical, metallurgical and chemical engineers, manufacturers and contractors. The number of directors is not to be less than two nor more than five. Qualification, £100. Remuneration, £300 per annum, divided between them.

CULLINGWORTH GAS COMPANY (LIMITED).—This Company was registered on September 1, 1891, with a capital of £10,000, in £5 shares, by Waterlow Brothers and Layton (Limited), Birchin-lane, E.C. The objects are :—To acquire and carry on the Gas Works at Cullingworth, Yorks, now belonging to the Hallas Gas Company (Limited). To carry on at Cullingworth and elsewhere in Yorkshire the business of an electric light company, including that of electricians, mechanical engineers, suppliers of electricity for light, heat, motive power, or otherwise, and manufacturers of and dealers in all apparatus required for the generation, distribution, supply, accumulation and employment of electricity. Not less than two nor more than seven directors will be appointed. Qualification, £250. Remuneration as the Board shall determine. Solicitors: Taylor, Jeffery and Jessop, Bradford.

DOBSON AND BARLOW (LIMITED).—This Company was registered on September 1, 1891, with a capital of £750,000, in £10 shares, by Woodcock, Ryland, and Parker, 15, Bloomsbury-square, W.C. The objects are :—To acquire the business of engineers and machinists now being carried on by T. H. Rushton and B. A. Dobson, under the style of "Dobson and Barlow." To enter into and carry into effect an agreement with the above-named for the purpose. To carry on the business of ironfounders, mechanical engineers, machinery manufacturers, machinists, spindlemakers, millwrights, toolmakers, brassfounders, electro-platers, galvanizers, &c. To acquire, construct, control, and work (*inter alia*) electric works, gas and waterworks. T. H. Rushton and B. A. Dobson are the first governing directors. Qualification, £1,000. Remuneration of ordinary Directors £100 per annum each, that of governing directors £800 per annum each.

FIBRATE SYNDICATE (LIMITED).—This Company was registered on September 7, 1891, with a capital of £15,000, divided 12,500 ordinary shares of £1 each and 500 founders' shares of £5 each, by Jacobs and Weldon, 16, St. Helen's-place, E.C. It purposes to adopt and carry into effect an agreement dated July 22, 1891, between J. R. Thame of the one part and J. W. Taylor (for the Company) of the other part, for the sale to the Company of an invention of improvements in the manufacture of electrical insulating materials, and an invention of improvements in the manufacture of seamless tubes or conduits for electrical and other purposes, and to use, exercise and develop the said invention. The number of directors is not to be less than three nor more than seven. Qualification Remuneration not less than £250 per annum divided, amongst them.

HEATH'S (LIMITED).—This Company was registered on September 2, 1891, with a capital of £50,000, in £10 shares, by Dunn and Duncan, 87, Chancery-lane. The objects are :—To acquire and carry out a system of displaying advertisements invented by Henry Heath, and to carry on the business of advertising agents, printers, iron and brass founders, electricians, mechanical, chemical and electrical engineers, &c. The number of directors is not to be less than three nor more than seven. Qualification, £250. Solicitor : R. Okell, Manchester.

R. S. NEWALL AND SON (LIMITED).—This Company was registered on September 5, 1891, with a capital of £50,000, in £10 shares, by Waterlow Brothers and Layton (Limited), Birchin-lane. The objects are :—To acquire and carry on the business of manufacturers of wire rope, electric and telegraph cables, suspension bridges, and aerial and cable tramways, and of wire drawers, mechanical and electrical engineers, carried on by the firm of R. S. Newall and Son at Washington, Durham. The number of directors is not to be less than three nor more than seven, the first being F. F. Sheppel, F. S. Newall, and C. J. Banks. Qualification, the holding of £500 in shares.

WELLINGTON ESTATES COMPANY (LIMITED).—This Company was registered on September 4, 1891, with a capital of £5,000, in £10 shares by E. Lee Michell, Wellington, Somerset. The objects are :—To purchase

Digitized by Google

develop, and turn to account land and house property of all descriptions; to acquire, construct, maintain and work roadways, tramways, electric power, heat, and light supply works, telephone works, &c. The regulations of Table A mainly apply.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the past week were £5,279.

CITY AND SOUTH LONDON RAILWAY COMPANY.—The traffic receipts of this Company for the week ended September 6, 1891, amounted to £672.

COMMERCIAL CABLE COMPANY.—This Company announces the payment on the 1st prox. of the usual quarterly dividend, at the rate of 7 per cent. per annum.

DIRECT SPANISH TELEGRAPH COMPANY.—The traffic receipts of this Company for the month of August, 1891, amounted to £1,631, as against £2,076 in the corresponding period of last year, or a decrease of £445.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic returns of this Company are as follows:—Receipts in August, 1891, £23,600; 1st January to 31st August, 1891, £189,400; corresponding months, 1890, £181,000; corresponding months, 1889, £178,200.

INTERNATIONAL OKONITE COMPANY (LIMITED).—The first ordinary general meeting of the shareholders will be held at the Cannon-street Hotel, on Friday, October 9th, at 12 noon. The transfer books will be closed from the 23rd to the 30th inst.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The traffic receipts of this Company for the month ended August 31st were £3,050.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended September 4th, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brasilian Telegraph Company, were £3,565.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The receipts of this Company for the month of August were £4,062, as compared with £5,013 in the corresponding period last year.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 696.—Vol. XXVII. FRIDAY, SEPTEMBER 18, 1891. Price Fourpence.

NOTES.

The Lauffen-Frankfort transmission experiment and the International Electrical Congress have drawn a considerable number of English and Continental electricians to the Exhibition; and the Congress, which opened on Tuesday, was attended by an audience of over 600. The value of such gatherings is considerable when there is anything definite to discuss, especially if there are any matters upon which resolutions can be taken. But the passing of such resolutions, if they are to carry any weight with the scientific or with the industrial world, cannot be left to a self-elected assembly. In this instance it is true that there was in one sense a representative body of English electrical engineers at Frankfort, since the Electrical Trades Section of the London Chamber of Commerce, instead of going for a picnic in a steam launch, had arranged an excursion to see the Exhibition; and as there were, we believe, about twice as many members at Frankfort as are generally to be found at Botolph House, they may be considered fairly representative. The Congress was divided into four sections, dealing with, (1) Theory and Measuring, (2) Powerful Currents, (3) Telegraphy and Telephony, (4) Electro-Chemistry, and a fifth section was subsequently formed to consider legislative matters, particularly the relations between the supply of currents for lighting and power, and telegraph and telephone circuits. As far as the Papers are concerned, we shall welcome any valuable ones, but shall not be surprised if the majority do not rise above the holiday style that is considered good enough for the British Association.

No small proportion of the interest which was taken in the recent Paper read by Mr. Ll. B. Atkinson and Mr. C. W. Atkinson, before the Institution of Civil Engineers, was due to the fact that no previous description of the construction or working of their coal-cutting machinery had been published. The conditions of safety and the economy of transmission of power were dealt with at greater length during the discussion than the mechanical details of the tools. It appeared to be admitted that the rock drills, both rotatory and percussive, were in a less developed condition than the coal-cutting machines; and for this reason we have omitted illustrations and parts of the discussion relating to them in the abstract of the Paper which is commenced this week in another column. We shall thus condense the long discussion into about one-half, without omitting all the extraordinary criticisms which were offered. It is difficult to say whether the Professor of Mining talking about electrical engineering, or the Science Professor talking about mining, distinguished himself the most. The Paper, besides describing a new and important application of motors, was a challenge to the advocates of transmission of power by compressed air. Between their confusion as to what is meant by the efficiency of transmission, and the mixture of facts and hypothetical improvements, they made so sorry a show that electric motor makers need have little fear of their competition.

A modified form of the Boulengé chronograph has recently been designed by Capt. H. Holden. This instrument is intended chiefly for measuring the velocities of projectiles, and short intervals of time are recorded and measured by marks made upon a falling rod. Two magnet circuits are provided, by one of these a rod is released, and during its fall another magnet brings up a knife edge, which makes a mark on the rod. A considerable number of adjustments and subsidiary mechanical devices have been introduced. The time is found from the formula $t = \sqrt{2\,h/g}$, and the value of g is given as 32·1908: but although a four-figure accuracy seems to be aimed at in the details given in a descriptive pamphlet, no table is given for the value of g at different places. There is a difference of more than one in a thousand between the value of g at Aberdeen and at Bordeaux or Turin; and if the instrument is capable of recording to within one tenth per cent. allowance must be made for the variation in the force of gravity. As far as we understand the instrument, the magnets are not arranged to do exactly the same mechanical work, and, therefore, it seems probable that the latency, or time which elapses between the breaking of the circuit and the action of the magnet, may introduce a much more serious error than will be produced by variation in the force of gravity. Sir William Thomson appears to have overlooked the correction for g in connection with his standard balance instruments, but attention was directed to it by Prof. Carey Foster, at the Electrical Standards Committee of the Board of Trade. In this case, the matter concerned this country only, yet the variation, though small, is appreciable, there being no kind of measurement in which greater accuracy is possible than in the delicate process of weighing. The difference between the value of g for Edinburgh and for Greenwich is 377 in a million.

A familiar item in both hypothetical estimates of the cost of steam power, as well as in actual accounts of expenses, is "oil

Digitized by Google

and waste" at so much a day. It would seem that Mr. FERRANTI intends to treat the lubricant for his dynamos as part of the plant and include it in the capital outlay, for the 300 H.P. dynamo which has been running for some time at Havre has been using the same oil over and over again for eighteen months. A circulating pump is employed, but on a very different scale to the wiper by which gas engines and marine engines dole out a drop at a time. The bed-plate contains a reservoir, and a pair of pumps throw a liberal supply through copper tubes, which are connected to wide channels in the white metal lining to the bearings. Oil dealers, like mustard manufacturers, probably make their fortunes out of what is wasted rather than what is used.

ON a recent occasion we alluded to the relation between the patent system and modern Socialism. A patent creates a property, and enables any man who has the requisite ability to turn the product of his own brains into an important form of wealth; it offers great encouragement to individuals, and affords an opportunity for any man to rise by his own exertions above his fellows. This opposition to the socialistic principle of uniformity is accidental, and, as far as we are aware, it is not recognised by social politicians. But another relation between patents and an important economical principle has turned up, and Mr. J. P. WILLIAMS, the Liberal Member for South Birmingham, in searching for some corner into which Free Trade has not penetrated, finds "a considerable grievance, namely, the extraordinary disadvantages under which an Englishman taking out patents abroad, labours, as compared with the treatment of foreigners in this country who take out patents." There is a vestige of truth in the grievance, but this, again, may be said to be accidental. The fees for foreigners are, we believe, the same in all countries as for the patentees of each country. In the United States and in Germany there is a more or less careful examination as to the novelty of the invention. In the former, the routine is often very dilatory, and a brisk local agent is sometimes needed. In the latter, we have heard of a few cases in which English applications have been refused on unreasonable grounds, but, after making allowances for the natural irritation of an inventor on being told that he is not the first, we are inclined to attribute many of these rejections by the German patent office to want of tact on the part of the patent agent in refuting the objections. As for the conditions of working the inventions in the country which grants the patents, and using native made machinery for manufacturing the patented articles, they are but part of the principle of Protection. Until lately these conditions were construed very liberally in France, but it is difficult to see how any country which adheres to Protection can do otherwise than enforce them. Free Traders should, instead of grumbling at the completeness of foreign Protection, comfort themselves by reflecting on the folly of any nation attempting to set itself up as self-supporting and independent of external help.

The Tangier-Tarifa Cable.—This cable was opened for service on Tuesday.

Dublin.—The contract between the Corporation of Dublin and the Electric Engineering Company of Ireland was completed on Saturday last.

Church Lighting.—It has been resolved to adopt the electric light for the lighting of Holy Trinity Church, one of the largest churches in Bournemouth.

Brighton.—The Brighton Municipal Electric Lighting station was inaugurated on Monday evening last, the light being switched on by the Mayoress.

Prof. Helmholtz.—An address of congratulation, signed by the Principal and Professors of Glasgow University, was forwarded to Prof. von Helmholtz on the occasion of his seventieth birthday.

Appointment Vacant.—The Chair of Physics at the University College of Wales (Aberystwith) is vacant. The commencing salary is £200. Further particulars will be found in our advertisement columns.

Obituary.—C. A. Nyström, who was for many years the chief of the Technical Department of the Swedish Telegraphs, and a frequent writer on telegraphic subjects, died at Gothysgard, near Wadsbro, Sweden, on August 19th, aged 60.

Dundee.—The Electric Lighting Committee of the Dundee Gas Commission having approved of the report on the question of electric lighting, recommended its adoption at the last meeting of the Board. The report was unanimously adopted.

The Lauterbrunnen-Murren Mountain Railway.—This railway, which consists of two portions, that between Lauterbrunnen and Grütschalp being operated by rope, whilst the rest is worked by electricity, commenced work on August 14th.

New Cable to Mauritius.—Tenders are invited by the Government for the laying and maintenance of a cable from the east coast of Africa, near Zanzibar, *viâ* the Seychelles, to Mauritius. Particulars will be found in our advertisement columns.

Society of Engineers.—The next ordinary meeting of this Society will be held at the Town Hall, Westminster, on Monday, October 5th, when a Paper will be read on "Retort Charging and Discharging Machinery for Gas Works," by Mr. Henry O'Connor.

The Telegraph in Siam.—There are nine telegraph lines in operation in Siam, having a total length of 1,780 miles. The longest line is that between Bankok and Chiengmai (450 miles). Three other lines are at present under construction, amounting to a length of 710 miles.

The West End Street Railway, Boston.—The August returns of the West End Street Railway of Boston show in a striking manner the reduced cost of motive power consequent on the coming into operation of the large new generating station. The motive power for an electric car has now been got down to seven cents per car mile.

Stockholm.—The Swedish State Telegraphs and the Stockholm municipal authorities have some little trouble in agreeing, the Telegraph Department objecting to comply with certain somewhat stringent regulations which the Municipality has seen fit to introduce recently. The matter has now been brought before the Government.

Electric Lighthouses.—In the course of next year the two powerful electric lights on the headland of La Hêve, near Havre, will be entirely altered. The Southern light will be extinguished, and for the present one in the North tower a 5-seconds flashing light will be substituted. The new light will, it is said, be 500 times as strong as the old ones.

A Portable Mining Pump.—The Goulds Manufacturing Company, of Seneca Falls (N.Y.), has recently brought out a triplex electric pump, intended to meet the special exigencies of mining work. It consists of an electric motor geared to a triplex pump and mounted on a little tram car that can be readily moved about on the ordinary mine tramways.

Frankfort Exhibition.—We learn from the *Electrotechnisches Echo* that Prof. Kittler has resigned the chairmanship of the jury, and that Prof. Kohlrausch has undertaken the duties in his stead. The work of the jury is in full swing. Some of the larger exhibitors, such as Siemens and Halske, the Helios Company, Fein and Co., &c., have refused the awards made them.

A New Use for the Electric Car.—Recently two Italians near Gravesend, Long Island, after committing a murderous assault on a fellow-countryman, tried to escape by running down the road towards Brooklyn. The conductor of an electric car, who had heard of the assault, immediately gave chase, overtook the men and captured them.

Hove.—At the last meeting of the Hove Commissioners the common seal was ordered to be affixed to an agreement for the purchase of a piece of land intended to be used for the purposes of the electric light. It will be seen by our advertisement columns that the Commissioners are prepared to receive proposals with regard to the taking over of their electric lighting order.

Royal College of Science, Dublin.—The autumn term of the Session 1891-92 of this College will commence on Monday, October 5th. The Royal College of Science supplies courses of instruction in the sciences applicable to the industrial arts, especially those which may be classed broadly under the heads chemical manufactures, engineering, and mining. Full particulars will be found in our advertisement columns.

Electric v. Horse Traction.—Referring to the forthcoming Street Railway Convention in Pittsburg and to the opposition to electric traction still persisted in by a few street railway men, the *Electrical World* opines that "street railway companies are by no means in business for their health, and if traction by horses really paid better than that by electricity, to find an electric road would require a professional detective."

The Portrush Line.—There was a narrow escape from a bad accident on the Portrush tramway line a few days ago. A steam tram left Portrush at nine o'clock, and at the same hour an electric car left the Giant's Causeway. The steam tram overran the passing place, and met the electric car some little distance further on. The passengers on the electric car became greatly alarmed, and some jumped off. The cars were, however, brought to a standstill just in time.

Launceston (Tasmania).—The Launceston City Council at a recent meeting adopted a report of the Public Works Committee recommending a scheme for supplying the city with electricity for public and private lighting, and for motive power, at an estimated cost of £50,000. The idea is to utilise the water of the South Esk for the generation of the necessary power. The water will be conveyed in pipes to a place where the available head will be 250ft., giving about 850 H.P.

Telegraph Extensions in France.—By a recent Parliamentary vote the French Government was granted some £29,000 for the purpose of improving the foreign telegraphic service. Two wires 500 miles long are to be run from Paris to the Pyrenees, to directly connect Paris and Madrid and Paris and Lisbon respectively. A wire 150 miles long will be run between Bordeaux and Bilbao, and another of 250 miles will be run to the German frontier. Finally two 210-mile wires will connect Paris to Calais.

Eastbourne.—At the monthly meeting of the Town Council on Tuesday last week, the Lighting and General Purposes Committee reported that the borough surveyor had submitted a letter from the manager of the Eastbourne Electric Light Company, stating that the charge in the proposed new contracts would be 10d. instead of 1s. per unit, representing a reduction of nearly 17 per cent. in the price. It was resolved that the borough surveyor be authorised to sign the contracts on behalf of the Corporation.

Thunderstorms.—Thunderstorms, writes our Scandinavian correspondent, continue unusually frequent in Scandinavia. On Sunday, August 23rd, not less than five persons were killed by lightning in the Vestergothland district, in Sweden, in addition to which several persons were injured. On the 26th two persons were killed at Saxhusa, not far from Lund, in West Sweden. On the night of September 3rd a tremendous thunderstorm raged all over Denmark. News has been received of about sixty fires caused by the lightning.

Chicago Exhibition.—Sir Henry Wood was presented to the President of the United States on Tuesday, and on Thursday proceeded to Chicago. The Secretary of the Treasury had a conference with the Exhibition officials on Wednesday, at which Sir H. Wood attended, as also did the German Commissioner, to arrange modifications of the Customs regulations affecting the exhibits coming to the Exhibition. The Secretary said he would do everything possible to meet the needs of foreign exhibitors, and where modifications of existing laws were necessary he would cheerfully recommend amendments to Congress.

Telephone Trunk Wire Development in the West of England.—The Western Counties and South Wales Telephone Company has already spent some £50,000 on trunk lines, and an additional expenditure of £30,000 will be required before the extensions at present contemplated are completed. It is expected that Bristol will be in telephonic communication both with London and Exeter within the next twelve months. To show the development of interurban telephonic communication, it may be stated that the calls between towns on the trunk lines in August, 1888, numbered 13,212; in August, 1889, they rose to 15,889; in August, 1890, to 22,253; and in August of the present year to over 28,000, or an increase of 112 per cent. in the four years.

The Production of Asbestos in the United States.—Asbestos is found in the United States in Pennsylvania, Maryland, Virginia, North Carolina and South Carolina, and Georgia. It is inferior in quality to the best that is mined in Italy or Canada. Asbestos is also found in considerable quantities in California and Wyoming. The production of asbestos in the United States has shown an annual decrease since 1882. The product for 1882 was 1,200 tons (short); 1883, 1,000 tons; and 1884, 1,000 tons. The output for 1885 showed a decided drop, being only 300 tons, and this was again reduced to 200 tons in 1886, and 150 tons in 1887. In 1888 the output was 100 tons, valued at $30 per ton. In 1889 the only asbestos came from California, amounting to 30 tons.

Callendar Electric Pyrometer.—In a recent number of the *Philosophical Magazine*, Mr. H. L. Callendar describes a modified form of the well-known Siemens electric pyrometer. In the Siemens pyrometer the zero is known to change largely and continuously. Mr. Callendar, however, points out that this effect is due to imperfect design, and he claims that if the wire is pure to start with, and is protected while in use from strain and from contamination, its resistance, after having once been annealed, is always very nearly the same at the same temperature. Mr. Callendar's improvements in the platinum resistance thermometer, or pyrometer, consist in the better protection and treatment of the platinum wire. This is differently treated, according to the heats to which it is to be exposed. Two recent communications to the Royal Society related to investigations carried out with the aid of the platinum thermometer.

The Application of Hydrocarbon to Arcs.—In order to overcome certain objections attendant upon the employment of tubular carbons, by which a supply of hydrocarbon may be introduced "to intensify and improve the quality of the light," Mr. W. S. Richards, of Natich, Mass., binds a refractory capillary conductor to the outside of a solid carbon. The chief objection which he thus overcomes is that the hollow carbon is patented by Mr. Saunderson, and a more simple and literal evasion it is difficult to imagine. We alluded to Mr. Saunderson's lamp on p. 594 of our last volume, and have heard nothing more of the idea. It is difficult to see what advantage can be obtained, except by the lengthening of the arc, and, therefore, a lessening of the obstruction of the light of one carbon by the other.

Inverness.—At a meeting of the Inverness Police Commissioners held on Monday, attention was directed to the report of the Manager of the Corporation Gas Works, in which it was stated that owing to the yearly increasing consumption of gas in the town, additional machinery and holders would soon be required at the Gas Works, the cost of which he estimated at about £10,000. Bailie Ross thought that the Commissioners, before embarking on such a heavy expenditure, should consult a practical engineer on the subject of lighting the town by electricity. It had, he said, been suggested that the necessary motive power might be obtained from the River Ness, or from Loch Ness, or even from the Fall of Foyers. He formally moved the appointment of a Committee to make full inquiry into the whole scheme of electric light being introduced into the town.

The Liverpool Electric Inspector's Fees.—The following is the draft scale of charges for testing to be paid by the Undertakers under the Liverpool Electric Lighting Order, 1889, to the Electric Inspector.

Tests to be taken.	Fees. s.	d.
Insulation resistance (in ohms) of main, each test	5	0
Conductivity (in mhos) of main	7	0
Insulation resistance of service line	2	6
Conductivity (in mhos) of service line	4	0
Insulation resistance and copper resistance of joint	3	6
Tests of energy at testing stations, per diem	2	0
Tests of energy at generating stations, per diem	1	6
Tests of instruments owned by undertakers, per instrument	1	0
Earth leakage tests under pressure, per station per diem	1	0

The Faure Accumulator Patent in Germany.—The action for the annulment of the Faure patent brought against the Joint-Stock Accumulator Company of Hagen (Westphalia), by the Berlin Accumulator Company, Correns and Co., de Khotinsky, Gelnhausen, and Gottfried Hagen of Cologne, came before the Imperial Patent Office on Thursday, last week. All motions made by the petitioners for annulment, in order to obtain a postponement of the case, the institution of experiments, hearing of witnesses both in this country and abroad, were disallowed, it being decided that sufficient material was already before the Court to admit of a decision being arrived at. The Imperial Patent Office granted the demand of the defendants' counsel that the appeal lodged by the petitioners should be disallowed, thereby declaring the validity of Faure's 1881 patent to be unconditional.

India-rubber in Madagascar.—Among the forests of Madagascar, india-rubber is everywhere to be found, but, says the Chancellor of the French Residency at Antananarivo, in those places which are easy of access it is beginning to be scarce, and the prices have considerably increased. The diminution in the supply is to be attributed, among other causes, to the cutting of the trees at the foot, in order to more easily arrive at the milk. India-rubber enters, to a very great extent, into the exports of the country, and, in order to encourage this industry, the Government ought, in M. Anthouard's opinion, to look carefully after the preservation of the forests, endeavour to prevent fires, and to induce the natives to abandon their habit of cutting down the trees bodily. In these circumstances, Madagascar india-rubber might, he thinks, successfully compete with the Para product.

The Montefiore Electro-technical Institute.—In common with similar institutions in this country, the well-known Montefiore Electro-technical Institute at Liége has rapidly developed since its foundation in 1883. At the present moment no less than 201 students attend the lectures and practical courses presided over by Prof. Eric Gérard; of these than 45 per cent. are foreigners, 5 being Englishmen. Owing to the rapid growth of electrical science and the constant increase in the number of students, the original laboratories and lecture rooms of the Institute had recently become quite inadequate. The Belgian Government, however, recognising the good work of the Institute, has now placed the spacious edifice formerly occupied by the École Normale des Humanités at its disposal, together with the necessary funds for its transformation, and the munificence of M. Montefiore has enabled the new premises to be fitted up in a manner worthy of the traditions of the Institute. The new home of the Montefiore Institute will be ready in October, when the autumn session commences.

Bradford.—At the last meeting of the Town Council the chairman of the Gas and Electricity Supply Committee moved the adoption of the minutes of that committee. The chairman made a statement of the result of the working of the electricity department for the half-year ended June last. He said that the total receipts during the half-year amounted to £2,093, including stock amounting to £109. The total expenditure, including stock at commencement, which was £110, amounted to £1,261, leaving a balance towards what might be called gross profit of £832. For interest on loans there had been paid £469. 16s. 10d., and for sinking fund £392. 16s. 8d., making a loss on the half-year of £30. 5s. 4½d. One hundred and fifty pounds which had been received during the half-year had been placed to capital account. If that had been put down to revenue account there would have been a profit of £120, in addition to interest and sinking fund. The losses on the department since it was commenced were as follows:—First half-year, £1,079; second half-year, £732; third half-year, £315; and last half-year, £30; making a total of £2,157. The amount transferred to the sinking fund to date was £1,942. 9s. 8d. He thought, although nothing had been taken off for depreciation, there was every prospect that the next time the balance-sheet was presented it would show a profit in addition to the payment for interest and sinking fund.

Patent Law in Germany.—Owners of German patents who reside out of Germany would do well, says the Berlin correspondent of *Industries*, to pay more attention to the section in the law relating to patents which provides that the invention embodied in the patent must be manufacured in Germany within a period of three years from the granting of the patent. Some important points in this connection were dealt with in a recent judgment. It was decided that the owner of a patent cannot escape the provision of the law as to the duty of manufacturing the subject of the patent by contending that the demand for it is insufficient to pay the cost of production or of the erection of machinery necessary for carrying on its manufacture. The owner of the patent is required to make every effort to create a demand in the market, and, above all, to manufacture the subject of the patent for that purpose. From these provisions it will be gathered that the German patent law lays especial stress on the duty of a patentee to bring his patent into active operation. It is difficult to give any more exact information to the patentee, as the law only contains a general provision that the subject of the patent must be introduced in Germany to a suitable extent. The judge decides each case on its own merits, with due regard to the special circumstances of each patent, and tries to discover whether a real attempt has been made to introduce the subject of the patent into Germany.

The Board of Trade and Steam Pipes.—The Board of Trade have instructed their surveyors that all new steam pipes are to be tested by hydraulic pressure to not less than twice, and not more than two-and-a-half times the working pressure, unless the case has been specially submitted to the Board for consideration. As regards old steam pipes, for a period of six months from the date of the instruction the surveyors may exercise their discretion as to the test pressure they apply—taking care that such test does not exceed twice the working pressure, and that when it is less than twice the working pressure, the declarations granted are limited to a period not exceeding six months. If in any case the surveyors cannot get such a test pressure applied to old pipes as they consider necessary, they are to forward full particulars of the case to the Board, in order that the necessary directions may be given. After six months from the date of the instruction old steam-pipes are to be tested to a pressure of at least double the working pressure; but double the working pressure is not to be exceeded unless the case has been referred for consideration. The surveyors may test steam-pipes at any time they consider necessary; but, except in special cases, possibly once in about three or four years may be found sufficient. When steam-pipes are tested, the lagging or covering is to be off the pipes, and the pipes are to be carefully examined before, during, and after the hydraulic test. The surveyors are to see that efficient means are provided for the draining of all the steam-pipes.

Priority in Alternating Current Motors.—In its issue of September 2nd, the *Electrical Engineer* of New York alludes to the Tesla-Ferraris priority controversy in the following terms:—"In his essay of March, 1888, Prof. Ferraris expressly denied the practicability of motors that Mr. Tesla already had in successful operation! He hinted at the possibility of using a proper generator for such motors, but no further did he go. Mr. Tesla had already taken coal out of the mine before Prof. Ferraris made his geological survey of the region. With this admission from Prof. Ferraris, it was not very likely that practical men would recognise the great value of the new principle. On examination of Mr. Tesla's now familiar work, we find that he, on the contrary, had not stopped short at a mere rotating field, but dealt broadly with the shifting

Digitized by Google

of the resultant attraction of the magnets; that he had evolved the multiphase system; that he had shown the broad idea of motors employing currents of differing phase in the armature with direct currents in the field; that he first described and used an armature with a body of iron and closed coils symmetrically wound; that he had shown both synchronising and torque motors; that he had shown how machines of ordinary construction might be adapted to his system, and had with specific purpose advanced boldly into new territory, of which there was not the slightest hint or suggestion in the work of Prof. Ferraris. In other words, Mr. Tesla not only went to the bottom of the fundamental principles, but tried them in every detail that inventive ingenuity could hit upon. If this is not so, it is time to have the contrary state of affairs proved before Mr. Tesla loses the credit that such work must give him."

Smoke Annihilation.—Among the innumerable devices which have been pressed into service for the purpose of mitigating the smoke nuisance, specially designed furnaces have not been forgotten. The main object of a system employed by the Gaseous and Liquid Fuel Supply Company is to furnish a secondary supply of heated air at the back of the fire bridge. The air, after passing under the fire grate, goes through an opening at the bottom of the fire bridge, and coming into contact with the carbon monoxide and hydro-carbons which have escaped combustion, consumes these gases, rendering them useful by utilising the heat produced in their combustion. There is a drop arch placed at the point where the heated air supply enters, which arch, becoming incandescent, maintains the temperature necessary for the secondary ignition. That the combustion is achieved in a satisfactory manner the following analysis, says the *Chemical Trade Journal*, will show. The coal employed gave upon analysis:—

Fixed carbon	54·22
Volatile matters, chiefly hydrocarbon, with some sulphur	28·35
Moisture	4·70
Ash	12·73
	100·00

Upon testing the residual gases which were obtained by taking a sample over a period of two hours from the boiler flue, the following results were obtained:—

Nitrogen	83·47
Oxygen	0·69
Carbon dioxide	15·01
Carbon monoxide	0·83
Sulphur dioxide, Free hydrogen and hydrocarbons	Absent.
	100·00

It thus appears that the whole of the hydrocarbons were removed by complete combustion, and the carbon monoxide present practically so, there being less than 1 per cent. present. That an economy is effected by thus obtaining more perfect combustion is proved by the fact that the hydrocarbons, usually allowed to escape unburnt, contain $\frac{3}{10}$ths of the heat of the original fuel, besides rendering the "economisers" more efficient by preventing the formation of sooty deposits upon the tubes.

The Telephone in Madrid.—The telephone made its appearance in Madrid, says M. Pierard in *l'Electricien*, in November, 1883, under State superintendence; the exchange subscribers numbered about 650, more than one-third of whom were officials. In September, 1886, the Madrid Telephone Company took over the business, the Government having worked it at a loss of some £2,000 per annum, and having refused the money necessary to render the system efficient. The Company has an authorised capital of £72,000, of which half has been called up. The exchange subscribers now number some 1,800, or about one to every 270 inhabitants. Ader transmitters and receivers are employed. The circuits are twin-wire and overhead. By a municipal decree no bare overhead wire of a greater length than half a kilometre is allowed, cables are consequently largely used; these are made by Rattier of Paris, and contain 12 7-strand $\frac{1}{10}$mm. wires, and weigh 1,160lb. to the mile. The cables are suspended by steel hooks placed four metres apart, from a 3mm. steel bearer wire. The overhead wires are of silicium bronze and 1·1mm. in diameter. The central exchange is situated in the upper stories of the Hotel de Madrid, the circuits all running to a huge circular metal tower. There are three auxiliary exchanges. There is no need for a multiple switchboard in Madrid, and an old-fashion board, made by the Compagnie des Téléphones de Paris, has proved quite equal to allowing the necessary connections to be effected for the average daily 7,000 calls. The annual rental was originally £24, and is at present £12. For points more than three kilometres from the central office four francs extra per 100 metres is demanded. Two public call offices have been opened, the charge being threepence per five minutes' conversation. The "theatrephone" has found considerable support. The instruments are installed at the "Continental Express" office. A pair of telephone receivers may be had for the entire opera season for £24, which amounts to 4s. per performance.

The Moebius Process.—The *Engineering and Mining Journal* of May 9th, contains an interesting account of the Moebius process of electrolytically separating gold from silver, as carried out at Pinos Altos, Chihuahua, Mexico. This process consists essentially of a mechanical brushing arrangement for keeping the cathodes free from the electro-deposited silver crystals. Oiled muslin bags surround the anodes to collect the separated insoluble substances, and beneath the cathodes there are trays for catching the silver scraped off by the brushes. The electrolyte, which is kept continually agitated, consists of a solution of nitrate of copper, nitrate of silver, and free dilute nitric acid. The silver only is deposited, and whatever copper there is, is left in solution. The *raison d'être* of the nitrate of copper is to make sure that all the lead present is converted into insoluble peroxide at the anode. The gold, platinum, antimony, peroxide of lead, &c., separate at the anodes and fall into the muslin bags. When too much copper has accumulated in the solution, the electrolyte can be regenerated by a simple electrolytic process. The plant at Pinos Altos has a capacity of 3,500 to 4,000 ounces of doré silver per 24 hours, and consists of a tank 12ft. in length, 2ft. wide, and 20in. in depth, divided into seven compartments. Four pure silver sheets are placed in each compartment, as cathodes and six doré bullion plates as anodes. The manual labour connected with the process is very light. Every 24 hours the separated silver and gold is removed. This is done by turning a crank, by means of which the electrodes, the trays containing the silver, and the bags containing the gold, &c., are raised up, leaving only the liquid in the cells. A movable tank on castors, provided with a filtering bottom and a chute extending under the silver trays, is pushed alongside the battery. By removing the pins holding the bottom of the trays, the silver drops on the chute and into the tank. After a superficial washing the silver is ready to be dried and melted into bars of ·999 to 1·000 fine. The bag frames containing the gold are also removed and turned into a tank filled with water, and also provided with a false bottom. The gold is filtered by drawing the water from the tank, dried and melted, whereby the lead and other impurities go into the slag. All the operations are very simple, and skilled labour is uncalled for. The process is a very clean one. There are no fumes and noxious gases, no handling and transferring of solutions. The current employed is 170 amperes, at about 8 volts, which corresponds to an expenditure of only 2½ H.P. for parting 3,500 to 4,000 ounces per day. The doré silver is cast into anode plates 10in. long and 8in. wide, and from $\frac{3}{16}$in. to ¼in. in thickness; the plates weigh, on the average, about 100 ounces. In each of the seven compartments there is room for six plates; therefore it takes 42 plates, or about 4,200 ounces of bullion, to fill the apparatus at the start. The stock solution contains variable quantities of silver up to 300 ounces. The cathodes, which are made of pure silver, represent an intrinsic value of about $1,000. In the United States the process has been in successful operation at the works of the Pennsylvania Lead Company, at Pittsburgh, since September, 1886, where 30,000 to 40,000 ounces of doré bullion are separated daily. The first plant was erected at the works of the Kansas City Smelting and Refining Company. The St. Louis Smelting and Refining Company has lately contracted for a plant of a capacity of 35,000 to 40,000 ounces a day.

MAGNETISM IN IRON AND OTHER METALS.*—L.

BY PROF. J. A. EWING, F.R.S.

(*Continued from page 519.*)

§ 173. **Group of Four Members.**—A better approximation to the facts will be obtained if we deal with a group consisting of four little magnets, with their centres at the four corners of a square (Fig. 141). When the field H begins to act, the members of the group are all slightly deflected, but without at first becoming unstable. If during this first stage the force H is removed, there is no residual displacement. But when H is sufficiently increased the original lines of the group break, and the members tend to pair themselves anew in lines which are more favourably inclined to the direction

Fig. 141.

of H (Fig. 142). Finally, when H is further increased, the members of the group are gradually compelled to take the position sketched in Fig. 143. Next, suppose H to be removed. There will be a return from the condition of Fig. 143 to that of Fig. 142, but the pairing shown in Fig. 142 will be maintained, and this implies a large amount of residual magnetisation. If the direction of H be then reversed, and its value gradually increased, a stage will presently be reached when the resultant polarity of the group suffers an abrupt change through the reversal of the lines in Fig. 142.

The curve of magnetisation—that is to say, the curve showing the resultant polarity in terms of H—for the single group of four members is sketched in Fig. 144.

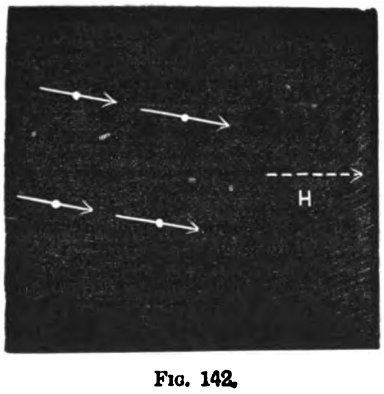

Fig. 142.

From this it is easy to see, in a general way, what would be the form of the curve for an aggregate of many such groups, variously inclined to the direction of H. The transition from one stage to another will be gradual in the aggregate, for it will happen at different values of H in different groups. Hence the curve will assume a rounded outline in place of the sharp corners of Fig. 144.

Moreover, the curve obtained during the removal of H will not coincide with that obtained during the application of H, except the process be stopped at a very early point in the first stage. Whenever the process is extended far enough to cause any of the groups to reach the unstable state we shall find hysteresis. The two curves will not coincide, even in the third stage. Some of the members will pass through an unstable state even there. After the first re-arrangement of the group has taken place, and the lines have become directed as in Fig. 142, there may be second breaking up and passage through instability on the way to the state of Fig. 143. This will happen when the lines of centres have a considerable inclination to H, and especially when the poles of the members are close together. In such an aggregate of groups we may therefore expect to find hysteresis in all possible cyclic changes of the magnetising force. The form of the curve obtained during reversal of H will evidently agree with the general form given by the magnetic metals. In proportion as the corner between stages 1 and 2 in the first curve is comparatively sharp or comparatively rounded so will be the corner at which the rapid descent of the curve begins while H is being reversed.

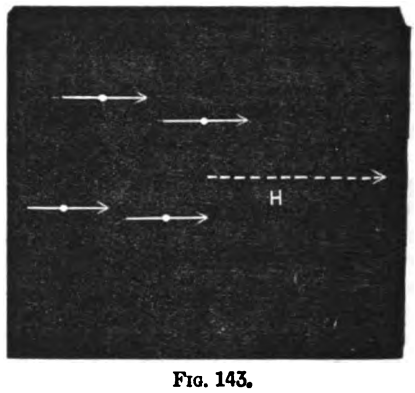

Fig. 143.

§ 174.—**Continuous Distribution in Cubical Order.**—From these considerations regarding groups of four members it is easy to pass to the case of a manifold group or a continuous distribution of members arranged so that the lines of centres form squares. All that has been said above is still applicable. The members arrange themselves in lines, and each individual is mainly constrained by its two neighbours in the same line, instead of by one neighbour as in the case already spoken of.

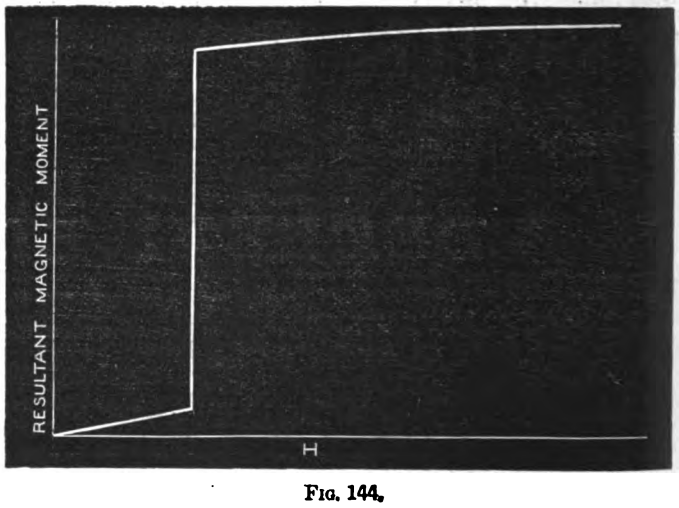

Fig. 144.

The equations of § 172 are readily adapted to members of a long row by substituting $2m^2$ for m^2 in the expression for the restoring moment. The three stages of (1) stable deflection, (2) instability, with rupture of the original lines and formation of new lines, and (3) further stable deflection are as readily traced as before, as will be evident by an inspection of Figs. 145, 146, and 147.

Fig. 145 represents an imaginary primitive arrangement. Fig. 146 is the configuration reached after the breaking up of the primitive lines, and Fig. 147 corresponds to saturation.

It appears, then, that the theory that the magnetic molecules owe their stability to the magnetic action of their neighbours gives results which agree with the observed facts, whether we conceive the molecular structure to consist of isolated groups, with a limited number of members in each, or to be continuous. Even with a continuous distribution the lines of molecules

* All rights are reserved.

Digitized by Google

will, in consequence of the imperfect homogeneity of the piece, be variously inclined at various places, so that the condition necessary to give a rounded outline to the curve will in any case be present. In no piece, except perhaps in a single crystal, could we expect to find that perfect regularity of structure which would be necessary to make the transition from one stage of the magnetising process to another quite sudden, and to give the curve the form of a series of sharp steps.

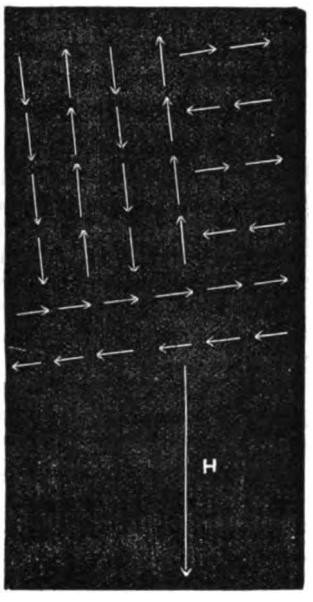

FIG. 145.

Whether we picture the structure as continuous or as built up of isolated groups, special importance attaches to square patterns from the fact that the magnetic metals crystallise in the cubic system. The behaviour of pyramidal forms presents some interesting features that need not be entered into here.

Enough has already been said to show that there is no need to assume that any arbitrary constraining forces act on Weber's

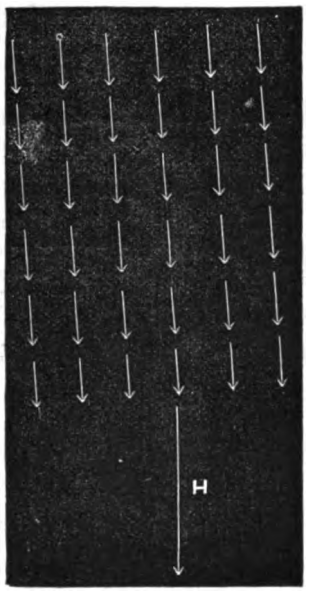

FIG. 146.

molecular magnets. The theory that their constraint proceeds only from their mutual action as magnets evidently suffices to explain, generally, the characteristics of the magnetising process. It may be useful, however, to point out how complete is the agreement, in point of detail, between the deductions which may be drawn from the theory and the facts which have been described in earlier chapters.

§ 175. **Agreement of the Theory with known Facts about Susceptibility.**—In the first stage there is no rupture of molecular ties until the magnetising force is sufficiently increased to bring about instability in the least stable lines or groups of molecules, and until that happens the application and removal of the force has no residual effect. Up to that point the deflections are small, and they are initially proportional to the applied force. All this is in complete agreement with Lord Rayleigh's experiments on the susceptibility of iron and steel to feeble magnetising forces (§ 87), which show that the initial value of the susceptibility is a small constant quantity, and that residual magnetism begins to show itself only when the magnetising force is so much increased that the proportionality of magnetism to force ceases. Again, it accords with the result that a small alternating change of H, superposed on a constant value of H, or acting on a piece which has residual magnetism in consequence of the action of previous forces, produces (after the first application) but a small coming and going of the molecules without breaking their ties, and that if this small alternating force is applied when the magnetisation is already strong, the changes which it causes are reduced in amount (§ 87). Again the theory might lead us to anticipate the fact that, if at any point of the ordinary magnetising process we stop increasing H and begin to decrease it, or stop decreasing

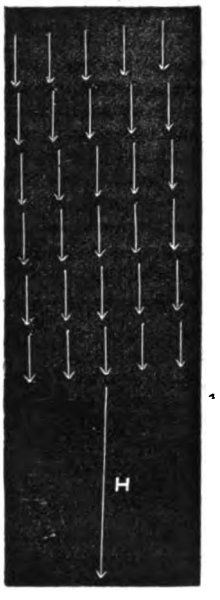

FIG. 147.

it and begin to increase it, the initial rate of magnetic change or value of $\frac{d\mathsf{H}}{d\mathsf{I}}$ is very small, depending, as it does, only upon the quasi-elastic return of the deflected molecules. Their movements through the condition of instability do not begin until the reversal of procedure has been carried some little way.

Again, in strong fields the behaviour of the little magnets accords with the gradually falling off in susceptibility which actually occurs in magnetic metals as the state of saturation is approached. To reach the state of perfect saturation would require an indefinitely strong directing force, but the alignment of the molecules is to all intents complete long before that. In view of the molecular theory it is not surprising that in iron, where many molecular groups break up under a force of no more than two or three C.-G.-S. units, a force of two or three thousand units produces (as we saw in § 102) so nearly perfect saturation that augmenting the force tenfold adds nothing perceptible to the magnetisation.

The quantity which tends to a limit when saturation is approached, is, as was shown in § 93-102, the intensity of magnetisation I, not the induction B. According to the molecular theory, I is the sum per unit of volume of the moments of the molecular magnets resolved in the direction of magnetisation. If n be the number of molecular magnets in unit volume, and m the moment of each, the saturation value of I is $m\,n$.

THE LAUFFEN-FRANKFORT POWER TRANSMISSION.

COMMUNICATED BY GISBERT KAPP.

The distance between the generating station at Lauffen and the receiving stations in the Frankfort Electrical Exhibition is 175 kilometres, or about 110 miles. Power was transmitted over this distance for the first time on August 25th, when the current was supplied to about 900 16 c.p. lamps in the Exhibition, and a few days later the output was increased to 1,100 lamps. There are in the Exhibition two receiving stations, side by side, one for the production of power and the other for the production of light, both being connected in such a way that either power or light, or both together, may be obtained at will. The generator at Lauffen is a Brown "three-phaser," made and supplied by the Oerlikon Works, and the line consists of three hard-drawn copper wires of 160mils diameter, supported on oil insulators fixed to wooden poles 26ft. high. There have been erected in all about 3,000 poles, at an average distance of 200ft., and the total weight of copper in the line is 60 tons. At Lauffen there are three transformers. One of these has been made by the Oerlikon Works, and the two others by the Berlin Electricity Works. At Frankfort there are also three transformers, two made by the Berlin and one by the Oerlikon Works. The transforming ratio of all the six transformers is 1-160, and they are oil insulated. In the power station at Frankfort, which was fitted up by the Berlin Works, the current is used for working a 100 H.P. three-phase motor, designed by Herr von Dolivo-Dobrowolsky. The motor is coupled direct to a centrifugal pump, which supplies water to an artificial cascade 30ft. high. The lighting station at Frankfort has been fitted up by the Oerlikon works, and the lamps are arranged partly on a large signboard of ornamental design in the Exhibition grounds, and partly on lamp-boards in the Exhibition building, which serve for varying the load within certain limits.

Mr. Brown's generator at Lauffen has already been described in *The Electrician* of August 7th. The machine is separately excited, and a rheostat is provided, so that the attendant can compensate the loss of pressure in the line by adjusting the excitation. The common junction of the three armature windings is connected to earth, and the excitation of the field is so adjusted as to obtain from 45 to 60 volts between each branch and earth, according to the amount of power flowing out of the station. The common junction of the low-pressure primary circuits in the transformers is solidly connected to the common junction of the armature windings, and by means of a fuse, to the common junction between the secondary or high-pressure coils of the transformers. The object of this connection will be explained presently. According to the voltage of the three-phaser, the pressure between any line wire and earth is, therefore, from 7,200 to 9,600 volts, and the pressure between any two line wires from 12,000 to 16,600 volts, being $2 \times \sin 60$deg. of that in each branch.

The general arrangement of the circuits from the generating station at Lauffen up to the branches which lead to the power and lighting stations in the Exhibition may best be described by means of the annexed sketch, Fig. 1.

In this sketch G represents the generator or "threephaser," the three sets of coils being diagrammatically indicated by the three thick lines O I, O II, and O III, forming angles of 120deg. with each other. The primary or low-pressure coils of the transformer, T, are similarly represented by thick lines, and the three thin dotted lines o 1, o 2, o 3 represent the high pressure or secondary coils of the transformer. The generator coil O I is connected with the transformer coil O I, first by the earthed wire O O, as already mentioned, and also by an insulated circuit which contains an alternate current ampere meter A_1, a relay magnet R_1, and a fuse, F. The other two set of coils on the threephaser and transformer respectively are similarly connected. The voltage in the three branches is indicated by the three voltmeters V_1, V_2, V_3. The relay magnets are arranged for minimum and maximum current, and if the current in any of the three branches of the threephaser should fall short of the minimum, or pass beyond the maximum value for which the relays are set, the relay in that branch cuts off the exciting current from the field of the threephaser. The voltage obtained then in the low-pressure circuit at the generating station is simply that due to the residual magnetism in the threephaser, and therefore perfectly safe even in case of a short-circuit in the primary wires. It would, of course, have been possible to so arrange the relays that in case the current in any branch becomes abnormal from whatever cause, the motive power (in this case a 300 H.P. turbine) is automatically shut down. This would, however, be a somewhat drastic remedy, especially if the disturbance is of a trivial character and capable of adjustment without stopping the machinery. As soon as the exciting power and with it the load is taken off, the turbine begins to race, and this is, of course, immediately noticed by the man in charge at Lauffen, who may then use his discretion whether he will shut down or not.

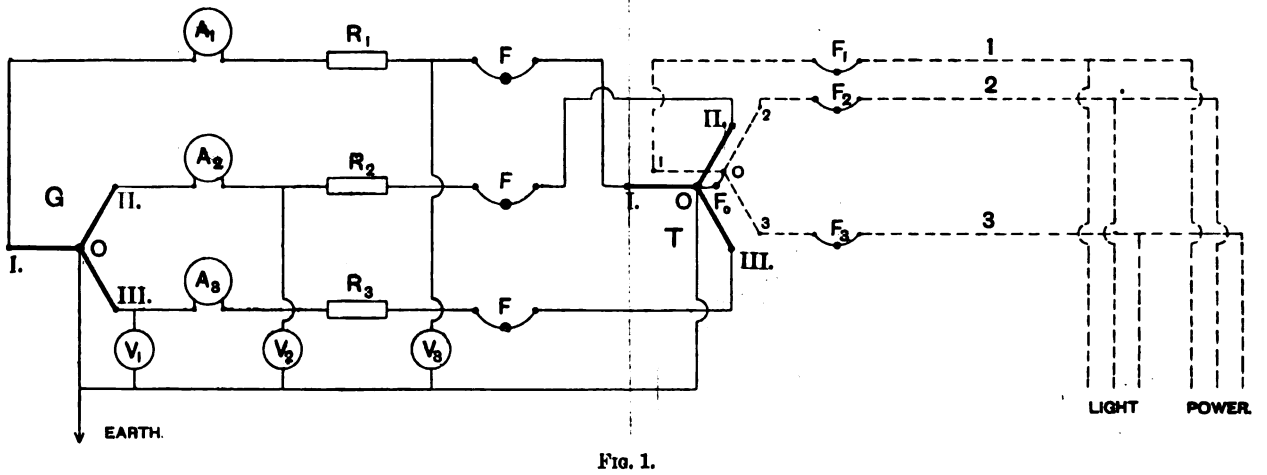

Fig. 1.

The fuses, relays, ampere meters, and voltmeters belonging to the low-pressure or primary circuit at Lauffen are mounted upon one board, which also contains the voltmeter and ampere meter for the exciting circuit, and the rheostats for the latter, by which the voltage of the threephaser is adjusted. In order to compensate for the ohmic resistance of the line, the attendant works by a table giving the primary voltage corresponding to various currents, so as to keep the pressure at Frankfort constant at varying loads.

It will be seen that the arrangements of switchboard and instruments at the generating station are of the simplest possible character. In the high pressure or secondary circuit there are no switches, but merely three fuses, F_1 F_2 F_3, as shown in the diagram. To make a fuse for 10,000 volts is not an easy problem, but it has been solved by Ferranti and others, and any of the existing forms of fuses might have been accepted for Lauffen. Since it is, however, the intention of the two firms

Digitized by Google

who have carried out this transmission plant to work later on at double the present pressure (by using two transformers at each end with their thick wire coils in parallel and their thin wire coils in series) it was thought safest to arrange the fuses in such a way that there can be absolutely no doubt as to their satisfactory working even at 20,000 or 30,000 volts. The method of mounting fuses on a board inside the station has, therefore, been abandoned, and the fuses have been placed out, side, where they form part of the line. As already mentioned, the line wires are 160 mils. in diameter. Close to the generating station there is a short piece of line in which each of these circuits consists of a pair of copper wires of only 6 mils diameter, and about 8ft. in length. There are two posts placed that distance apart to which the line wires are shackled, and the fuse wires serve to bridge the space between the posts. To facilitate the renewal of the fuses the posts are provided with steps. This provision is necessary because the line is at Frankfort frequently short-circuited on purpose to advise the man in charge at Lauffen that he may shut down. For this purpose there is suspended over the three line wires at the Exhibition an angular stirrup or bridge of iron, which can be lowered by a cord so as to make metallic contact between the three wires. The fuses at Lauffen are thereby melted, and the man in charge stops the machinery. Telephones are then switched on at both ends, and the line wires are used to speak between the two termini. As long as the stirrup is on the wires in the Exhibition, it is perfectly safe to use the telephone, even if by some mistake the machinery at Lauffen were started whilst a person is on the telephone. The only effect in this case would be to immediately melt the fuses again, and as their replacement gives some additional trouble to the man in charge, he will in his own interest take care not to start the machinery before the appointed time.

It remains yet to describe the provision made to guard against accidental injury to life or property in case one of the line wires should break and fall to the ground, or an earth should occur on the line through some other cause. As will be seen from the sketch the common junction O of the thick wire coils of the transformer at Lauffen is joined by means of a fuse F_0 with the common junction O of the thin-wire coils.. The electrical centre of the whole system is, therefore, permanently connected to earth. Suppose now that the line wire 1 should break at any point between Lauffen and Frankfort and fall to the ground, the broken end will make earth, and the corresponding fuse F_1 in the line at Lauffen will go. Possibly the junction fuse F_0 will go. The line 1 is thus cut out. In all probability the fuse in the low-pressure circuit I will also melt; but should this not be the case, the current in this branch will be very much reduced, and set the relay R_1 in action, whereby, as already explained, the excitation is cut off, and the dangerous pressure is immediately taken off all the three line wires.

We have yet to describe the general arrangement of the circuits in the power station at Frankfort (Fig. 2). The primary and secondary of the transformers (of which only one is shown, the other being a spare transformer at present) are again earthed at their electrical centre, and the same remark holds good for the field and armature of the motor. The latter is shown diagrammatically in the same way as if it were a transformer, though this representation is not quite correct. The armature and field coils do, of course, not remain in the same relative positions to each other, but for the sake of simplicity the diagram may be accepted as sufficient for our purpose. In reality, the field revolves with a greater speed than the armature, the difference in speed or magnetic slip producing the E.M.F. in the armature. Now the torque of the motor is proportional to the strength of the field and to the armature current, which latter increases with the E.M.F., and, therefore, with the magnetic slip. If the magnetic slip were zero, that is, if the armature revolved with the same speed as the field, there would be no E.M.F. in the armature coils, and, therefore, no current and no torque. A motor of this class can, therefore, not run synchronously, but must run the slower the more the load is increased. The variation in speed between full load and no load can, however, be made as small as desired by the simple expedient of using an armature of low resistance, so that even a slip of 5 per cent. or 10 per cent. shall produce the maximum current required at maximum load. In this respect the three-phase motor is identical with an ordinary continuous current motor with constant field, since also in this case the speed of the armature decreases as the load increases. To obtain more or less uniformity of speed is, therefore, simply a question of the amount of iron and copper which the designer chooses to employ for a given output; but it should be remarked that by increasing the section of the armature conductors so as to get very little magnetic slip, there is danger of producing a machine which will not readily start at full load. The reason is obvious. A very low armature resistance means

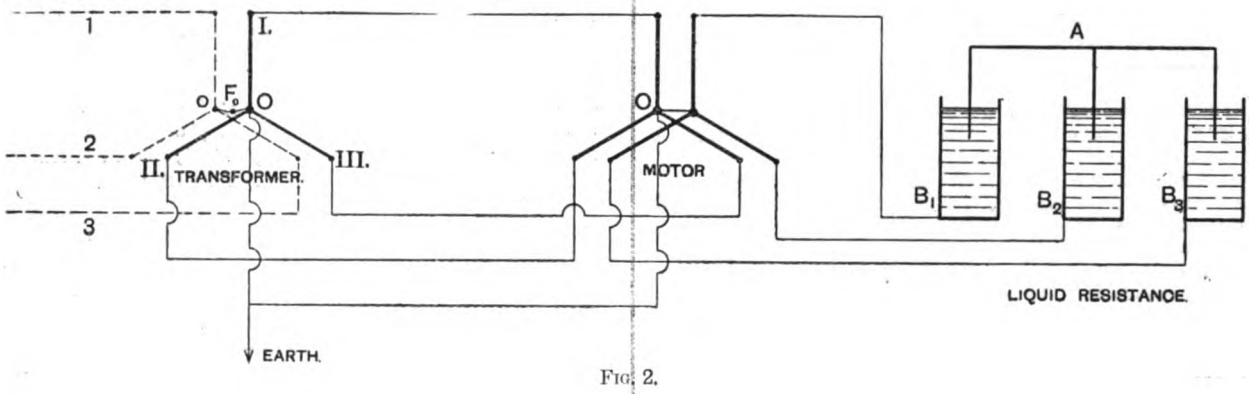

FIG. 2.

an enormous armature current at the moment of starting when the magnetic slip is 100 per cent. Now, this enormous armature current reacts very strongly on the revolving field, which is, so to speak, blown aside by the ampere turns in the armature. This may, at first sight, seem a very serious drawback to the three-phase motor, but Herr von Dobrowolsky has hit upon a very simple and ingenious remedy. Instead of short-circuiting the armature coils at starting, he inserts into each of the three branches a liquid resistance, consisting of an iron vessel filled with an alkaline solution, into which an iron plate can be dipped to a greater or lesser depth. The three vessels, B_1, B_2, B_3, are insulated from each other, but the three iron plates are joined by a metallic bridge, A. At starting, the plates are immersed only slightly, and the resistance which is thereby interposed in each of the three armature circuits prevents the creation of abnormally strong armature currents, which would otherwise blow the field aside. As the motor gathers speed the plates are more and more lowered until the whole of the liquid resistance is short-circuited, and the motor works without external waste of energy. As regards the question of efficiency, no definite data are, as yet, available, since the Commission have not yet begun to make their measurements. If we may judge from the absence of heating, vibration, noise, and the general sweetness of the running of this motor, there is every reason to hope that the efficiency will be as high as with a direct-current motor of the same size. A rough test, which the writer was permitted to make on a three-phase motor of 2 H.P., gave an efficiency of 82 per cent.

Advertisement Rates, &c., forwarded on application as above.

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday. Renewals of expiring advertisement orders and alterations to standing advertisements should be in Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday.*

SMALL PREPAID ADVERTISEMENTS *accepted up to 4 p.m. Thursday.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, 1891, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with well-written Biographical Notices of leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1891 should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Prospectuses free.

ELECTRICAL BOOKS AND PUBLICATIONS

All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

"THE ELECTRICIAN" *Series at present consists of—*

THE ALTERNATE CURRENT TRANSFORMER IN THEORY AND PRACTICE. By Dr. J. A. FLEMING. Vol. I. Price 7s. 6d., post free.

THE ART OF ELECTROLYTIC SEPARATION OF METALS (Theoretical and Practical). By Dr. GEORGE GORE. Price 10s. 6d., post free.

PRACTICAL NOTES FOR ELECTRICAL STUDENTS. By A. E. KENNELLY and H. D. WILKINSON. Vol. I. Price 6s. 6d., post free.

THE STEAM ENGINE INDICATOR AND INDICATOR DIAGRAMS. Edited by W. W. BEAUMONT. Price 3s. 6d., post free.

ELECTRO-CHEMISTRY. By Dr. GEORGE GORE. Price 2s., post free.

Several Further Volumes in Active Preparation.

NOW READY, IN TWO VOLUMES.

"THE ELECTRICIAN" PRIMERS.

Fully Illustrated.

Price: Stout paper covers, 2s., post free, 2s. 2d. each; strong cloth, 2s. 6d., post free, 2s 9d. each. Single Primers, 3d., post free, 3½d. Abroad postage extra.

CONTENTS OF THE CURRENT NUMBER.

STEEL-PLATE PORTRAITS

Of W. H. Preece, F.R.S.; Michael Faraday (out of print); Sir John Pender, K.C.M.G.; Sir William Thomson, F.R.S. (Past-President of the Institution of Electrical Engineers); C. H. B. Patey, C.B. (Late Secretary of Telegraphs, G.P.O.); Dr. John Hopkinson, F.R.S. (Past-President of the Institution of Electrical Engineers); Dr. Oliver J. Lodge, F.R.S.; Prof. William Crookes, F.R.S. (President of the Institution of Electrical Engineers); Willoughby Smith (out of print); and Prof. von Helmholtz, have been issued as Supplements to "THE ELECTRICIAN."

A few Copies of these admirably-executed Steel Engravings can be supplied, price 1s. each, post free on roller, 1s. 2d. Or framed in neat Black Pillar or Brown Ornamental Frames, price, 4s. 6d, carriage paid (U.K.)

NOTICE.

"THE ELECTRICIAN" PRIMERS, in 2 volumes, bound in cloth (2/6, post free 2/9, each), or in paper covers (2/-, post free 2/2, each), are NOW READY.

Full particulars and Prospectus on application to the Publisher.

UNITS, NEW AND OLD.

The question of units and their nomenclature will, in all probability, afford a topic for discussion, an excuse for suggestion, and a subject of controversy for many years to come. There are a good many busy people who are well content with our present supply of units; they make daily use of some of them, such as the ampere, volt, and ohm, and never even think about others, such as the dyne, the erg, and the coulomb, from one year's end to another. To some of the ultra-scientific minds there is a quasi-sacred character about the C.-G.-S. system; it appears to them that it should be accepted by that inferior animal the practical man as a revelation, and they accordingly try to trip him up if they hear him speak of an ampere-hour. If he happen to know that by an ampere-hour he means three thousand six hundred coulombs he will, perhaps, ask what could have induced the apostles of the C.-G.-S. gospel to invent such a miserable little unit. Coulombs and dynes may be suitable for gnomes and elves to use in the laboratories where glow-worms get their tails charged; but a ROTHSCHILD might as well transact his operations in cash with centime coins as an engineer measure his engine output in ergs.

Digitized by Google

There will always be some one to suggest new units, to modify the present ones, and to coin fresh names. The amusing occupation of name-making is not confined to the christening of brand new units like barads and boles, but may be practised with the praiseworthy motive of bringing unpopular units into common use. The professor in his lonely study may contemplate a gramme moving with the velocity of a kine and delivering the blow of a bole. He hardly dare teach these things to his class; and such matters remain, like the esoteric doctrines of the Egyptian hierophants, as a subject which they may only discuss with one another. Units can acquire a vital existence only by becoming used in daily work, and they must not merely be fit for use but there must be a need for them.

An attempt was made by Prof. STROUD at the British Association this year to vitalise the dyne. The idea seems to be that it must first be multiplied until it is big enough for the practical man to recognise it as being comparable to the forces with which he is concerned, and, secondly, it must be given a name sufficiently free from pedantry. Neither dynam nor hebdomadyne have the smallest chance of success, and there is no precedent for torturing the honoured name of a distinguished man into a slang title for a mechanical unit. That has been left for electricians; slang being defined in the dictionary before us as "the jargon of some particular calling or class in society, as the slang of the theatre, of college, of sailors, &c." How few colleges of science are guiltless of contributing to such slang as this?

There has been an uneasy feeling among a few of the priesthood who look after these mysteries, that even the volt and the ampere were rather hastily chosen, and that the practical man might get along with fewer figures if these units were multiplied by ten. When professors get from five to seven months' holiday it can easily be understood that, as far as their mere duties go, they have time enough to pay attention to these matters; and such a change as this might even be rather pleasant, and would form an item to be corrected in the next edition of the text book. But the unhappy practical man, whose attendance at his office from ten to six nearly all the year round is but a portion of his work, finds the erg and dyne to be hopelessly infinitesimal, though he has never been heard to complain of the smallness of the unit of current and voltage. He may well be thankful that the Electrical Standards Committee, with all their science and lofty attitude towards him, have allowed these to pass, and have by their resolutions rendered any further change impossible.

A new and shockingly unscientific unit, the electrical horse-power, is insensibly coming into use, although no sanction has been asked from the Committee of the British Association, which is kind enough to look after these matters. The watt is a paltry little unit. Unit-making was in its infancy when Sir WILLIAM SIEMENS called this into existence. There had been a long pause, broken only by the change of the ambiguous weber into the ampere. But the watt, though popular enough in this country, is not generally accepted on the Continent, perhaps on account of its extremely foreign spelling, not a few founts of French type being destitute of the initial letter. Popular as it is, we very rarely have to deal with a single watt in practice. For most engineering purposes the sixty-fourth of an inch, being the smallest division on a rule, is the smallest length that is considered; so the watt, of which sixty-four go to a sixteen-candle lamp, is the smallest amount of power that need frequently concern the engineer. He unconsciously sins pretty often in using the watt as a unit of energy, but the priesthood never call him to account for it.

It might have been expected that as the smallest dynamo which it is worth while to build—except for amateurs to amuse themselves with—gives from one to two thousand watts, the unit of power would be found rather small. Of course the kilowatt was produced almost before the inconvenience was recognised, and a few dynamo makers wishing to appear to be up to date, timorously adopted it. It has been confidently hoped that the kilo-watt would quietly supersede "the picturesque term 'horse-power,'" as it has been called; but we see, as yet, no indication of this. It has, however, become more common of late to speak of an electrical horse-power, and the 746 seems to disconcert the practical man as little as the 112, the 2240, the 1760, or any other of those numbers which the decimalist bids him renounce, or even the 3·14159, from which there seems to be absolutely no possible escape, even by the joint action of the British Association, the Board of Trade, and the Privy Council.

REVIEWS.

Primary Batteries. By HENRY S. CARHART, Professor of Physics in the University of Michigan. (Boston: Allyn and Bacon. 1891.)

Many people, we believe, share our feeling that there is something innately immoral about "primary batteries." They are associated with so many lies and so much impudent imposture, with nonsense talked and money wasted, that the title of the present book at once conjures up a vision of wonderful secret depolarizers at so much a gallon, of valuable waste products, and of smelly offices of syndicates whose chief discovery is that a little nitric acid freshens up a bichromate battery.

Prof. Carhart does not deal with such matters, but, beginning with Volta's pile, he developes the subject of the theory and the construction of batteries, discussing the practical effects of polarization and amalgamating zincs very fully. The Bunsen cell does not hold quite so important a position as it did a few years ago, since most laboratories and lecture-rooms are provided with dynamos or storage batteries; but it is worthy of more than a single page, and some hints might be given as to securing a good contact with the carbon, and the need for taking to pieces after use. The author divides batteries into the open circuit and the closed circuit class. The former are adapted, and the latter are unfitted, for standing idle on open circuit. The distinction is worthy of consideration, but the conditions cannot be clearly defined in practice. A number of forms of the Leclanché cell are described and illustrated, several of them being unknown in this country. The Gassner and Meserole dry cells are the only two of this important class which are mentioned; and we hope that the author will turn his attention to the several very useful batteries of this kind which are now on the market. A short chapter deals briefly with standards, including various forms of Clark and Daniell cells. An interesting chapter is devoted to the testing of batteries, and contains numerous diagrams giving plotted curves of output, polarization, resistance, and recovery of voltage. One section, on the "Analysis of the Temperature Co-efficient of a Battery" has already appeared in our columns (p. 167 of the present volume of *The Electrician*). This excellent little book concludes with a chapter giving a short sketch of the thermal relations—that is, the heat evolved, the heat of combination of ions, and Helmholtz's thermo-chemical considerations.

In common with nearly all other books, too little attention is given to the actual internal resistance of the cell as a whole, of the various parts of the internal circuit, or the relation between the polarisation, internal resistance and dimensions of the elements and thickness of porous cells, and of solutions and their density. A little more exactness as to output would be useful, as when, after describing a Gethins battery, the author informs us that "three of these cells in series will keep a storage battery charged so that it will run a phonograph as much as is required

Digitized by Google

for a private office." We gather from this that it would heat to redness quite a considerable piece of platinum wire. Sir William Thomson's Tray battery, it is said, may have an internal resistance as low as 0·2 ohm, but no quantitative information is given as to the connection between this resistance and the dimensions of the battery. We are quite aware that no other author has taken the trouble to go into this, but Prof. Carhart gives us so much that is useful in this work that we are tempted to ask for more. We notice that no reference is made to "lithanode," but though this has been talked about for some years, circulars relating to its practical use have only just been issued, and perhaps the author has done wisely in confining himself to his own experience. Another omission, justified no doubt for the same reason, is the Weymersch battery, for which the language in the opening paragraph of this review is perhaps a little too strong.

Telegraphy. By W. H. PREECE and J. SIVEWRIGHT. Ninth edition; revised and enlarged. (London: Longmans, Green and Co. 1891.)

The whole of the telegraphic communication of this country being practically in the hands of the Post Office, there is no great demand for text books on the subject of telegraphy. There is, as a matter of fact, only one book in general request—that is, the one which has reached its ninth edition, and is now before us. It is by no means a mere reprint, but has been brought thoroughly up to date by including, *e.g.*, descriptions of the Delany multiplex system and its development, and a good elementary account of telephony. The second chapter, in which the practical forms of batteries are described, is full of hints as to setting up and maintenance, but says little or nothing about the actual internal resistance, or the number of cells required on different lines in practice. We cannot find any mention of the current or the number of cells required for working the Wheatstone automatic; and though the number of cells for the Delany system is given, there is no clue to the working current. Milliamperes are still regarded as new-fangled innovations by some telegraphists. It is only a few years ago that resistances were given in miles of iron telegraph wire and voltage was measured in Daniells. Our Post Office engineers and operators are perfectly familiar with milliamperes, and it would be well to let the student know from the first the kind of currents he has to deal with. For clearness of style and completeness of description this book cannot be beaten, and in this respect we are not aware that it has a competitor.

Chapters on Electricity. An Introductory Text Book for Students in College. By SAMUEL SHELDON, Professor of Physics and Electrical Engineering, Polytechnic Institute of Brooklyn. (New York: Charles Collins.)

This rather meagre book is Part VII. of Olmstead's College Philosophy, and is "intended for use as a text-book by students in those colleges which devote but thirty or forty hours to the subject." It is open to question whether a smattering can best be obtained from the careful study of a few chapters into which the author has attempted to compress the leading principles, to the exclusion of details of apparatus or demonstrative experiments, or by a perusal of a larger and more attractive treatise which will not demand so much mental concentration.

Telephones, their Construction and Fitting. By F. C. ALLSOP. (London: E. and F. N. Spon. 1891.)

Coming most opportunely when telephones of all sorts and qualities are being at length freely sold, this book will enable anyone of ordinary intelligence to fit up ready-made instruments, and it contains sufficiently complete and well-illustrated descriptions of them to allow many of them to be made at home.

Thoroughly practical directions are given for running overhead wires and leading in; but the chapter on connecting up is, if anything, rather alarming, since the author discusses some twenty different arrangements with as many diagrams. A brief chapter on small exchanges for hotels, &c., and one on testing conclude the book. The last section describes very clearly and with full detail a number of common faults, and gives simple directions for locating the trouble and remedying it.

An Introduction to the Mathematical Theory of Electricity and Magnetism. By W. T. A. EMTAGE, Examiner in the School of Natural Science, Oxford. (Clarendon Press. 1891.)

This text-book aims at being "complete in itself, and may be read without previous knowledge of the subject." We do not know to whom it is addressed, but we suppose that as a science school is springing up at Oxford, text-books must be written by the examiners as elsewhere. The treatment of the subject is purely academical; it goes over a good deal of the ground covered by Maxwell in an elementary style, considerably too stiff for the ordinary engineer, but yet offering few apparent advantages to the mathematical student. The real want of to-day is some explanation of the more difficult branches of electrical science, treated, perhaps, in a mathematical manner, but with the view of teaching something or of elucidating something, and not as a mere branch of mixed mathematics. It is possible that such a book as this may interest some mathematical student who, having thus had his attention turned to electrical science, might eventually assist in developing it. If this should happen, the book will, in an indirect manner, prove of some use. Without wishing to detract in any way from the educational value of the book, we may mention the fact that the alternate current transformer is not alluded to in its pages, lest students of this difficult branch of electrical science may turn to them hoping to find some help.

THE ETHER AS A POWER TRANSMITTER.

BY S. TOLVER PRESTON.

It may be of interest to view the ether in the aspect of a transmitter of power. We know that a belt will convey more power by the same stress, the greater the velocity at which it runs. So now that the ether in the case of our batteries and dynamo circuits is recognised to be a power conveyer, or to play the function of a belt or belts, we may comment on its adaptation for that object as a mere question of mechanics. The ether conveys power at the velocity of a well-known speed unit, viz, that of light. So that the ether may be very well compared to a belt moving at this speed when carrying over energy.

It may be a fact worth noticing (since heat waves and electric waves are now recognised as identical) that singling out any column of ether, say, one square foot in sectional area resting on the sun's surface normally, then, as a truth, it carries off 7,000 H.P. continuously. This is a fact recognised to be grounded on the firm basis of experiment. It is easily computed by remembering that the energy of the heat waves next the solar surface is 46,000 times their energy (measurable) at the earth's surface. The 7,000 H.P. equals 1,720 foot tons of energy propelled through the ether column a foot square per second; and in carrying off this energy, no more than 27 foot grains of energy is traversing or contained in any prismatic section of the transmitting ether column a foot long and a foot in area at any given instant. This is evidently because the column transmits the energy so rapidly that it does not require to carry much all at once. It is somewhat comparable to a belt going at the velocity of light, which in conveying 7,000 H.P. would only be under a stress of 27 grains; this being cursorily mentioned in a previous article (*The Electrician*, August 14th). The realisation of facts of the character above cited may contribute to make one regard the ether as a highly practical mechanism, rather than as the vague, purposeless sort of existence some are liable to consider it, unless the meaning of the above *rôle* played by the ether be grasped as a true physical conception.

It may be difficult to imagine that there should be no back pressure or reaction of the ether against the solar surface in carrying off such an enormous total of energy, even if the impulses be mainly transverse; and it would seem probable that there is some reaction, as we, perhaps, never deal with radiant energy on a scale sufficient to measure any. Perhaps the only ether structure where an entire absence of reaction might be imagined is one partly based on an idea of mine relative to the

Digitized by Google

mechanism of gravity. Maxwell, in reference thereto, suggested (perhaps more as an interesting mechanical point than with a serious view of the existence of his idea in nature) that "It is easy to see that we might form a theory in which the molecules [of ether] never interfere with each other's motion of translation, but travel in all directions with the velocity of light; and if we further suppose that vibrating bodies have the power of impressing on these molecules [of ether] some vector property (such as rotation about an axis) which does not interfere with their motion of translation, and which is then carried along by the molecules, and if the alternation of the average value of this vector for all the molecules within an element of volume be the process which we call light, then the equations which express this average will be of the same form as that which expresses the displacement in the ordinary theory" ("Encyc. Brit.," 1878, article "Ether," p. 572, &c.)

There is an obvious difficulty about the molecules, or rather ether atoms *never* interfering with each other's motion of translation, but it may be diminished to any extent by imagining the atoms adequately small. Might I venture to ask here if vortex atoms, which, it seems, have a natural proper motion, would not tend to acquire all the same velocity, if the path were adequately long, and to have a velocity equal to that of light under suitable conditions? Here it may form at least a noteworthy point of mechanics to imagine how such ether atoms could, in passing through the open structure of the vibrating molecules of gross matter, receives *transverse* impulses, without the slightest back reaction or rear thrust against the body emitting* the light. This, I must confess, is the only way in which the idea of a total absence of back stress in the conveying away of energy can present itself to my mind. The above suggestion of Maxwell may be viewed at any rate as a thoroughly clear mechanical conception.

THE DETERMINATION OF CURRENTS IN ABSOLUTE ELECTRO-MAGNETIC MEASURE.

BY G. F. C. SEARLE, M.A.

(*Continued from page 527*).

§ 9. **Stokes's Theorem.**—We can now proceed with Prof. Stokes's proposition. This may be stated as follows: Take any closed surface S (Fig. 7) in a magnetic field. Take a small area, α, at P and let F be the magnetic force at P resolved in the direction of the outward normal to the surface. Take each

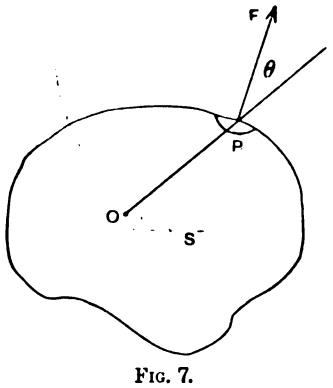

Fig. 7.

element of the surface and find the product $F\alpha$ for each, add all these products together, and let $\Sigma F\alpha$ denote the sum. The proposition we have to prove is that $\Sigma F\alpha = 4\pi$ + (quantity of north magnetism inside).

Take, first, the case of a single north pole of strength m at any point O inside the surface. Let OP produced make an angle θ with the outward normal, and let $OP = r$. Then the magnetic force at P is $\frac{m}{r^2}$. Resolved along the outward normal this gives $F = \frac{m\cos\theta}{r^2}$. The contribution of the small area α at P to the sum $\Sigma F\alpha$ is, accordingly, $\frac{m\cos\theta \times \alpha}{r^2}$. But $\frac{\alpha\cos\theta}{r^2}$ = solid angle subtended by α at O. Let this small solid angle be ω. Then the contribution from α to the sum is $m\omega$. Adding all the contributions together we have $\Sigma F\alpha = m \times$ (whole solid angle subtended at O). When O is inside the surface the solid angle $= 4\pi$, so that we have for this case $\Sigma F\alpha = 4\pi m$. If we had taken O outside the surface, the solid angle would have been zero, and in this case $\Sigma F\alpha = 0$. We may accordingly write quite generally $\Sigma F\alpha = 4\pi \times$ (strength of pole inside surface). If there are any number of poles, some inside and some outside the surface, the above result applies to each one, and hence by addition we obtain the result $\Sigma F\alpha = 4\pi \times$ (total amount of north magnetism inside the surface). A south pole must, of course, be counted as a negative north one.

§ 10. **Tubes of Force.**—Now (Fig. 8) take a small area α at A perpendicular to the direction of the field at A, and draw lines of force from all points of its boundary. Let the tube so formed be cut at A′ by another area α' perpendicular to the lines of force at A′. We suppose that there are no magnetic substances inside the part of the tube included between A and A′. Let F, F′ be the magnetic forces at A and A′ respectively. Since there are no poles inside the surface formed by the sides of the tube and the two ends A, A′, we have, by applying Prof. Stokes's theorem,

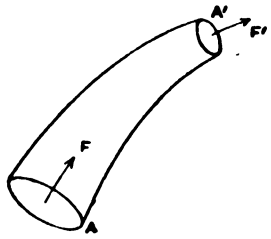

Fig. 8.

$\Sigma F\alpha = 0$. But since the magnetic force at any point on the side of the tube is parallel to the side of the tube, the sides contribute nothing to the sum. The contribution from A′ is $F'\alpha'$, and that from A is $-F\alpha$. Hence $F'\alpha' - F\alpha = 0$, or $F\alpha = F'\alpha'$. Thus the product of the magnetic force and the cross-section of any very small tube of force is constant for all points along the tube.

Now let us draw a number of lines of force through the area A, arranging them so that there are F lines of force passing through each square centimetre of the area A. The whole number passing through A is therefore $F\alpha$. These lines run along inside the tube, emerging again at A′, $F\alpha$ lines of force passing through an area α'. Hence the lines per square centimetre passing through A′ is $\frac{F\alpha}{\alpha'}$. But by Stokes's theorem $F\alpha = F'\alpha'$, and therefore $\frac{F\alpha}{\alpha'} = F'$. Thus the number of lines per square centimetre passing through the area at A′ = magnetic force at A′. Thus, if we take any surface so that the magnetic force is everywhere normal to it, and from this surface draw lines of force so that the number of lines per square centimetre passing through this surface anywhere is equal to the magnetic force there, then this system of lines of force will represent completely at all points of the field both the direction and magnitude of the magnetic force—the direction being indicated by the direction of the lines, and the magnitude by the number of lines passing through a square centimetre placed perpendicular to the lines.

We have just seen that when the strength of the field is F the number of lines of force through a square centimetre, placed perpendicular to the lines, is F. Hence, the area occupied by

* Of course, it will be seen that this is not an emission theory of light. Particles are not ejected from the luminous body under this theory. It is an undulatory theory where the mechanism of light is always in motion—streams of particles moving equally in all directions through space, and acting as "vectors" to carry the luminous energy off. Here no other than transverse impulses are mechanically possible.

Digitized by Google

each line is $\frac{1}{F}$ per square cm. We obtain, perhaps, a better idea of the state of the field if we suppose it filled with *tubes of force*, the cross section of each one at any point where the magnetic force is F, being $\frac{1}{F}$ square cm. We may, if we like, regard the *lines of force* as core lines of the tubes of force. For most purposes, we may use either the lines or the tubes of force indifferently. When we consider how the energy is stored in the magnetic field, we shall find it better to use the tubes of force.

§ 11. **Number of Lines from a Magnetic Pole.**—Take a single pole of strength m, and about it as centre describe a sphere of radius r. At any point on this sphere the magnetic force due to m is $\frac{m}{r^2}$. Hence, according to the plan which we have adopted for drawing lines of force, there are $\frac{m}{r^2}$ lines of force passing out through each square centimetre of the surface. The whole surface of the sphere is $4\pi r^2$, so that the whole number of lines passing out through the sphere, or, what is the same thing, the number of lines proceeding from the pole is $4\pi m$, independent, as it ought to be, of the size of the sphere. Thus, from every pole of strength m there proceed $4\pi m$ lines of force. If we take any solid angle ω with its vertex at m, then, since the lines proceed equally in all directions, the number of lines passing out through the solid angle is $m\omega$. If we have a magnet each of whose poles is of strength m, there will be $4\pi m$ lines of force proceeding from the north pole, and as many converging into the south pole. The lines

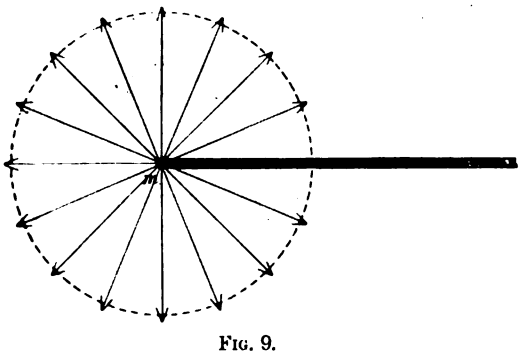

Fig. 9.

complete their course by running back again through the iron to the north pole. When in the iron, they have to be drawn so as to represent not the magnetic force but the magnetic induction. In air the magnetic induction is the same as the magnetic force, but in iron the two are very different, but as we are only going to deal with the action of currents in air, we have no need to go into the question of the difference between the magnetic force and the magnetic induction in iron. We shall, however, use the term *magnetic induction*, even when we are dealing with air, since our results would then be true in case the air were replaced by a magnetic medium; on other occasions, when the result depends upon the magnetic force, whether in iron or air, we shall use the term *magnetic force*. The magnetic induction in passing from iron to air is continuous, *i.e.*, does not suffer any sudden change in its value, while the magnetic force experiences a sudden alteration in its amount. In isotropic media the magnetic induction and the magnetic force are everywhere both in the same direction. We ought now to restate the proposition of the present section as follows. From a pole of a magnet of strength m (Fig. 9) there proceed $4\pi m$ lines of induction into the air, and $4\pi m$ lines of induction run through the iron up to the pole. In fact, the relation of the magnetic induction in the air to that in the iron is very much like that of the spray from a fine rose to the stream of water flowing to it from the supply pipe; the law of continuity applies in both cases. The tubes of induction are very thin in the iron, and spread out into much fatter tubes in the air.

§ 12. **Superposition and Resolution of Magnetic Fields.**—It is often convenient to resolve the magnetic force (or induction) into components in any chosen directions. We may suppose that each of these component fields is represented by the appropriate distribution of the tubes of magnetic induction in its own direction. But we must only make use of this representation in a perfectly uniform field, or in a part of the field so small that we may consider it uniform throughout that part. The reason for this is that except in a perfectly uniform field the tubes drawn to represent the field in any given direction would not be continuous, *i.e.*, they would have to start with *ends* in order to represent the magnitude everywhere of the component of the induction in their direction. A tube of induction is always closed upon itself so that it cannot do this, and our representation would fail. But in a very small part of the field we may use the principle indicated above with safety.

§ 13. **Magnetic Potential.**—The work, measured in ergs, expended upon a unit north pole in bringing it from an infinite distance to any point of the magnetic field is called the *magnetic potential* at that point. If infinity is too great a strain

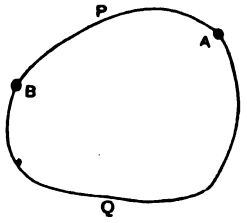

Fig. 10.

upon our imagination, we may say that the potential at any point is the work done in bringing a unit pole to that point from a very distant region where the action of the system producing the magnetic field is inappreciable. This is the same as the potential energy of the unit pole when at the chosen point. One or two very important propositions concerning the potential are very easily established.

(1.) The work done in taking a unit pole from A to B (Fig. 10) does not depend upon the path taken; for if the work were different for the two paths, A P B, A Q B, we could, by making the pole go round the complete path, A P B Q, in the right direction, obtain as much work from the system as we please by making the pole go round its path a sufficient number of times; this, unless some energy has been supplied from other sources, is contrary to the principle of the conservation of energy, and must be considered impossible. Thus the work done in going from A to B, or the difference of potential between A and B, is the same by whatever path we go.

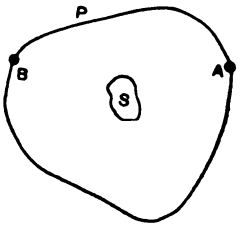

Fig. 11.

There is, however, a very important exception to the above statement. If there is an electric current flowing along a conductor, of which S (Fig. 11) is a section, then, unless we can transform the path A Q B into the path A P B, without making the moving line cut through the conductor S, the difference of magnetic potential between A and B is different according as we suppose the unit pole to be taken along the path A P B or by the path A Q B. If we can transform the one path into the other without making the moving line cut through S, then the proposition stated in (1) holds good. But if the two paths cannot be transformed one into the other without cutting through the conductor, then there is a definite difference in the work done in taking the pole from A to B by the one path or the other. As we shall see later, this difference is equal to $4\pi C$, where C is the electric current through the conductor S. It might seem at first sight as if this statement were at variance with the principle of the conservation of energy, but it is not

Digitized by Google

so, for energy is either supplied or absorbed by the system of wires and batteries which is conveying and producing the current. For the present we shall not take this exceptional case into consideration.

(2.) If we know the value of the potential V at every point of space, we can at once find the force in any desired direction experienced by our unit pole when placed at any point. Take two points, P Q (Fig. 12), close together, and let the line joining them be the direction in which we wish to find the force. Let V_P, V_Q be the potentials at P and Q respectively, and suppose that the potential at Q has a greater value than the potential at P, so that we have to expend work upon the unit pole in bringing it from P to Q; thus, the force exerted by the

Fig. 12.

magnetic system upon the unit pole along the line P Q is in the direction Q to P. Since we have taken P and Q very close together, we may consider that the force experienced by the unit pole is uniform over the small space, P Q. Let F dynes be the force on the pole in the direction Q to P. In moving the pole from P to Q we must do F × P Q ergs of work. But we have another expression for the work spent on the pole, viz., $V_Q - V_P$.

$$\therefore V_Q - V_P = F \times P\,Q,$$

and therefore $$F = \frac{V_Q - V_P}{P\,Q} = -\frac{V_P - V_Q}{P\,Q}.$$

Thus we see that the force in any direction experienced by the unit pole is equal to − (the rate of increase of the potential in that direction). We can express this result in the language of the differential calculus as follows:—Let S (Fig. 13) be the

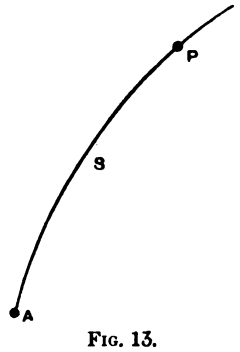

Fig. 13.

length of a curve A P measured from a fixed point A. Then the force experienced by the unit pole placed at P along the tangent to the curve at P in the direction in which S increases, or, in other words, the magnetic force in that direction is $F = -\frac{dv}{ds}$.

(To be continued.)

COPPER AND ALUMINIUM.

Repeated references have been made for the last year or two in the American electrical and engineering journals to "tempered copper." We have been at some pains to discover what is meant by this, and have inquired from copper manufacturers in this country and from our American correspondents. We have been inundated with testimonials and eulogistic accounts of its behaviour; but the only figures that have reached us give a tensile strength of 30,400 pounds per square inch, which, so far from being extraordinary, is about the inferior limit of good sheet, which should show 30,000 to 33,000, while bolts stand 30 per cent. more, and wire twice as much. This peculiar kind of copper is supposed to be particularly adapted for bearings and commutators; but it is not known in this country, and we have lost all interest in it since we have learned that the preparation is a secret. We have seen a chemical analysis from the Franklin Institute which revealed nothing, and which gave neither the amount of oxygen or carbon, or the specific gravity. It is doubtful whether the minute traces of oxygen and carbon which exercise so great an effect on the physical properties of copper can be estimated with any degree of accuracy; and it is to be hoped that some such methods as those which Mr. H. Tomlinson has employed to investigate the influence of stress and strain on metals by means of magnetic cycles may be applied to those cases where chemistry fails to give any useful information.

The alloys of copper are at present the most important that we possess, and the time when they will be supplanted by mixtures in which aluminium exists in larger proportion seems to be yet far distant. Elsewhere will be found two metallurgical articles bearing on these matters. One on the annealing of copper gives an account of some of the physical changes which take place during manufacture, and those which may be produced by subsequent treatment. There is no question but that the progress of electrical engineering has had a very marked effect upon the copper industry, though the probability of any considerable increase in demand, owing to the spread of electric lighting, is not great. The actual quantity already laid in our streets and hung over our heads is, after all, but a small part of that which is used for sheathing of ships, or for brass founding, every year. By the demand of the electrical trades, copper manufacturers have been made aware of the impurities with which crude copper is contaminated, and they have been compelled to change their processes and to modify their treatment, both of the ore and of the fine metal. The care which has been exercised in the production of high-conductivity copper, a care necessitated by the requirements of tests of a totally different character to those which were considered sufficient some twelve years ago, have contributed in no small degree to the improved mechanical qualities of the refined material. The excellent qualities of electro-deposited copper, and the certainty that no minute and unsuspected traces of arsenic or antimony could remain, led to the recovery of the metal from sources which it had not been worth while to work, and a secondary result of no small importance has been the recovery of gold and silver which could not otherwise have been separated. The latest modification of this process is being shown by Messrs Siemens and Halske at the Frankfort Exhibition, the novelty being the use of a solution of metallic salt other than copper, to assist in the extraction from the ore. Iron is used for this purpose, and it exists in the solution alternately as ferrous sulphate and as ferric sulphate. On combining with the copper in the ore, a reduction of the ferrous salt takes place, and when the copper is deposited electrolytically the iron sulphate becomes oxidized and may be used again without any consumption or waste. There is, therefore, no attempt to use the copper ore as an anode, but the extraction and the deposition are conducted as two distinct processes.

In the manufacture of electrical conductors it is sufficient, as a rule, to say that the purer the copper is the better, though silicium bronze and other alloys of an analogous character have their important uses when low resistance is not of the first importance. But for the mechanical engineer, the peculiar physical properties of copper deserve more attention than has been given to them, and almost as many varieties of copper are to be had as of iron and steel; nor are the causes so dissimilar as the widely different chemical characteristics of the elements suggest. It might be imagined that since iron is attacked by the oxygen of the atmosphere so much more readily than copper, which shows but little affinity until it is heated considerably, it would part with its oxygen during manufacture as easily as does iron in the blast furnace. However, not only is oxygen retained, but on re-melting it will, like silver, absorb oxygen, to give it out, partially, during solidification. Copper has two states of hardness and brittleness, as far as oxygen is concerned, the one containing too much, and the other too little, and both of these have been avoided with care by manufacturers. But so tenacious and ductile a metal cannot pass to the brittle stage without passing through various degrees in which it acquires hardness, and before brittleness is reached it must pass through

Digitized by Google

a tough condition; and it is probable that if some of these intermediate stages can with certainty be produced, we may have in practically pure copper a material which offers very considerable advantages to the engineer. For bearings and commutator bars and other purposes where tensile strength is either unnecessary or can be provided by the surrounding parts, the toughening would be highly desirable. The presence of carbon in minute quantities acts on copper as it does on iron, but the proportion, which varies in steel from 0·6 to 1·8 per cent., is difficult enough to estimate by analysis. In copper, however, even 0·2 per cent. of carbon will render it almost useless, while that amount is always to be found in good bar-iron. The difficulties of producing a steeled copper present, therefore, some difficulties, but the result would be well worth attaining. Some such modification has, probably, been arrived at in the "tempered copper" to which we have alluded; and while we would always respect a patent, we have no such feelings for a trade secret; and, always supposing that the article is really better than a mild bronze, we hope that the process will soon be discovered by our copper manufacturers, if, indeed, it is not the one described in the article by Mr. Cummings which we reprint in another column.

Aluminium, before it was produced in a nearly pure state, was said to be of immense importance for alloying with copper; and the gold-like bronze which has for so many years been used for little else than pencil-cases and tawdry watch chains, was expected to take a prominent place in engineering and many other industries. We have ourselves had some experience of it for small castings, where it was expected that the lightness would be advantageous, but they were so spongy, and in some cases so rotten as to be useless. In instrument-making, solder and paint cannot be used as freely as in engine-building for stopping blow-holes and bubbles, and although these do not occur so frequently in heavier pieces, the difficulty of casting and of soldering this alloy places it at a considerable disadvantage. As far as mere lightness goes, the extreme stiffness of phosphor bronze affords to a skilful designer the opportunity of producing a very light casting by careful attention to the mechanical requirements of the case. Aluminium is analogous to copper in being very soft in its pure state, but becoming extremely hard and brittle when very slightly alloyed with other elements; and, on the other hand, it resembles iron in forming a series of compounds when combined with carbon and silicon, the different varieties exhibiting the well-known grey, granular, brittle, and crystalline characteristics of cast iron. The production of nearly pure aluminium created another stir, unconnected with the mere price, but founded on the attractive properties of the metal. According to enthusiasts there was nothing that it would not do; and although after many months there is little to be seen of it, it is probable that some more good will come of it than the production of a few enormous dynamos, which were destined to be employed in turning out tons of the metal.

SCOTT-SISLING SYSTEM FOR SMALL ELECTRIC LIGHT PLANT.

Private lighting generally involves the use of accumulators, and to charge these the dynamo voltage must, of course, be raised some 25 per cent. above the lamp voltage. In many cases this is inconvenient and wasteful, as the dynamo must be "run up" to this increased voltage, although only a portion of the current generated may be used for charging, the remainder being required for the lamps at the normal voltage.

We illustrate an arrangement devised by Messrs. W. B. Sisling and W. H. Scott having several features which ought to prove advantageous in a private installation. The arrangement may be described as a compound dynamo, with a small supplementary winding on its armature connected to an extra commutator, which gives a voltage usually about one-quarter of that given by the main commutator. A branch is taken from the main circuit, and connected so that the extra commutator raises its voltage by about 25 per cent. This forms the charging circuit. The dynamo can thus be driven at constant speed, and will supply constant voltage to the lamps from its main circuit, undisturbed by the increasing voltage from the cells during charging.

The whole of the cells can be charged by a large current supplied to the lamps at the same time, as this does not pass through the regulating cells. The charging can, therefore, be accomplished during the hours of lighting, instead of the dynamo having to be run specially during the day.

The diagram shows the general arrangement. The dynamo armature has a main commutator M, and an extra commutator N. These two commutators are connected in series, either directly or through the dynamo series winding W. The switchboard contains two switches, viz., the dynamo switch D,

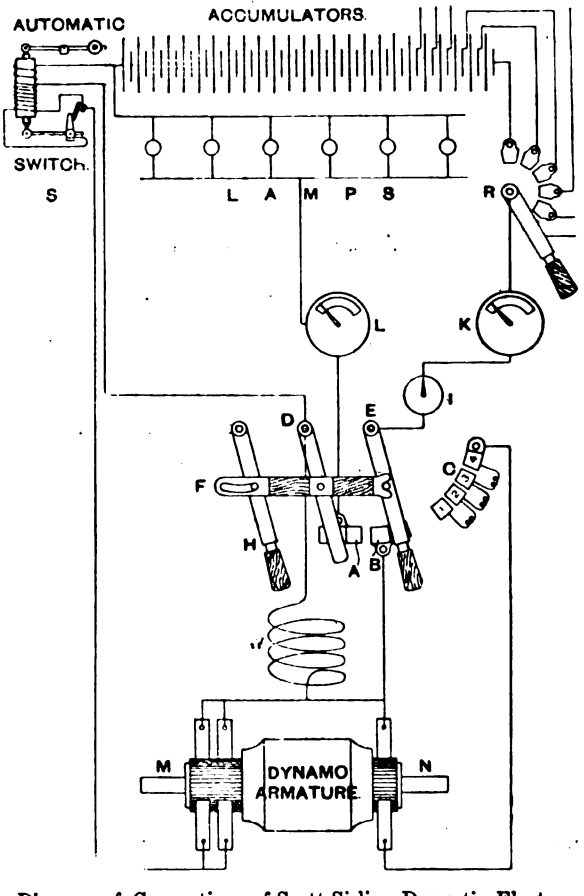

Diagram of Connections of Scott-Sisling Domestic Electric Lighting Plant.

which connects the dynamo to the lamps and the accumulator switch E, which connects the accumulators in either of three different ways, viz.:—

A to the lamps alone, or
B to the lamps and dynamo, or
C to the charging circuit.

These two switches are of the lever pattern, and are interlocked by the thrust rod F. The handle H acts on the thrust rod so that it can only put the dynamo switch "on." To take it "off" the accumulator switch must be moved so that the accumulators are connected to the lamps alone.

When the dynamo switch is put "on" the thrust rod moves the accumulator switch from A to B, thus connecting the accumulators to the dynamo in such a way that they are in readiness to assist the dynamo in supplying current to the lamps, without risk of weakening or reversing its magnetism.

If the dynamo does not need assistance and spare power is available the accumulator switch may be moved further from B to C, when the dynamo will begin to charge the cells by means of its extra commutator N, without interfering with the constant voltage which is supplied to the lamps from its main commutator M. An index I shows whether the accumulators

Digitized by Google

are being charged or discharged, whilst an ammeter K indicates the *amount* of the charging or discharging current. A second ammeter L shows the current taken by the lamps. A pilot lamp on the switchboard lights when the dynamo starts up.

An automatic switch S, having shunt and series coils, may be used to disconnect the dynamo when its speed slackens, and will connect it again when the proper speed is recovered.

This switch consists of a solenoid having two windings. One is of thick wires or copper strip connecting the dynamo to the terminal common to the lamps and cells. The other winding is of fine wire, and forms a shunt circuit across the main terminals of the dynamo. An iron core is supported in the interior of this solenoid in such a way that when the dynamo gives its normal voltage, the iron core is drawn upwards into the solenoid, closing the switch. If now the current flows in the right direction to the lamps or cells, the core will be more strongly drawn up into the solenoid, thus increasing the pressure on the switch contact, which is a stencil copper brush. If, however, the voltage of the dynamo decreases and current flows from the cells in the wrong direction, the effect of the shunt winding is partially neutralised, and the core falls, thus opening the switch.

By means of this arrangement, the manipulation is made simple, and the charging current can be adjusted to form a complementary load, thus working the plant at its maximum efficiency, and shortening the hours of running.

The arrangement is in use in some private installations, the latest being one erected at Brandon Park, Suffolk, which is driven by an oil engine, giving 11 B.H.P. The engine is started by the accumulators, and these also work the coil which ignites each charge in the engine cylinder. The whole arrangement works satisfactorily, and without specially skilled attention, which is an important matter for country houses.

ELECTRIC MINING-MACHINERY, WITH SPECIAL REFERENCE TO THE APPLICATION OF ELECTRICITY TO COAL-CUTTING, PUMPING, AND ROCK-DRILLING.*

BY LLEWELYN B. ATKINSON AND CLAUDE W. ATKINSON, ASSOC. MM. INST. C.E.

The employment of electricity in mines for pumping, hauling and coal-cutting, is a subject which has already received some attention in Papers read at the meetings of the more strictly mining institutions. The authors have been, during the last four years, constantly connected with the applications of electricity to mining, and have spent a considerable amount of time underground, both in making experiments, and in teaching those who would have to take charge of the electrical machinery. They propose in the present Paper to show in what way the conditions of mining work differ from those of other industries, and how the problem has been dealt with, illustrating the subject by describing some of the machinery now in actual use.

The principal uses to which electrical power is likely to be put in coal and metalliferous mines, and in quarries, are the driving of pumps, of hauling and underground winding-machines, of coal-cutting machines, of drilling-machines, both rotary and percussive, and in certain cases of fans for subsidiary ventilating purposes. It will be unnecessary here to dwell at any great length on the question of the relative merits of different methods of transmitting power in mines, practical experience having shown that compressed-air is almost the only rival to electricity, although in particular instances other systems are still in use for certain purposes. Compressed air has one advantage, on which much stress has been laid, namely, that the exhaust product is in itself a valuable assistance to ventilation; but from circumstances that will presently be described, it would appear that the method of ventilating a mine by first compressing air, transmitting it under pressure, and then expanding it, is the most costly that can be devised. If power must be spent in ventilation, the best way to do it is to deliver a given volume of air, with the proper difference of pressure between the intake and the upcast. In using compressed air, in order to keep the machinery as small as possible, and at the same time to limit the expense of the piping, it is necessary to work at as high a pressure as is feasible. On the other hand, increase of pressure, which in a steam engine conduces to greater economy and efficiency, is, in the case of compressed air, the one item which reduces the efficiency.

The following table* gives the result of experiments made some years ago by Messrs. J. Fowler and Co., of Leeds, who have had considerable experience with air compressors.

Gross Efficiency of Compressed Air in the Transmission of Power.

Air-pressure. lbs.	Efficiency = Brake H.P. of Motor. / I. H.P. of Compressing Engine. Per cent.
40·0	25·8
34·0	27·1
28·5	28·5
24·0	34·2
19·0	45·8

The above results are borne out by the experiments made more recently by Prof. A. B. W. Kennedy, F.R.S., M. Inst. C.E., on the transmission of power by compressed air in Paris on the system introduced by Mr. Popp. These experiments show that the brake H.P. of the motor (10 H.P.) is 31 per cent. of that of the engine driving the air-compressor if the air is not heated before it is used in the motor. If the air is heated and expanded before passing into the motor this efficiency is increased to 45 per cent. In mining work it is generally difficult to do this, and consequently engineers are content if they can obtain the lower result.

The great advantage of heating and expanding the air before passing it into the cylinder was so far realised by Mr. Frederick Hurd, in 1872, that he devised an arrangement for placing a heating apparatus inside the valve-chest, in which the oxygen for the combustion of the fuel (a mixture of coke and scrap iron) was supplied by the air working the motor. By this means the possibility of exploding fire-damp is completely overcome, and the formation of ice is avoided.

In practice 40lb. or 50lb. is about the pressure now adopted for working compressed-air machinery, although in the case of rock-drills, where lightness, portability of the machines, and smallness of the connecting hose, are of greater importance than efficiency, 70 to 90lb. per square inch is frequently used. The final result, however, of experiments at these pressures, agrees with that already given, namely, that it is impossible with compressed air to transmit to the distant motor more than from 20 to 30 per cent. of the power expended in the engines, and probably, taking due account of the friction and loss in the piping, which, however, is not often excessive, the average efficiency of compressed air as applied to mining work would be below 20 per cent. In the case of electrical transmission of energy, except when distributed into very small units, there is little difficulty in obtaining 50 per cent. of the power expended in the engine, and there are cases in which no less than 75 per cent. is transmitted without any extraordinary precautions being adopted.

These figures are frequently contradicted by the advocates of compressed air, but after the precise particulars which have been published of experiments with electricity, and in view of the scanty information obtainable as to actual trials of compressed air, the onus lies with its advocates to show that the results which can be obtained in regular working by this method exceed those already given. In addition to this lower efficiency, which means not only a greater expenditure of coal, but also a large increase in the dimensions of the engine, and consequently in the price of the generating plant, there is the cost of laying and maintaining the connecting pipes. To make the matter clearer, a simple case has been chosen, and Table II. prepared, showing the comparative economy of these two methods of transmitting power.

Table II.

System.	B. H.P. of steam engine.	B. H. P. of motor.	Distance from engine to motor in yards.	Size of cable or pipe.	Price of engine and dynamo or compressor.	Price of cable or pipe.	Price of motor.	Total cost of plant, without erection.	Efficiency.
				Ins.	£	£	£	£	%
Electric	15·4	10	2,000	$\frac{7}{16}$	210	192	95	497	95
Compressed air	33·3	10	2,000	4	130	700	63	893	30

It must be borne in mind that the size of the cable plays a large part in determining the efficiency of the electric transmission of power. In the case of steam, compressed air, or hydraulic transmission, the losses in the pipes are frequently neglected, as they are usually small. This cannot be done with electrical plant, first, because the cost of the copper conductors forms a considerable item in the whole, and it is therefore desirable to have them as small as possible under the particular circumstances of each case, and, secondly, because, unless the cables are proportioned to the

power to be transmitted, they may become heated and damaged by the current passing through them.

In dealing with dip-draining pumps the authors have given a table showing the loss of power in the cable in two particular cases, with small machines; but they think that a similar table dealing with large machinery and varying sizes of cable may be of interest. They have, therefore, in Table I., given the losses in each part of an electrical pumping system, first, with a pump delivering 350 gallons per minute against a vertical lift of 900ft. and a pipe line 1,800 yards long of 6in. pipes, and secondly, with a similar pump delivering 200 gallons per minute to a height of 480ft. through the same pipe line. It will be seen that an efficiency of 67 per cent. can be readily obtained even when transmitting nearly 100 H.P. to a distance of more than 2 miles, and without any attempt being made to get specially good results, the whole plant being such as can be worked by unskilled men.

The results given, are, it is true, now recognised to a large extent as being, in the abstract, correct statements of the facts; but in the minds of the owners and managers of collieries and mines, there still exists a doubt as to when they are justified in adopting the use of electricity. One of the most important points which has been raised in this connection, and which was brought very strongly to the front in the discussion on a Paper by Mr. Blake Walker,* read at a meeting of the Midland Institute of Mining Engineers, is the question "of the safety, or otherwise, of an electric motor in a coal-mine, in view of the fact of the explosive nature of the gases existing in some parts of most mines."

The problem resolves itself into two parts—First: Will a motor, working under ordinary and satisfactory conditions, be likely to cause an explosion, assuming that it is placed in the positions where motive power is usually required in mines? Secondly: Is it possible under what may be termed extraordinary, but perfectly realisable conditions, to produce an explosion under similar circumstances? A variety of opinions on the subject have been given, and some experiments have been tried bearing upon it, and the authors consider that the following may be taken to be a correct summary of the results obtained.

In the case of an ordinary motor working up to, say, 500 volts, having the brushes properly adjusted upon the commutator, no sparking can be perceived, but if from wear of the contacts during long runs, or variation in the load, slight sparking should occur, it is produced in contact with large masses of a highly conducting metal (copper), with the result that the rise of temperature is not sufficient to fire explosive mixtures of coal-gas and air, or ordinary marsh-gas and air. The temperatures required to explode these gases at ordinary pressures may be taken to be, for a mixture of 1 volume of coal-gas, with 5 volumes of air, or for a mixture of 1 volume of marsh-gas with 9·4 volumes of air, from 900° to 1,100°C.

Copper combines with oxygen in air so as to produce oxide of copper at about 700°C., and as under normal conditions the formation of this oxide is not observed, either on the collector or on the point of the brush, this fact may be taken as further evidence that the temperature there existing is not sufficient to fire an inflammable mixture of gases. It may be said, then, that under normal conditions, an electric motor is not a dangerous machine to use even in an atmosphere charged with considerable quantities of explosive gases; but having shown this, it may be admitted that supposing a brush, for example, is worn so far that it ceases to be in contact with the commutator, or supposing it to become seriously displaced from its proper position, an amount of sparking may ensue, which will cause a temperature sufficiently high to oxidize the copper of the brushes, and farther, to ignite inflammable mixtures. The question then arises, how is it possible to obviate the danger which may arise from this cause?

* *Transactions* of the Midland Institute of Mining Engineers, Vol. XI., p. 317, "Electricity as a Motive Power," with special reference to its application to mine-locomotives, December, 1889.

The authors, have devoted considerable attention to this matter. It should be taken as an axiom that the machine will not normally be placed to work in an explosive mixture; but that what has to be guarded against is, in the case of a motor which perhaps is not attended to for some hours at a stretch, the accumulation of such gases in its neighbourhood during this time. Moreover, where a motor is in use at the coal-face or in a heading, means should be adopted to allow the machine to be stopped if, in the working of the coal, or from the fall of a roof or other reason, an inrush of fire-damp should take place, before this explosive gas has had time to come in contact with the commutator and brushes.

To effect this purpose, the authors have adopted the practice of enclosing, either the whole armature together with the commutator and brushes, or when this is inconvenient, the commutator and brushes only, in a casing which is air-tight, or practically so. It has been objected to this plan, that although it may be feasible in the case of small motors, it is impracticable with machines of any size, owing to the diminished ventilation of the armature and commutator. The authors have, however, adopted the method with success for a motor which has developed up to between 40 and 45 H.P., and with no greater difficulty than in the case of one as small as 1 H.P. In the winding of field-magnets, it is now recognised that any desired temperature of working may be obtained by allowing well-defined amounts of external cooling surface for the dissipation of the heat developed. This proportion, for a final temperature of 70°F. above the atmosphere, may be taken as 2·3 square inches per watt to be dissipated.

The armatures of ordinary dynamos and motors are constructed to revolve in contact with the air, and the continual cooling thus obtained allows the surface for each watt to be dissipated for the same rise of temperature, to be diminished to about 0·7 square inch. In the case of the authors' mining motors, it is only necessary to revert to the basis adopted for the field-magnets, that is to say, to allow a cooling surface on the exterior of the armature-casing of the proportions which would be adopted for a stationary magnet-coil, in order to obtain the same result as to temperature. The armature revolving inside quickly brings the contained air to the same temperature, and this, being in rapid movement, conveys the heat to the external casing, from the surface of which it is dissipated by radiation and convection. It is true that to obtain a proper proportion between the cooling surface and the heat generated, it has been necessary to be careful as to the magnetic and electrical design of the armature; but with these precautions, the authors have found that the temperature of the armature of these enclosed motors at the end of a long run does not exceed that of the field-magnets.

Having thus disposed of the objection which has been raised by electrical engineers to this method, it remains to consider the question from the point of view of the mining engineer. The argument of the mining engineer is that if these casings should become filled with an explosive mixture and ignited, the result would be as disastrous as if they did not exist. The answer to this objection is as follows:—Seeing that under certain sections of the Coal Mines Regulation Act it is not allowable to work where the proportion of explosive gas exceeds about 1 in 30, it is not likely that any electric motor will be placed in such a position as to be run continuously in an explosive atmosphere for a longer period, at the outside, than two or three hours. The casings with which they are provided are tightly fitted at all the joints, many of them being packed with rubber, and it is not likely that an inflammable mixture could penetrate to a dangerous degree within that time. Should there, however, be any leakage into the covers, as soon as the proportion of marsh-gas in the air reaches 3 or 4 per cent., combustion will take place quietly, producing carbonic acid gas, which will tend to prevent explosion.

If, however, it is required to work for long periods in such an atmosphere, the authors would provide means for the introduction into the armature of an inexplosive mixture. The simplest

Digitized by Google

method of producing this result would be to attach to the motor a steel cylinder containing carbon dioxide under pressure, and to connect this with the armature casing by a pipe which should allow a slow but constant stream of this gas to reach the interior of the casing. The efficacy of this method may be judged when it is pointed out that the presence of 14 per cent. of carbonic acid gas in the most explosive mixtures of fire-damp renders them absolutely uninflammable. The authors consider that this method of protecting the armature and commutator, and preventing the ingress of an explosive mixture, is generally more satisfactory than that of enclosing the commutator and brushes only as mentioned before. Conditions may, however, arise which render this latter method desirable. In that case the point to be aimed at is to produce a cover which shall give a similar protection to that afforded by a safety-lamp, and allow the ingress of the explosive atmosphere, but prevent the egress of flame. In order to do this it is necessary that the volume of the enclosed gases should be small, and that the passages through which the flame can escape should be of sufficient length, and the metal surfaces close enough together to cool it below the point of combustion. If the commutator were enclosed by a cylindrical case or otherwise, so that the volume of gas was small to begin with, yet as it wore away the space would increase to an undesirable extent. The authors have, therefore, designed methods by which it can be contracted and the volume of gas kept constant. But the brushes are not the only part which should be protected; for if a wire on the armature should break, or the insulation give way, or if anything should get between the armature and the pole-pieces, sparking might occur, and such a contingency should be provided for.

induction of the line and armatures. In order further to diminish this, the switch itself has, on its lower side, a resistance coil connected to the several points with which it makes contact, the wire being large enough to carry the current for the short time during which the switch is passing over them. By this means, even when the generator is short-circuited, the current is so far diminished that if the switch be moved slowly over the contacts, it is less than what has been termed the critical magnetising current of the dynamo. The result is that by the time the circuit is open the series-wound dynamo has practically ceased to excite itself, the electromotive force and current are very small, and the sparking practically *nil*.

As an additional safeguard, the switch itself is constructed in the form of an airtight box, which, in the same manner as the commutator covering, will exclude an explosive mixture for many hours. Although the authors have never tried the experiment, they have reason to believe that the amount of gas which could be possibly contained in the switch is not sufficient, should it ignite, to blow the cover off; while the surface of contact between the cover of the base and the cylindrical hole through which the handle passes, are sufficiently long to cool the escaping gas below the temperature of ignition. These precautions, which have been carried out successfully in practice, are, in their opinion, amply sufficient to meet all objections on the point of safety in connection with the application of electric motors to mining work.

Having so far dealt with the general question of the applicability of electrical power for mining machinery, and having indicated the methods adopted by the authors in their designs, it is proposed now to illustrate the application of these principles by some actual

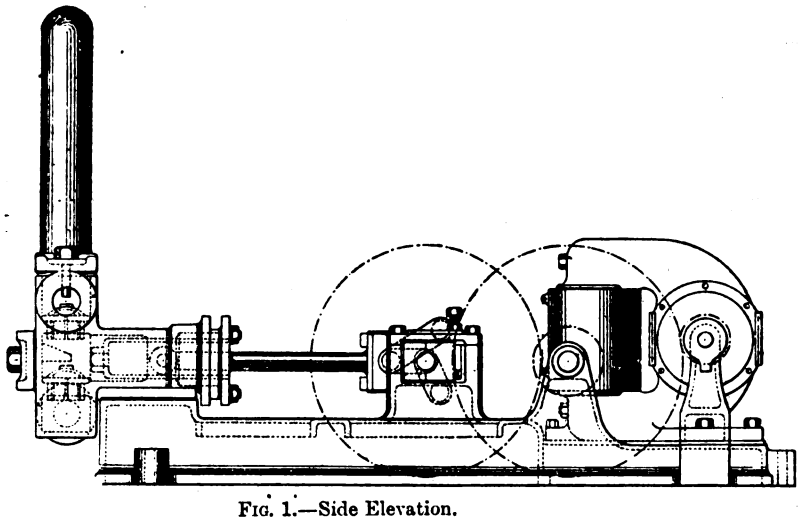

Fig. 1.—Side Elevation.

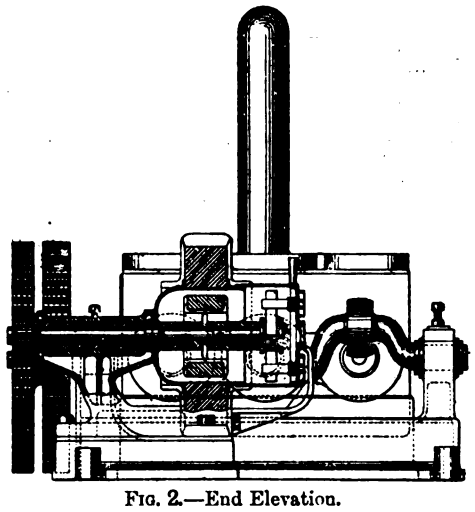

Fig. 2.—End Elevation.

Goolden Electric Dip Draining-Pump, with Enclosed Mining Motor.

There now remains the question of the switches connected with the motor, which will, of course, develope a spark on opening the circuit, when the current is flowing. This, in the opinion of the authors, is a more serious difficulty than the former one, and they have endeavoured to meet it in two ways, namely, by diminishing, as far as possible, the tendency to sparking, and by arranging a switch which, even in the event of a spark, would be safe under any conditions likely to occur. The first idea that occurs is that by using a shunt-wound dynamo as a generator and a shunt-wound motor, the self-induction in the circuit is so far diminished that little sparking is likely to occur. But for many purposes, the conveniences arising from using a series-wound motor, as will presently be pointed out, are such that this method is in general to be abandoned, although the principle underlying it may be adopted. The reason of the diminished sparking with the shunt-wound dynamos and motors is, that the self-induction of the cable circuit is insignificant, and that of the armatures is also small, whilst the circuits of the magnetising coils in both dynamo and motor, which have large co-efficients of self-induction, are always closed through the armature. Thus, although on breaking the circuit the current in the magnet-coils tends to continue, it has a path of discharge through the armature of low resistance and of small self-induction. The authors have, therefore, adopted the following plan:—In the case of a series-wound dynamo they have provided a resistance coil of small self-induction, which is always connected to the ends of the magnetising coil, so as to form a path through which a current in the latter may continue, even when the main circuit is broken. In the same way, they have arranged the switch in such a manner that before breaking the circuit the coil of the magnets is short-circuited. By this means, the act of breaking the circuit reproduces the conditions which exist in the case of a shunt-wound generator and shunt-wound motor, and the only sparking which results is that due to the self-

examples. Full descriptions have been already given of the application of electric power to mining work under conditions analogous to those existing in ordinary power transmission installations above ground; for instance, Mr. A. Snell, Assoc. M. Inst. C.E., has elaborately described a large pumping plant working at Normanton,* and, in a Paper previously mentioned, by Mr. G. Blake Walker,† the application to locomotive work of accumulators has been fully discussed. The authors, therefore, propose to confine their attention to two or three illustrations of the use of electrical power, both in fixed plant and in machinery which is constantly moving from place to place whilst at work. For this purpose they have selected some dip-draining pumps, which are portable but are fixed whilst working; and they propose also to describe electrical coal-cutting machinery, electric coal-borers and electric rock-drills, as examples of constantly moving plant.

The earliest example of the application of electricity in mining work was its adoption by Mr. W. B. Brain, for draining a certain part of the Trafalgar colliery in the Forest of Dean.‡ An ordinary horizontal pump was driven by a belt from the motor, which was fixed upon a permanent bedplate. The arrangement has worked well and given satisfaction; but, in the opinion of the authors, the use of belts in coal-mining work, unless under very exceptional conditions, is entirely out of the question, owing to want of space and the difficulty of keeping them in good working condition in dirty and wet situations.

In Figs. 1 and 2 is illustrated a horizontal drip-draining pump, designed by the authors, and constructed by Messrs. W. T. Goolden and Co. Three-throw ram-pumps are used, the reason being that it

is important in using electric motors that the load should be as regular as possible throughout the revolution. The pumps are mounted upon a bed-plate, which is extended to carry the motor. The motion is communicated from the motor shaft to the pump shaft by gearing. This method of reducing the speed is perhaps more noisy than the use of belts, but in practical working this is not of much importance; and, provided that the armature is properly constructed for the purpose, ample strength being given, and proper materials being used to avoid the result of the jar or shock, gearing may be confidently recommended. It requires no adjustment, and is so compact that the whole machine is self-contained, whilst, when the pinion on the motor, which is subjected to the greatest wear, is worn out, it can be replaced in a few minutes at a trifling cost.

Table III. gives the data of a pump of the horizontal pattern, and vertical pattern, and shows the relative efficiency of the various parts together with the size of rams. The gross efficiency is not very high, owing largely to the power used being small. But it was specially intended to produce a durable machine, suited for the rough conditions under which it was likely to be worked, and adapted also to be handled by persons who have not the necessary knowledge to keep any delicate mechanism in adjustment. These considerations necessitated the adoption of a large clearance for the armature, ample space for insulation, &c., all of which tended to diminish the efficiency. The motors, it will be observed, are of the authors' enclosed type, the field-magnet coils being lagged with steel to prevent mechanical damage. These machines have, in some cases, run for many weeks, day and night together, with no attention beyond an occasional feeding up of the brushes and lubrication. This form of pump is well adapted for mines where the electric light is already installed, and in this connection attention may be drawn to a point which is worthy of note. In the use of electricity for motive power for lighting it has often been objected that the variations in the load upon the motor cause a considerable alteration in the lights upon the same main at some distance from the dynamo. The remedy for this is simple. By employing a well-governed engine, and compound wound dynamo, the electrical pressure at the terminals of the generator may be kept constant; if, then, a separate pair of mains is run for the motors, the pressure on the wires feeding the lamps is constant, whilst any variation at the terminals of the motor is not a matter of importance. These electrical pumps appear to meet every requirement of practical mining work, and have replaced steam and hydraulic pumps with considerable advantage.

(To be continued.)

THE PICARD SYSTEM OF SIMULTANEOUS TELEGRAPHY AND TELEPHONY.

In view of the recent satisfactory tests which have been made by the French Postal Telegraph officials, the following description of a new system of simultaneous telegraphy and telephony will prove interesting. The idea is due to M. Pierre Picard, belonging to the French Telegraphs, and the following particulars are from an article by M. A. Michaut in *L'Electricien*.

M. Picard employs a device which he calls a "differential transformer," which is nothing more than a cylindrical induction coil with four wires of equal resistance and the same dimensions wound together on a soft iron core. The coil is mounted on a wooden base provided with four terminals, by means of which the four coils are connected to the line and to the local circuit as shown diagrammatically in the following figures.

In Figure 1 we have a diagram of the simplest arrangement. The opposite ends of the coils *a b* are joined together. To each of their other extremities one of the line wires is attached. The two line wires are thus looped together for telephony, and are at the

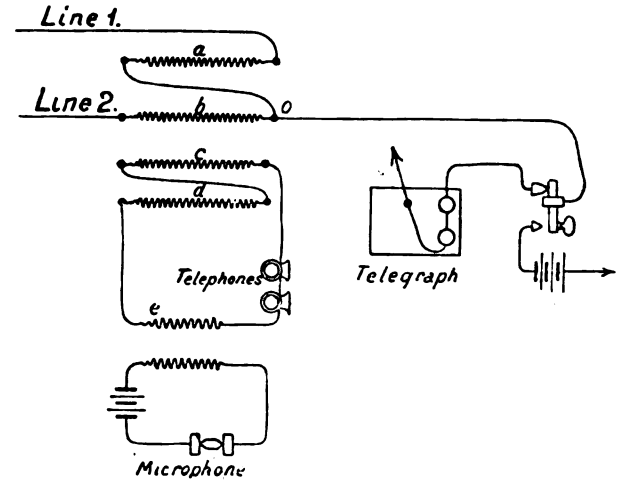

Fig. 1.

same time connected in parallel for telegraphy. The ends of the other two coils *c* and *d* of the "transformer" are similarly connected, a local telephone circuit taking the place of the line.

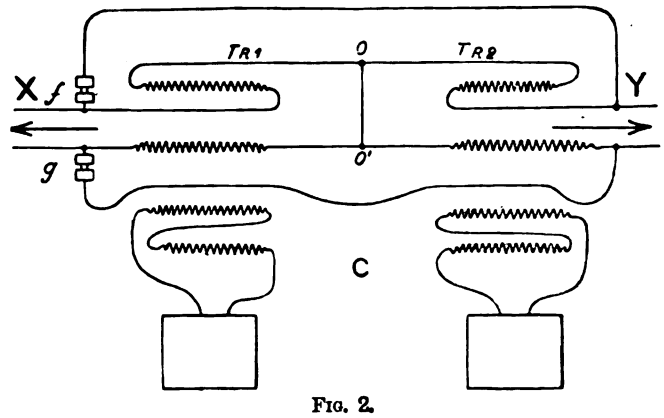

Fig. 2.

If we look at the diagrams we can easily see (1), that the *telegraphic* currents divide equally between the two coils *a* and *b*, and while they go along the two line conductors in the same direction traverse the coils *a* and *b* in opposite senses; (2), that the *main telephonic* currents, which take opposite directions along the line, traverse the transformer coils in the same sense; (3), that the *local telephonic* currents traverse the coils *c* and *d* in the same direction. The result of all this is that telegraphic currents, whether they bifurcate

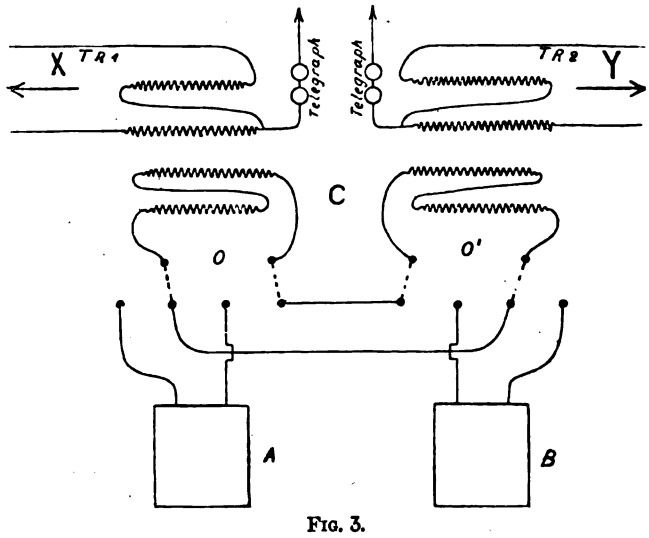

Fig. 3.

Digitized by Google

at O on going to line or unite at this point on going to the receiving instrument, have an equal and opposite inductive influence when traversing the coils *a* and *b*, and the telephone consequently remains silent. When the microphone is spoken to, the induction currents developed in *e* traverse the coils *c* and *d* in the same direction, and induce currents in the coils *a* and *b* which actuate the telephone at the far end of the line.

If it is required to cut the telegraph line in half without interrupting through telegraphy, the *modus operandi* shown diagrammatically in Fig. 2 is followed. At the intermediate station C are the two transformers, A and B. The first transformer, Tr_1, is connected, as described above, to the two wires going to station X, the transformer Tr_2 being similarly connected to station Y. From the intermediate post C it is, therefore, possible to telephone to X and Y, or these two stations may be placed in through communication by operating the connections O O′ at station C.

The converse problem can also be solved—that is to say, the telegraph circuit can go through, and the telephone circuit can be divided. This is shown diagrammatically in Fig. 3. As before, two "transformers" are employed at C, but the wires, instead of being looped on either side of C, run through without being broken; they are, however, connected together between the two "transformers" by a conductor, O O′, of negligible resistance, called by M. Picard a "telephonic bridge." The presence of the conductors O O′ does not in any way disturb the condition of the telegraph line, since the two wires are in parallel for telegraphic purposes. It is not, however, the same for the two looped telephone wires on the right and left of station C. In this case O O′ acts as a short circuit, and prevents the through passage of the telephone currents, so that conversation may be carried on simultaneously with C from X and Y. If it is required to speak through from X to Y, the transformers, &c., are cut out of circuit by inserting plugs at the points *f* and *g*.

In the tests made between Paris, Lyons, and Marseilles the interposition of the "transformers" permitted the simultaneous exchange of telegraphic and telephonic communication. But when the Picard apparatus was fixed to the Paris-Troyes line a very different result was obtained. One wire was old, the other recently erected; their electrostatic capacity was by no means the same, and audition was impossible. On equalising the capacities all went well. The Picard system, it is stated, will allow the Baudot apparatus to be used, which is not the case with that of Van Ryssel-berghe.

A METHOD OF DETERMINING INSTANTANEOUS VALUES OF A PERIODIC E.M.F.*

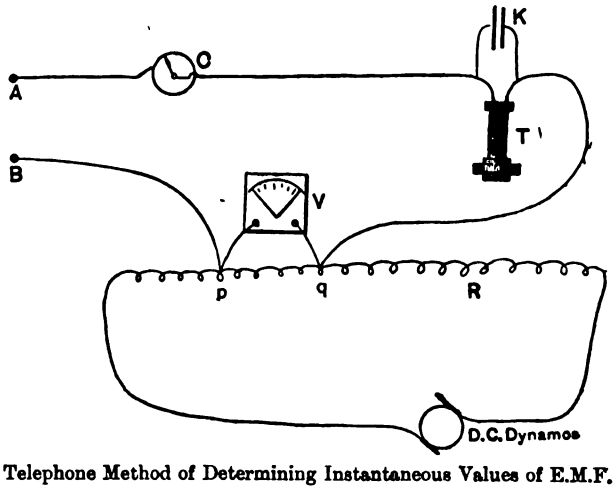
BY RALPH D. MERSHON.

The methods heretofore in use for measuring instantaneous values of E.M.F. in the determination of the wave form of a periodic E.M.F. are those employing the ballistic galvanometer and electrometer. Some time ago another method suggested itself to me, which, by the kindness of the Westinghouse Electric and Manufacturing Company, through Mr. Chas. F. Scott, the assistant electrician, I have been enabled to thoroughly test, and have found both convenient and accurate.

The needle of a galvanometer in series with a contact device and the periodic E.M.F. will, if its time of vibration is sufficiently great, be steadily deflected by the succession of impulses it receives. If there be placed in series with the contact device, galvanometer and periodic E.M.F., a steady E.M.F., which at the instant of contact opposes the first, and it be varied until the galvanometer deflection is zero, its value will be that of the periodic E.M.F. at the point on its wave for which the contact device is set. This mode of procedure is unsatisfactory, however, for small voltages, as in that case the deflections on an ordinary low-resistance mirror galvanometer in fairly delicate adjustment are small, even though there be a condenser of several microfarads in parallel with it. A plan much better both as to accuracy and convenience is that of replacing the galvanometer with a telephone receiver.

In the diagram let A B represent the terminals of the source of a periodic E.M.F. whose wave form is to be determined. C is the contact device attached, of course, to the shaft of the generator furnishing the periodic E.M.F. T is a telephone receiver which may have in parallel with it a condenser K. R is a resistance in series with a direct current dynamo or storage battery; a part of R consists of a slide wire resistance along which the sliding contact *p* can be moved. V is a direct-current voltmeter. Suppose the sliding contact *p* to be moved to *q*. The contact device C being set for some point on the E.M.F. wave other than zero, there will be heard in the telephone a succession of sharp clicks—one for every revolution of the contact device. If *p* be moved away from *q* and the fall of potential between the points *p* and *q* on the resistance R be in such a direction as to oppose that between A and B at the point on the wave for which the contact device is set, the loudness of the clicks heard in the telephone will diminish with such movement, and a place may be found at which they are no longer heard, and beyond which they become again audible. This place corresponds to an approximate equality of the steady and the unknown E.M.F., and the reading on the voltmeter gives to a certain degree of accuracy the required instantaneous value of the periodic E.M.F. For a more accurate determination we must adjust to zero sound by moving *p* up first from one side of the zero point, then from the other. In general the two settings obtained in this way will not coincide, since there is a limit to the current which can be detected by the telephone, and the point midway between them on the slide-wire resistance must be taken as the true setting. The voltmeter reading gives them the true value.

The delicacy of the telephone is much increased by placing in parallel with it a condenser. Great delicacy is not at all times, however, desirable. Should the belt driving the generator of the periodic E.M.F. have bad joints in it, or vibrate much, the variation in speed due to either or both of these causes can be plainly noted in the telephone, as some of the clicks will be louder than others. With a delicate telephone it will probably be the case under these conditions that no point can be found at which there is no sound; whereas, if the instrument be less delicate, we may find two points of zero sound and interpolate as explained above.



Telephone Method of Determining Instantaneous Values of E.M.F.

Hence, in some cases it is desirable to diminish the delicacy of the telephone by putting resistance in series with it. There is, practically, no limit to the accuracy with which settings can be made with the proper form of apparatus. Using an ordinary Bell telephone receiver, it is easily possible to make settings to $\frac{1}{100}$ of a volt.

The apparatus for the method is simple. It can be put in compact form, and thus be always available at an instant's notice, as it requires neither adjustment nor calibration.

* From *The Electrical World*.

THE ANNEALING OF COPPER.*

BY MR. C. W. CUMMINGS.

Copper is at present almost universally annealed in muffles, in which it is raised to the desired temperature, and subsequently allowed to cool either in the air or in water. It is necessary to watch the copper carefully, so that when it has reached the right temperature it may be drawn from the muffle and allowed to cool. If the copper is heated to too high a temperature, or is left in the muffle at the ordinary temperature of annealing for too long a time, it is "burnt," as the workmen say. Copper that has been "burnt" is yellow, coarsely granular, and exceedingly brittle—so much so, that in some samples it cannot be bent once at a right angle without breaking. It is even more brittle at a red heat than when cold. In the case of coarse wire it is found that only the surface is "burnt," while the interior is damaged to a far less extent. This causes the exterior to split loose from the interior when bent or rolled, thus giving the appearance of a brittle copper tube with a copper wire snugly fitted into it. Cracks a half-inch in depth have been observed on the surface of an ingot on its first pass through the rolls, all due to the exterior "burning." It is quite apparent that copper that has been overheated in the muffle is entirely unfit for rolling, either for rods, or sheet-copper, or for wire-drawing. It is found that the purer forms of copper are far less liable to be harmed by over-

* From the *Journal of Commerce and Inter-Colonial Trader*.

Digitized by Google

heating than samples containing even a small amount of impurities. Even the ordinary heating in a muffle will suffice to "burn" in this manner the surface of some specimens of copper, and thus render them entirely unfit for further working. Copper that has been thus ruined is of use only to be refined again. As may be inferred from the above, only the highest grades of refined copper are at present used for drawing or rolling. This is not because the lower grades, when refined, cannot stand sufficiently high tests, but because the present methods of working are not adequate to prevent these grades of copper from experiencing the deterioration due to overheating. This is unfortunate for the manufacturer, since, I understand, he has to pay cash in advance for the highest grades of refined copper.

In order better to appreciate the explanation of the various phenomena of copper annealing, let us see what refined copper is.

The process of refining copper consists in an oxidising action followed by a reducing action which, since it is performed by the aid of gases generated by stirring the melted copper with a pole, is called poling. The object of the oxidation is to oxidise, and either volatilise or turn to slag all the impurities contained in the copper. This procedure is materially aided by the fact that the suboxide of copper is freely soluble in metallic copper, and thus penetrates to all parts of the copper, and, parting with its oxygen, oxidises the impurities. The object of the reducing part of the refining process is to change the excess of the suboxide of copper to metallic copper. Copper containing even less than 1 per cent. of the suboxide of copper shows decreased malleability and ductility, and is both cold short and red short. If the copper to be refined contains any impurities, such as arsenic or antimony, it is well not to remove too much of the oxygen in the refining process. If this is done, "over-poled" copper is produced. In this condition it is brittle, granular, of a shiny yellow colour, and more red short than cold short. When the refining has been properly done, and neither too much nor too little oxygen is present, the copper is in the condition of "tough pitch," and is in a fit state to be worked. "Copper is said to be tough pitch when it requires frequent bendings to break it, and when, after it is broken, the colour is pale red, the fracture has a silky lustre, and is fibrous like a tuft of silk." On hammering a piece to a thin plate, it should show no cracks at the edge. At tough pitch copper offers the highest degree of malleability and ductility of which a given specimen is capable. This is the condition in which refined copper occurs in the market, and if it could be worked without changing this tough pitch, any specimen of copper that could be brought to this condition would be suitable for rolling or drawing.

We have seen that tough pitch is changed if we either add oxygen to, or take oxygen from, refined copper. By far the more important of these is the removal of oxygen, especially from those specimens that contain more than a trace of impurities. That is shown by the absolutely worthless condition of overpoled copper. The addition of carbon also plays a very important part in the production of overpoled copper. That the addition of oxygen to refined copper is not so damaging is shown by the fact that at present nearly all the copper that is worked is considerably oxidised at some stage of the process, and not especially to its detriment.

Let us see how the above facts are related to the process of annealing copper. I have already referred to what is known as "burnt" copper. This is nothing more nor less than copper in the overpoled condition. This is brought about by the action of reducing gases in the muffle. By this means the small amount of oxygen necessary to give the copper its tough pitch is removed. This oxygen is combined with impurities in the copper, and thus renders them inert. For example, as explained by Dr. Peters, the oxide of arsenic or antimony is incapable of combining more than mechanically with the copper, but when its oxygen is removed, the arsenic or antimony is left free to combine with the copper. This forms a very brittle alloy, and one that corresponds almost exactly in its properties to overpoled copper. To be sure, overpoled copper is supposed to contain carbon, but that this is not the essentially ruining principle in case of annealing is shown by the fact that pure copper does not undergo this change under conditions that ruin impure copper, and also by the fact that the same state may be produced by annealing in pure hydrogen and thus removing the oxygen that renders the arsenic or antimony inert. No attempt has been made to deny the well-known fact that carbon does combine with copper to the extent 0·2 per cent., and cause it to become exceedingly brittle. It is simply claimed that this is probably not what occurs in the production of so-called burnt copper during annealing. The amount of impurities capable of rendering copper easily "burnt" is exceedingly small. This may be better appreciated when it is considered that from 0·01 to 0·2 per cent. expresses the amount of oxygen necessary to render the impurities inert. The removal of this very small amount of oxygen, which is often so small as to be almost within the limits of the errors of analysis, will suffice to render copper overpoled and ruin it for any use.

It is quite apparent that a really good method of annealing copper will prevent any change in the state of oxidation. To accomplish this it is necessary to prevent access to the heated copper both of atmospheric air, which would oxidise it, and of the reducing gases used in heating the muffle, which would take oxygen away from it. Obviously the only way of accomplishing this is to enclose the copper when heated, and till cool, in an atmosphere that can neither oxidise nor deoxidise copper. I find that by so doing copper may be heated to the melting point and allowed to cool again without suffering at all as regards its pitch. There are comparatively few gases that can be used for this purpose, but, fortunately, one which is exceedingly cheap and universally prevalent, fulfils all requirements—viz., steam.

In order to apply, then, in practice the principles already enunciated, it is necessary only to anneal copper in the ordinary annealing pots, such as are used for iron, care being taken to enclose the copper while heating and while cooling in an atmosphere of steam. This will effectually exclude air and prevent the ingress of gases used in heating the annealer. Twenty-four hours may be used in the process, as in the annealing of iron wire, with no detriment to the wire. This may seem incredible to those manufacturers who have tried to anneal copper wire after the manner of annealing iron wire. By this method perfectly bright annealed wire may be produced. Such a process of annealing copper offers many advantages. It allows one to use a grade of copper that has hitherto been worked only at a great disadvantage, owing to the ease with which it gets out of pitch. It allows one to use annealers such as are ordinarily used for annealing iron, and thus cheapens the annealing considerably as compared with the present universal use of muffles. There is no chance of producing the overpoled condition from the action of reducing gases used in heating the muffles. There is no chance of producing underpoled condition due to the absorption of suboxide of copper. None of the metal is lost as scale, and the saving that is thus effected amounts to a considerable percentage of the total value of the copper. The expense and time of cleaning are wholly saved. Incidentally bright annealed copper is produced by a process which is applicable to copper of any shape, size, or condition, a product that has hitherto been obtained only by processes (mostly secret) which are too cumbersome and too expensive for extensive use, and, as in the case with at least one process with which the author is acquainted, with the danger of producing the overpoled condition, often in only a small section of the wire, but thus ruining the whole piece. If it is desired, the copper may be annealed in an apparatus so arranged that the copper when heated may be dropped into a body of water without access of air, and thus make a far smaller annealing plant suffice. It may be mentioned that copper seems to be made neither softer nor harder by being cooled suddenly in this manner than if cooled slowly, though some of the alloys of copper are rendered somewhat softer by a sudden cooling; in fact, there is not the slightest evidence anywhere to justify the quite prevalent belief that an art of hardening copper was known to the ancients. The hardest tools of the ancients were made of bronze, not copper. By application of the same principles it is possible to prevent both deoxidation and oxidation in the heating of copper ingots for the rolls, and thus, by keeping copper at tough pitch all along, any copper that can be given tough pitch can be used for rolling sheet copper or for wire. I think it also practicable to produce bright copper rods direct from rolls.

ELECTRICITY IN THE PRODUCTION OF ALUMINIUM.*

BY ALEXANDER S. BROWN.

The glamour that has surrounded this metal since 1856, when H. St. Claire Deville first obtained it in sufficient quantities to study its physical and chemical characteristics, and the almost monthly presentation before one or other of our scientific societies of Papers treating of its properties, &c., make it a most difficult subject to handle with originality. Scientific and newspaper eulogists have expended a great deal of time and many words in extolling the unusual combination of useful properties which it possesses, and have given their imaginations full play in describing its future triumphs in the metallurgical world; but as yet little has been actually accomplished in the way of accurately determining the commercial status and mechanical value of this metal compared to others more familiar to us. While it must be confessed that in certain respects its merits seem such as to warrant great expectations, those interested in its production and its commercial success have experienced not only the usual difficulties inseparable from the introduction of any new metal, but many others due to the too great esteem which the public has been led to bestow upon it. When sufficient knowledge of its characteristics has been acquired there is little doubt it will make for itself new and important fields of usefulness.

Patronised by Napoleon the Third, who entertained great expectations concerning the use of the metal in war equipment,

* A Paper read before the American Institute of Electrical Engineers.

Digitized by Google

Deville established commercial works near Paris, which, after varying fortunes, were finally permanently located at Salindres, France, and these works for many years produced substantially all the pure aluminium consumed in the world. It may interest you to know that up to 1886 the annual production of this metal was less than 10,000 pounds, of which 6,000 to 8,000 pounds were produced in France. In 1860 it sold at over $90 per pound. In 1887 it was sold at $5 per pound, and is now selling at $1 for a commercially pure article—this term signifying about 97 per cent. purity in the metal. Spasmodic attempts to establish aluminium works were made in Germany and other countries; but it may be truthfully said that France, which created that industry, remained its home until the development of the electrical processes which have now superseded all others.

During the development of the various sodium processes the possibility of utilising electricity was not neglected. Among the earliest patentees in this field were Camille A. Faure, in 1880-84, and R. Grätzel, in 1883.

On April 2, 1889, Mr. Charles M. Hall, of Oberlin, Ohio, secured patents for a process of reducing pure aluminium. In this process alumina is dissolved in a fluid bath composed of aluminium fluoride and potassium fluoride, with, perhaps, an addition of lithium fluoride; this bath then being electrolysed by means of an electric current conveyed to a carbon-lined furnace through an anode of some non-carbonaceous material. In electrolysing this bath, the containing vessel is made to serve the purpose of the negative electrode. In another patent Mr. Hall claims the use of a bath composed of alumina dissolved in compound fluorides of aluminium with alkaline earthy metals, and in still another patent the use of a bath composed of alumina dissolved in the fluorides of aluminium, calcium, and sodium, these materials being obtained by melting together aluminium fluoride, fluorspar, and kyrolite. With this latter bath a carbon anode can be used without the bath being affected by its disintegration. The Hall group of patents is now controlled by the Pittsburgh Reduction Company, of Pittsburgh, Pa., which has had its metal on the market since March, 1889. The plant has a daily capacity for producing about 300lb. of metal, the selling price of which was $2 per pound until the early part of March last, when it was reduced to $1 per pound for commercially pure aluminium of a guaranteed purity of 97 per cent.

The reduction in price, considered in conjunction with the limited amount of pure metal produced, would appear to confirm the generally received impression that while the pure metal is specially adapted to the manufacture of articles of art and ornament, it is not displacing tin, platinum, silver, &c., to anything like the extent its admirers have supposed it would. The fact is, aluminium as a pure metal is not destined largely to supplant other metals in the arts and manufactures; it is to its alloys that we must look to redeem the inflated reputation of the pure metal. The true value and use of aluminium seems to have been forecast by Deville, who predicted for it an intermediate position between the precious and baser metals, in which relation to manufactures he said it was destined to fill a long-felt and important want. He doubtless referred to the pure metal, but, curiously enough, his prediction applies with greater force to its alloys, which have been demonstrated by actual use and thorough tests to possess physical and chemical properties that place them above all other alloys of copper, iron, and in some instances even of steel.

The electric smelting process of the Messrs. Cowles, of Cleveland, Ohio, was the first to secure a commercial footing in this country. The process may be described as the reduction of metals by smelting their ores with heat produced by the passage of an electric current through broken resistance material—that is, in the presence of an incandescent material (carbon being generally preferred). Stress is laid on the alleged fact that the reduction is purely and solely a smelting operation, due to a heat far greater than can be obtained by any agency other than the electric current. The electrical (chemical) effect of the current is distinctly disclaimed. The furnaces used are rectangular, and oblong in shape, comparatively shallow, and are composed exteriorly of walls of firebrick or metal, lined with pulverised charcoal or other form of carbon or similar material of electrical conductivity inferior to the ore to be smelted, this material being generally previously saturated with lime water to increase its resistance to heat. At each end of these furnaces are inserted rods of carbon, which, passing through the walls and linings, are brought very nearly into contact within the body of the furnace, and being connected to suitable wires or cables coupled to the dynamo, constitute the positive and negative electrodes. The charge consists ordinarily of a mixture (in different proportions) of an electrically resisting material—such as electric light carbon—and the ore to be reduced; though (in cases where the ore itself has sufficient electric resistance) the carbon is sometimes dispensed with. When a current of electricity is passed, the electrodes are so adjusted as to form an arc, and the current then flows from the sides and ends of the electrodes through the broken resistance material, which, of course becomes incandescent, and the intense heat developed by this incandescence reduces the ore, the metal flowing to the bottom of the crucible and being subsequently tapped or dipped out when the charge is consumed. Neither aluminium nor any other metal is produced on a commercial scale by this process *as pure metal*.

The principal rival to the Cowles process for producing aluminium alloys is the Heroult process, which reduces aluminium and other metals from their refractory ores in the presence of another alloying metal, and is contradistinguished from the Cowles process mainly by the fact that it operates exclusively—or at least almost entirely—by utilising the chemical or electrolysing action of the current.

Though the Heroult processes have been very little discussed or even described in print, and are therefore almost wholly unknown to the public, their commercial success abroad has been far greater than has attended any other aluminium process; and while those owning the American patents seem as yet to have done little in the way of exploiting them, the success of a small plant put into operation at Boonton, N.J., for private demonstration purposes, in April, 1890, has been such as to give it rank among the prominent aluminium processes in this country. The crucible in the Heroult process is composed of a strong iron box, which has a deep lining of carbon, previously ground very fine, mixed with sufficient tar and thoroughly compacted on the bottom and around the sides of the containing iron box. After the furnace is thus relined, the carbon is baked in order to drive away the tar and harden the lining. You will see that the position of this crucible is directly the reverse of those used by the Cowles Company, and that the carbon crucible itself actually forms part of the electric circuit. Unlike the Cowles process, Heroult's is a continuous process, the reduced metal being tapped from the bottom of the crucible, while the machine is merely stopped or slowed down for a few minutes. The interior dimensions of the crucible vary with the ore to be reduced and the size and character of the anode used. Ordinarily it has an interior depth of about 22in. and a clear space of 6in. between the walls and exterior surface of the anode. The electric current passes into the crucible through the suspended carbon anode, the vertical position of which is controlled by an attendant, who lowers it from time to time, to preserve an approximately constant distance between the bottom of the anode and the surface of the molten bath in the crucible. The anode usually dips several inches into this molten bath, and, in practice, the intervening space between its bottom and the surface of the molten metal is kept at about an inch by the attendant, who, by watching the needle in the ammeter, is enabled to maintain the electrode in its proper relative position without difficulty. In order to get as perfect a contact as possible, between the furnace and the cables leading therefrom back to the dynamo, the cables are firmly clamped to a large block of zinc, which projects from the rear of the furnace, and is kept cool by water circulating in pipes, around which the zinc is cast.

There are a few distinctive, but not important differences, between Heroult's method of making alloys and reducing pure metals simply. In making alloys, the base alloying metal is first melted in the crucible by the current, or molten metal is poured into the furnace, to form a liquid metallic cathode. This is usually simply and economically accomplished by throwing pieces of the metal—copper, for instance—into the furnace, seating the anode upon them, and passing the current. At first the current is very unsteady, and constantly forming between the copper and the anode, but when the copper is entirely melted (and it takes but a very few minutes to melt 200 or 300lb.) the ore to be reduced is added in sufficient quantities to form a bath, and floats on top of the molten copper. The anode having been raised so as to leave a space of about an inch between its bottom and the molten copper, the current becomes steady, and the operation is established. Thereafter the ore is introduced in small quantities, at frequent and regular intervals, until the desired percentages of aluminium or silicon contained in the alloy have been secured. This percentage can be regulated entirely at will up to about 70 per cent. of reduced metal. No external heat is used, and the process is absolutely continuous at the will of the operatives, which are special features of the Heroult system. The passage of the electric current through the bath serves not only to keep the copper in a fluid state and to melt the ore, but also electrolyses and decomposes the latter. It is a point of careful regulation in the Heroult processes to maintain only sufficient heat to keep the bath fluid, since any further expenditure is not only useless, but lessens the output. The oxygen from the reduced metal combining with the carbon, of which the anode is composed, is burned with the production of carbonic oxide gas, which escapes from the crucible around the sides of the anode and at the feed hole. The product is withdrawn at intervals by tapping the bottom of the crucible as in ordinary smelting. Each time the metal is tapped, a sample is carefully preserved for accurate analysis, to determine the percentage of contained aluminium.

From a metallurgical point of view, the amount of labour required to operate this process is astonishingly small. The metal

Digitized by Google

produced in the Heroult furnace is sold generally in ingot form, just as it is tapped, without re-melting or being subjected to any purifying manipulation. It is always, however, very pure, sometimes dropping as low as 98½, but generally running over 99 per cent. of absolute purity.

The compounds of aluminium formed by the addition of copper, brass or iron, are unquestionably the most commercially important of the aluminium alloys. Aluminium combines with copper in all proportions, but its alloys are as easily influenced by impurities as is the pure metal. It is an important fact worth noting that, when alloys are made by mechanically mixing aluminium and copper, iron, &c., the product must be re-melted a number of times to secure any uniformity in the texture of the alloy. The finest alloys, by far, are those made by uniting the aluminium to the basic metal in atomic proportions as it is reduced, as in the Heroult process, the uniformity of whose alloys is remarkable. Probably the most useful compound of aluminium and copper is what is known as 10 per cent. bronze, containing 10 per cent. aluminium, and 90 per cent. of copper. This alloy is an almost perfect imitation of gold in colour, and is susceptible of taking and retaining a most beautiful polish. It can be rolled, or drawn, or cast very readily, but in casting the bronze shrinks considerably, and care must be taken to have the feeders amply large. The tensile strength of this bronze is enormous.

THE TELEPHONE.

The following letter appeared in *The Times* of Monday :—

TO THE EDITOR OF THE TIMES.

SIR,—Since my name has been mentioned several times in the course of the correspondence, I would crave indulgence for a few remarks, especially as Mr. F. Faithfull Begg, in his last letter, puts the plain question, "Can London be telephoned efficiently and profitably for a £10 subscription ?" a query which I anticipated and answered in the affirmative in the Paper I recently contributed to the British Association at Cardiff. If Mr. Begg has access to the National Telephone Company's books, he will find therein plenty of material to convince him of the practicability of the proposition. Especially would I refer him to the accounts relating to Dundee, Aberdeen, Inverness, Galashiels, and Dumfries, in Scotland, between the years 1883-90, and to Whitehaven and Carlisle, in England, between the years 1885-9. It was in these towns that modern telephone construction was first introduced and practised, and where the results flowing from good work and intelligent, conscientious supervision were first demonstrated. He will find that these centres yield, or did until last year, a greater return on the capital invested than any of the richer English towns, where the bad management which for the two first years of its existence (1881-82) characterised the old National Telephone Company held sway long after it had ceased in the north. He will discover that a company undertaking the telephoning of moderately-sized towns on a £10 tariff, and having to earn interest only on the capital actually invested, will be able to pay a dividend closely approaching 20 per cent. per annum. Now, a new company undertaking the telephoning of London would have nothing to pay for patents, and, I trust, would not be burdened with any bogus capital. It would have the example of the Scottish practice before it, and the benefit also of the Mutual Telephone Company's more recent experience in Manchester. It would likewise possess the sympathies of the London public, so long alienated by the imbecilities of the existing company. Starting thus with a fair wind it would need no favour, and only persistent bad management could prevent its earning a 10 per cent. dividend on a £10 tariff. Mr. Begg may say that Aberdeen is not London, and that what is possible in the one place may be visionary in the other. But I have had experience in managing telephonic exchange business in London as well as in Scotland, and, although I am aware that conditions differ in some respects, I also know that the variations are not radical, and are capable of being allowed for. It was to equalise these differences that the plan set forth in my Cardiff Paper was designed. The average length of a London subscriber's line, according to my plan, would be only 440 yards, while the average length of a Scottish subscriber's is very much greater, so that the prime cost of each would not be markedly different, even allowing for the additional expense of the twin wire which would be used in London. The approximate cost, including labour and general expenses, of each subscriber's connection would be—

Office instrument and fittings	£3	0	0
Line (440 yards average)	5	10	0
Switch-board and other exchange fittings	1	10	0
Total	£10	0	0

This would join the subscriber to the sectional switch-room, but he would still have to bear a proportion of the cost of the junction wires linking the sectional-room to the central. After mature consideration I have estimated that £10 per subscriber would be a most liberal allowance for this purpose, and thus arrive at a total of £20 as the cost of each subscriber's installation. Deducting 50 per cent. of the £10 subscription for working expenses (including Post Office royalty), which prolonged experience teaches me is amply sufficient, a dividend of 25 per cent. would result. But I do not anticipate such an issue on a £10 tariff. Much of the work would have to be underground, and the special conditions existing in London must be provided for. To meet these contingencies I would add £30 to the cost of each subscriber's installation, making the total £50 per subscriber, which, with a net revenue of £5, would yield a dividend of 10 per cent. Mr. Begg may realise the weakness of his contention by asking an experienced, independent telephone engineer, who knows how to obtain material in the best markets, to jot down for him how it would be possible, with fair dealing, to expend £50 on a twin line 440 yards long and a proportion of a junction line. I have taken a £10 rate because Mr. Begg specially mentions it, but personally, as I state in my Cardiff Paper, I believe that a good dividend could be earned on £8. Mr. Begg must discard all of the old company's figures and statistics except those for the northern towns I have named, for such are entirely misleading and inapplicable. They would be useful as a basis of comparison if the new company proposed to erect silver wire plated with gold and to embellish their subscribers' instruments with emeralds, but not otherwise.

Mr. Begg, in his first letter, expressed great belief in the efficacy of the reconstruction of the London over-house work now proceeding. I am sorry that I cannot share this faith. With the nature of this reconstruction we are made acquainted by the report of the National Telephone Company's recent annual general meeting. It consists in the introduction into London of the system I designed for the old National Company's Scottish centres so far back as 1883, and which, established at first in the face of vehement opposition, was subsequently copied in all their other provincial districts. It is now, after the lapse of eight years, being copied in London also, at the cost of many thousands of pounds, and is relied upon to extricate the Company from all its troubles. But, Sir, flattering to me as this expectation unquestionably is, I must point out that this system of mine, consisting of channel-iron cross-arms, upright insulators, and light bronze wire forms but a mere detail of an efficient telephonic exchange. It is insufficient in itself to improve the service; it must be supplemented by as radical changes in every other department and such changes, according to the reports which reach my ear, are not being made. This view is confirmed by the complaint made at the general meeting by one of the shareholders—a Mr. Harris, I believe—that, although his line had been reconstructed, his service continued as inefficient as before. That is exactly what I should have predicted, and I anticipate that, after the whole over-house reconstruction has been effected, the service generally will be as bad as it is now. I consider the position of the Company the more serious because, from the statement made by their Chairman at the general meeting, it is evident that they do not understand the nature of the disease which is consuming their vitals. To expect the changes he indicates to save them is absurd. His position is comparable to that of an architect who might propose to counteract the effects of unstable foundations by changing the shape of the weather vane on his building from a cock to a butterfly.—I am, Sir, yours, &c.,

A. R. BENNETT.

Britannia Hof, Frankfort-on-Main, September 9th.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *September* 5, 1891.

The Edison General Electric Company.—A report is current about town that Mr. Henry Villard, president of the Edison General Electric Company, has sent in a peremptory letter of resignation. It is understood that a considerable amount of the capital brought into the organisation through Mr. Villard's influence is now out, the stockholders having unloaded on the public at the time of the incandescent lamp decision. This fact may account for the small rise in the stock at that time, and its subsequent sharp decline. It has been felt for some little time, especially by Drexel, Morgan and Co., the largest holders of the Edison stock, that a change in the executive department might be productive of good results; and although some who are in a good position to judge of the affairs of the Edison Company deny Mr. Villard's actual resignation, they generally admit that the next annual election in January, 1892, will be productive of considerable changes. Since the reorganisation that brought Mr. Villard to the front the company has lost the services of a large number of valuable men, among whom may be noticed Mr. E. H. Johnson, Mr. Frank Sprague, Mr. O. T. Crosby, Mr. H. Ward Leonard, Dr. Hutchinson, Mr. Jackson, and others almost equally well known. Apparently Drexel, Morgan and Co. are taking cognisance of this and similar facts, and are making ready to take action thereon.

The Gearless Motors.—Reports that have been floating around of late suggest that the gearless street railway motors brought out early this summer are not altogether successful. The Short motor has given good satisfaction in and about Cleveland, where it has been, for the most part, used, but most engineers seem to doubt its ability to operate over con-

Digitized by Google

siderable grades with any degree of success. The Westinghouse gearless motor is said to have met about the same degree of success, the trouble in both cases being lack of torque. Indeed, from the size and general design of both these motors, it was rather difficult to see how both efficiency and high torque could be attained; it was not altogether evident where the power was coming from, so far as could be judged from the designs. I shall hope at a later date to give you some accurate tests of one or both of these gearless motors. The single-reduction gear motors have met with decidedly better success, in fact, hardly anything else is now being manufactured, although complaints are sometimes received of the same difficulty of too little torque that I have referred to in speaking of the gearless motors. There is, however, no good reason to expect that this difficulty will not be surmounted, as there is no particular trouble in designing single-reduction gear motors to give a good general result with a commercial efficiency probably somewhat greater than that of the old double-reduction gear machines.

The National Electric Light Convention.—Extensive preparations are now being made for the exodus of electricians to the National Electric Light Convention. The Edison and Thomson-Houston companies have made special efforts, and everything indicates that the Convention will be a success, and that the attendance will be large. My next letter will be from Montreal, and I shall hope to be able to give you some interesting news.

High Speed Traction.—Apart from things immediately electrical, a fact that will attract the attention of those interested in high-speed traction, whether electrical or otherwise, is the recent breaking of all previous speed records by a train over the Bound Brook route between New York and Philadelphia. One mile was run in 39⅘ seconds, equivalent to a rate of 90·45 miles per hour, while 10 miles were reeled off at an average speed of 43 seconds per mile, about 83¾ miles per hour. This speaks well both for the track and for the locomotive, which was of the Wootten pattern, provided with an exceptionally large and well-arranged furnace.

CORRESPONDENCE.

THE TELEPHONE MONOPOLY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR,—I have read with interest in your issue of Sept. 11th a letter from the Duke of Marlborough and your leading article upon the subject of the Telephone Monopoly. An experience through which I have myself just passed seems to me to be not unworthy of record. In April last I signed an agreement with the National Telephone Company, and at the same time obtained the permission of my landlord for the erection of a standard on the roof. Telephone wires run immediately in front, immediately behind and in fact on all sides of my house; yet it was only last week that I saw any attempt made to make the connection. In the meantime I had given notice to the Company that I considered four months ample time for the completion of the work and had withdrawn my order; for it appeared to me that if the management was so dilatory in respect to securing new customers, there was every probability that I should find it to be much worse when once I had paid my subscription.

Under these circumstances, therefore, you may readily imagine that I feel more than usually interested in the scheme proposed by the Duke of Marlborough; but I must confess that I do not quite understand how any new *company* is going to obviate the difficulties of existing corporations, except by obtaining parliamentary powers so vast and so arbitrary in their nature, as at once to create a monopoly of far greater stringency than any which has ever existed in this country; powers without which their efforts would be of no avail, but which it is hardly possible the House of Commons will be persuaded to grant.

I cannot help thinking that precisely the same arguments which were used in inducing the Government to take over the telegraphs are even more strongly applicable in the case of the telephones. In fact, I hold very strongly to the opinion that all matters in which the communications of the people are concerned should be under State management, being far too complicated and important for private enterprise.

Trusting you will not consider this letter too unimportant for insertion, I am, Sir, &c., J. F. W. S.

London, W.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

NOW READY.—"THE ELECTRICIAN" PRIMERS (38 in all. Vol. I., 20; Vol. II., 18), in two volumes. Price per volume 2s. paper covers, 2s. 6d. cloth; post free, 2s. 2d. and 2s. 9d. respectively. Single copies, 3d.; post free, 3½d. Prospectus on application to the Publisher.

TENDERS WANTED.—The Hove Commissioners are prepared to receive proposals from companies or persons willing to take over the undertaking and statutory powers for the supply of electrical energy in Hove vested in the Commissioners by the Hove Electric Lighting Order, 1890. Proposals are to be sent to Mr. Charles A. Woolley, town clerk, Town Hall, Hove, by October 26th. Further particulars appear in our advertisement columns.

——— The Bray Township Commissioners announce in our advertisement columns that they are prepared to receive tenders for the lighting of the streets of the township and Marine Promenade with electric light or gas for a period of one or three years. Tenders are to be delivered to Mr. Patrick MacDonnell, town clerk, not later than 11 a.m. on Monday, October 5th.

——— The Bradford Corporation invite tenders for lighting by electricity certain rooms in the Municipal Buildings. Plans and specifications may be seen at the office of Mr. W. T. M'Gowen, town clerk, Town Hall, Bradford, to whom tenders are to be forwarded by the 28th inst.

——— Tenders are required for the supply of electricity for lighting and power purposes to the Free City of Hamburg. Specifications and plans may be seen at the office of the Secretary of the Finance Deputation (Rathaus, I. Stock, Zimmer No. 34), or may be obtained on payment of 5s. Tenders are to be sent to the Finance Deputation by noon on October 10th.

DERBY INDUSTRIAL EXHIBITION.—During the past month an Industrial Exhibition has been held at the Drill Hall, Derby, where electrical appliances were exhibited by Messrs. John Davis and Son, of Derby, and the National Telephone Company. In the engine-room at the entrance were some four or five engines at work, and here Messrs. Davis exhibited an 18-unit compound-wound dynamo, driven by a Trent gas engine. This dynamo was used for lighting the hall and stage with incandescent lamps of from 16 to 500 c.p. A 2½-unit dynamo driven by another engine was used to work motors, for an automatic grain-weighing machine, an engraving machine, and a ventilating fan machine placed in the hall. On Messrs. Davis's stand in the hall were exhibited a large variety of telephones, mining bells and keys, portable, primary, and secondary battery lamps. Their exhibit obtained the gold medal, as was also the case last year at the Mining Exhibition.

THE ANDREWS' SYSTEM OF CONCENTRIC WIRING.—The wiring of the Waterloo Grain Warehouses, belonging to the Mersey Docks and Harbour Board, on the Andrews system has just been completed. The warehouses consist of three six-storey blocks, 80ft. wide, built along three sides of the Waterloo Corn Dock. The dynamo in connection with this installation is of Messrs. W. T. Goolden and Co.'s manufacture. The installation has been carried out to the specification of Mr. G. F. Lyster, the Dock Engineer, by Messrs. J. D. F. Andrews and Co., 41 and 42, Parliament-street, London, S.W., with the assistance of Mr. W. S. Boult, Assoc. M. Inst. C.E., 60, Castle-street, Liverpool, their sole agent for Lancashire and Cheshire.

KERITE INSULATION.—Under the name of Kerite an insulating compound, which has been used with success in the United States, is being introduced into this country. It is claimed that it withstands corrosion, and within a range of temperature extending to 200°F. it retains its flexibility and insulating properties. It is said to withstand exposure to the sun, and does not suffer from long storage; it is not attacked by marine borers or by white ants.

Digitized by Google

FORTHCOMING BOOK ON TELEPHONES.—We are informed by Messrs. Whittaker and Co. that they are about to publish a practical handbook on telephones, dealing especially with telephone exchanges, by Mr. Joseph Poole.

CATALOGUES, &c.—GALLOWAYS (LIMITED).—We have received a very compact and well-got-up little *brochure*, being a miniature reprint of Messrs. Galloways' large catalogue. It contains a short account of the design of boilers and Galloway tubes, the testing, planing, riveting, flanging, and other numerous machines employed; a large number of sectional views of different systems of setting, &c. While most English boiler makers have stuck to the stupid description of the size of boilers by giving the nominal horse-power for which they are suited, Messrs. Galloway give the pounds of water evaporated per hour, the indicated horse-power at 20lb. of water, a table of pounds of water required for various sizes of cylinders at various pressures, and many other useful notes. A little more energy of this kind would enable the thoroughly reliable English types of boiler to compete more successfully with the American importations, since these have in many cases been chosen merely because the agents were ready to save their customers the trouble of selecting the right size, and giving them all possible information about setting, &c. Illustrations and particulars of a number of engines, pumps, and other machinery given.

——— THE CONSOLIDATED TELEPHONE CONSTRUCTION AND MAINTENANCE COMPANY (LIMITED).—This Company, which has had so large an experience in the manufacture of telephones, issues a fully illustrated list of the numerous patterns of transmitters and receivers, made under the Edison, Blake, Gower-Bell, and Hunning's patents, including many ingenious combinations for desk, domestic, and operators' use.

——— FELTEN AND GUILLEAUME.—This firm have sent us a pamphlet describing their wires and cables for telegraphy, telephony, torpedoes, and electric light, together with several kinds of junction and distributing boxes. The numerous systems of insulation are described, and an account is given of the Ferranti conductors.

——— MESSRS. BLAKEY, EMMOTT, AND CO. send us a catalogue of the electric light machinery and sundries sold by them.

BOOKS, &c., RECEIVED.

"Die Versorgung von Städten mit Elektrischem Strom." Edited by F. Uppenborn. (Berlin: Julius Springer. Munich: R. Oldenbourg.)

"Special and Atomic Energy." Part III., Heat. By Frederick Major. (London: Eyre & Spottiswoode. August, 1891.)

"The Durham College of Science Calendar, Session 1891-92."

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.

August 31, 1891.

14,663. A. SHIELS. Glasgow. Improvements in couplings for connecting electric wires.

14,702. H. HAUSER. London. Improvements in or connected with accumulators or secondary batteries.

September 1, 1891.

14,752. A. HEALD. London. Improvements in appliances for use with incandescence lamps.

14,754. B. P. SCATTERGOOD. London. New or improved apparatus for electrically indicating the over-heating of bearings.

14,764. W. P. THOMSON. Liverpool. Improvements in armatures for dynamo-electric generators and electric motors. (J. F. McLaughlin, United States).

14,768. W. P. THOMSON. Liverpool. Improvements in lightning arresters. (J. P. Freeman, United States).

14,780. B. B. TOYE. London. Improvements relating to telegraphy.

14,786. J. M. RILEY. London. Improvements in electrical combs.

14,790. W. P. ADAMS. Barnes. Improvements in electrical switches.

14,794. SIEMENS, BROTHERS, AND CO. (LIMITED). London. Improvements in percussion drills and other percussion tools worked by electricity. (Siemens and Halske, Germany).

14,796. C. D. ABEL. London. Electric meter for continuous or alternating currents, also applicable as speed indicator and speed regulator. (La Compagnie Anonyme Continentale pour la Fabrication des Compteurs à Gaz et autres Appareils, France).

14,800. H. H. LAKE. London. Improvements in and relating to electric metal working apparatus. (H. Lemp, United States).

September 2, 1891.

14,834. W. E. HEYS. Manchester. Improvements in and connected with electrically propelled vehicles. (C. Brown, France).

14,854. G. A. CANNOT. London. Improvements in materials for insulating electrical conducting wires, and for making carbons and incandescent filaments for electric lighting.

14,859. E. A. GIMINGHAM. London. An improvement in incandescent electric lamps.

September 3, 1891.

14,874. R. H. NEWINGTON and E. PRIDDLE. London. An improvement in electric light switches.

14,911. W. N. MARCUS. London. Telephone receiver supports. (Date applied for under Patents Act, 1883, Section 103, February 10, 1891, being date of application in United States).

14,912. W. N. MARCUS. London. Telephone mouthpieces. (Date applied for under Patents Act, 1883, Section 103, February 10, 1891, being date of application in United States).

14,916. T. W. ARNOLD. Birmingham. Improvements in magnetic separators.

14,920. K. SCHMAUS. London. Improvements in insulators for telegraph and other wires

September 4, 1891.

14,962. W. H. BROWN. London. Improvements relating to telephones.

14,967. G. STEINLE. London. Improved process and apparatus for extracting aluminium and its alloys by electrolysis.

14,987. SIEMENS BROTHERS and Co. (Limited), A. H. DYKES, and F. G. BAILY. London. Improved electrical drill.

September 5, 1891.

15,014. W. N. NAYLOR. London. An improved electric belt or band.

15,025. A. MCLEAN GORDON and E. K. IRWIN. London. An improved apparatus for propelling one or more imitation birds by electricity for shooting at.

16,050. E. A. LE SUEUR. London. Improvements in or connected with electrolysis.

15,051. C. P. STOVIN. London. Improvements in medical electric appliances.

15,052. C. P. STOVIN. London. Improvements in medical electric appliances.

September 7, 1891.

15,075. R. THOMPSON and H. S. PAYNE. Castletown, Isle of Man. An improved portable electric lamp.

15,094. H. TROTMAN. London. Improvements in the manufacture of leaves for lamp, candle, or electric light shades.

15,096. A. A. GOLDSTON. London. Improvements in feed mechanism in relation to arc lamps.

15,123. H. EDMUNDS. London. Improvements in or connected with systems of electric distribution wherein electrical storage batteries are used.

15,125. A. J. JARMAN. London. Improvements in electrical storage cells and elements therefor.

September 8, 1891.

15,162. M. A. HILLOCK and E. PENABLE. London. The improved medical electrode or electro-medical battery.

15,214. R. R. HARPER. London. Improved construction of telephone receiver.

15,240. SIEMENS BROTHERS AND COMPANY (LIMITED) and F. HIRD. London. An improvement in bobbins for dynamo-electric machines.

September 9, 1891.

15,268. J. H. THOMAS. Bristol. An improved miners' electric safety lamp.

15,299. W. R. LAKE. London. Improvements in electrical signalling apparatus, chiefly designed for police service. (The Newhaven Clock Company, United States.)

SPECIFICATIONS PUBLISHED.

1890.

12,440. DAY and DOWSING. Electric testing apparatus. (Price 1s. 1d.)

12,874. BONNE. (The Actien Gesellschaft Mix and Genest). Electric switch. (Price 8d.)

12,914. JARMAN. Electric switches. (Price 8d.)

12,957. DAVIES and TOURTEL. Electric lighting by coin freed apparatus. (Price 8d.)

12,958. DAVIES and TOURTEL. Producing electric light by insertion of coin. (Price 8d.)

13,123. HOOKHAM. Electricity meters. (Price 8d.)

13,357. SIEMENS. Electromotors. (Price 6d.)

14,624. ELMORE. Making metallic articles by electrolysis. (Price 8d.)

15,573. DOWN. Attaching electric fittings, &c. (Price 6d.)

15,635. HALL. Commuting alternating electric currents, &c. (Price 8d.)

15,643. HOPKINSON. Electric tramways. (Price 8d.)

15,819. JOHNSTONE. Electric dynamos, &c. (Price 8d.)

16,054. SERRIN. Electric batteries. (Price 8d.)

12,243. KAISER. Magnetic compasses. (Price 8d.)

COMPANIES' MEETINGS & REPORTS.

Direct Spanish Telegraph Company (Limited).

The following is the Directors' report for the half-year ended June 30, 1891, to be presented at the general meeting of shareholders, to be held at Winchester House, Old Broad-street, E.C., on Tuesday, September 29, 1891 :—

The annexed accounts for the half-year ended June 30, 1891, show, after providing for debenture interest, a balance to the credit of profit and loss of £5,525. 16s. 10d.

The traffic receipts show a decrease of £1,620. 10s. 6d., as compared with those for the corresponding half-year of 1890. The falling off in the receipts is principally attributable to the comparative failure of the early fruit crop in Spain, owing to the severe frost, and to the iron ore trade having been adversely affected by the strikes in England and at Bilbao.

The working expenses are £284. 11s. 9d. in excess of those for the corresponding period of last year.

With the exception of the interruption of the Barcelona cable from April 3rd to 14th, the Company's cables and the land-lines in connection with them have continued in good working order throughout the half-year. The entire cost of the repairs of the Barcelona cable, amounting to £1,695. 1s. 2d., has been paid out of the "Contingencies Account."

Of the balance of profit and loss, £2.500 have been put to the reserve fund (which now amounts to £25,928. 7s. 8d.), leaving a balance of £3,025. 16s. 10d. Out of this amount the Directors recommend the payment of the dividend at the rate of 10 per cent. per annum on the Preference shares, and a dividend at the rate of 5 per cent. per annum (free of income tax) on the ordinary shares. This will admit of a sum of £270. 4s. 10d. being carried to the "Contingencies Account." The dividend warrants will be issued on October 1, 1891.

Brush Electrical Engineering Company (Limited).

The following is the second annual report to be presented to the shareholders at the general meeting of the Company, to be held at Cannon-street Hotel, London, on September 25, 1891, at 3 o'clock p.m. :—

The Directors beg to submit the balance-sheet and profit and loss account for the year ended June 30th last.

The profit and loss account shows a gross profit of £42,712. 8s. 10d., inclusive of the amount brought forward from last account, but exclusive of any profit derivable from the City of London Electric Lighting Undertaking. After deducting all standing charges, &c., maintenance of plant, buildings, and patents, and interest on debentures, there remains a balance of £19,354. 2s. 1d. It is proposed to apply £630 to reduction of preliminary expenses, and to reduce property, patents, and goodwill account by £3,000. An interim dividend, absorbing £4,199. 15s. 2d. has already been paid upon the Preference shares for the six months ended December 31st last, and it is proposed to apply £4,199. 15s. 2d. to the payment of a further dividend upon these shares, making up the full preferential dividend at the rate of 6 per cent. per annum. The Directors further recommend that a dividend be paid on the ordinary shares of the Company at the rate of 6 per cent. per annum for the half-year ended June 30th last, and that the balance of £306. 11s. 5d. be carried forward to next account. It is proposed to make the dividends on both the Preference and the ordinary shares payable on October 1st next.

The accounts include the returns from the Australasian branch, made up to the 30th April last. The business of the branch is now established on a satisfactory basis, and the result of the working shows a small profit.

The capital account has during the year been increased by £5,000, being the amount of fully paid shares issued to the Australasian Company in completion of the purchase of their stores and other assets in Australia.

The property account stood at the date of the last balance-sheet (after writing off £3,000) at				£294,400	8 10
During the year the account has been increased by—					
Proportion of shares issued to the Australasian Company, and cost of establishing branch	£1,918	10	6		
Additions to buildings, plant at Loughborough and other places ...	5,226	2	4		
Expenditure on new patents and developments	564	2	1		
				7,708	14 11
				£302,109	5 9
The account has been reduced by—					
Sales of properties, amortization of leases, and proportion of compensation received from South-Eastern Railway	£13,294	3	3		
Amount this year included in balance-sheet of foreign and colonial branches, pages 8 and 9	22,544	2	8		
				35,838	5 11
The account now stands at				£266,270	19 10

During the past year sums amounting to £21,070. 18s. 1d. were expended upon the City of London Electric Lighting Undertaking, arrangements having been made with a provisional Company called the City of London Electric Lighting (Pioneer) Company for the carrying on of the work. Since the closing of the books the whole of the interests of the Brush Company in the City of London Electric Lighting Undertaking have, with the consent of the Board of Trade and the Commissioners of Sewers, been transferred to a larger Company called the City of London Electric Lighting Company. As, however, the transfers were not completed until August 21st, no profits on the large amount of work done have been included in the profit and loss account to June 30th.

In consideration of this transfer the Brush Company has received contracts for the equipment of the central stations, amounting in the aggregate to over £300,000, to be executed by instalments as specified by the City Company. A satisfactory profit will accrue from the carrying out of these contracts, and an amount of about £53,650 is now payable to the Brush Company on account, in addition to £25,700 already received.

A strip of land adjoining the Lambeth Works has been sold to the South Eastern Railway Company in consideration of the payment of £6,500. A portion of this amount has been applied to reduction of property account, and the balance has been placed to a reserve account to meet the expenses caused by the disturbance. The main factory premises will not be affected by this sale of land, but the present office accommodation of the Company will be much curtailed, and the Board have decided to take the opportuuity of removing the Head Offices to the City.

The Bournemouth undertaking, consisting of provisional order, land, buildings, and plant, has been transferred to a local company in consideration of the sum of £17,275 which has been paid partly in cash and partly in fully paid shares of the Company, and the stores have been sold for cash at a valuation. As part of the arrangement this Company has guaranteed a minimum dividend of 5 per cent. per annum for three years upon the capital of the Company, not exceeding £30,000. The profit on the sale has been placed to reserve account.

The Austro-Hungarian business continues to increase and to give satisfaction, and the new factory at Vienna will shortly be completed. The negotiatiens for a rearrangement of the Company's interest in the business are still pending.

The volume of the Company's business in the manufacture and installation of electrical apparatus and in the construction of steam engines, and of rolling stock generally, continues to increase, and the prospects for the current year are encouraging. Besides the work to be done for the City Company several other important contracts have been secured which should result in profit to the shareholders.

The large amount of work in hand and in view has demonstrated the wisdom of acquiring and extending the Falcon Works, as without these additional manufacturing facilities the Company would not have been able to undertake the carrying out of these large central station contracts.

Owing to pressure of other engagements, Lord Thurlow felt compelled to resign his seat at the Board, and the Chairmanship of the Company, and his Grace the Duke of Marlborough has succeeded him as Chairman. The Directors also regret the retirement from the Board of Mr. John S. Sellon, on account of his health. Mr. E. Garcke, formerly manager and secretary, has been appointed Managing Director. The Duke of Marlborough and Mr. Sanderson retire by rotation, and offer themselves for re election. Messrs. Cooper Brothers and Co., the auditors, offer themselves for re-election.

NEW COMPANIES, STATUTORY RETURNS, &c.

ANGLO-AMERICAN CONSTRUCTION COMPANY (LIMITED).—This Company was registered on September 11, 1891, with a capital of £100,362, divided into 10,000 £10 shares, 12 £1 shares, and 7,000 1s. shares, by Norton and Co., 57½, Old Broad Street, E.C. The objects are :—To undertake in any part of the world the construction, equipment, completion, maintenance, or working and carrying on, of any railway, tramway, dock, harbour, water-works, gas-works, system of electric lighting, or other work of a public, private, or commercial character. The numbe of

Directors is not to be less than six nor more than eight. Qualification, £500.

MARLAND, NORTH DEVON, BRICK COMPANY (LIMITED).—This Company was registered on September 8, 1891, with a capital of £3,C00, in £10 shares, by Crowders and Vizard, 55, Lincoln's Inn-fields, W.C. The objects are :—To manufacture and deal in bricks, lime, cement, pottery, electric insulators, tiles, &c. The number of Directors is not to be less than three nor more than seven. Qualification, £50.

MID-DEVON BRICK COMPANY (LIMITED).—This Company was registered on September 12, 1890, with a capital of £25,000 in £5 shares, by Waterlow Brothers and Layton (Limited), Birchin-lane. The objects are : —To acquire and carry on the business of brick and tile manufacturers, and to produce and use electricity, magnetism, and other power. The number of Directors is not to be less than 4 nor more than 7, the first being C. Green, T. V. Cooke, C. Stanbury, and S. Stanbury.

MORECAMBE ELECTRIC LIGHT AND POWER COMPANY (LIMITED).—This Company has been formed for the purpose of supplying electric light and motive power in Morecambe and district, with a capital of £15,000, divided into 50 founders' and 14,950 ordinary shares of £1 each, and applications are now invited for these shares. After 7 per cent. has been paid on the ordinary shares, the surplus is to be divided one-third to founders, one-third to reserve, and one-third as further dividend on the ordinary shares.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the past week were £4,430.

CITY AND SOUTH LONDON RAILWAY COMPANY.—The traffic receipts of this Company for the past week amounted to £664.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended September 11th, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £2,971.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 697.—Vol. XXVII. FRIDAY, SEPTEMBER 25, 1891. Price Fourpence.

NOTES.

The Convention of the National Electric Light Association, which was held during this month at Montreal, appears to have been of a thoroughly commercial and practical character. Discussions on C.-G.-S. units and theories of magnetism are not to be found at this gathering, but manufacturers, and managers of supply stations were well to the fore, and the Papers which we have glanced over are full of practical suggestions and records of experience. We propose to publish abstracts of some of them, but a great deal of the matter can only have an outside interest to our readers, since the conditions differ so largely from our practice and requirements. A considerable discussion took place on the rates to be charged for the intermittent supply to motors for lifts. One company charges 25 cents and another 10 cents for a thousand watt-hours, but both charge $60 per horse-power year. Coal costs $2.65 per ton at the latter station, and the "indicated consumption is not more than two pounds per horse-power hour." The term "indicated consumption" requires a little explanation: if it refers to consumption per indicated horse-power, we are not much wiser; for in another Paper we find that the ratio of the electrical horse-power at the dynamo terminals to the indicated horse-power of the engine ranged from 70·3 per cent. to 77·5.

The frank way in which these station managers discussed their customers is rather amusing. "The charges to customers have been, according to my experience," said one of these gentlemen, "regulated with what the customers were willing to pay for the service." A former speaker had alluded to rebates. "The Paper," he continued, "speaks of the rebates costing only one-hundredth of 1 per cent. The rebates do not cost us that, as we only give rebates back to men who kick so outrageously that we cannot get rid of them." Rebates of this kind, and, perhaps, also the outrageous kicking which is a necessary antecedent, are developments of transatlantic civilisation with which we are not familiar. One-hundredth of 1 per cent. is certainly not worth any very violent exertion of this kind.

The correspondence in *The Times* on the London telephone service still continues—a not surprising phenomenon when we remember the peculiarly "live" subject under discussion, and the dead season of the year. Whether or not the Act of 1882 adversely affected the progress of electric lighting in this country can only interest social economists. But the present unsatisfactory condition of telephonic communication in London, the possibility of its improvement, and the probability of £10 rentals are matters which appeal to the public generally. Hence copious correspondence and innumerable suggestions.

The question at issue, as we have said before, is a very plain one. Granted that having got the telephone the most sensible thing to do is to make the utmost use of it, it cannot be denied that this ideal is not even approximated in London. For this state of affairs three remedies are suggested. The National Company, at any rate until quite lately, looked upon the multiplication of overhead wires which would result from complete metallic circuits and lower rates as not to be thought of, owing to parochial prejudices. It, therefore, endeavoured to satisfy its subscribers by concentrating its wires upon a few exchanges, and re-running all its lines in a more modern manner. These efforts have had but a small measure of success. The New Company proposes numerous small exchanges, the Mann system of switching and twin-wire circuit as *the* remedy for the present situation. The public, if we may take the daily press as a guide, incline to a Post Office monopoly. It is difficult to resist the conclusion that there is much to be said for this view.

The statement which we made in a recent leading article that no telephone system could be considered of much account unless complete, has been met with the ingenious argument that the National Company would be sure to bring down their rental to the £10 level to kill competition; hence all those who now use the telephone could subscribe to both systems for the same price as they now pay to one. This might be so; but in that case the unfortunate telephone subscriber, it seems, will be exactly where he was before, £20 a year still being exacted of him if he is desirous of conversing with anyone and everyone in the Metropolis. Seriously speaking, however, a telephone company competing in London would be certain ultimately to amalgamate, crush or be crushed; and, pending that consummation, something like telephonic chaos would prevail.

It is not easy to find any reason for the complacency with which Joule's equivalent is accepted in the scientific world, or the small attention which is paid to new determinations of it. The mechanical equivalent of heat appears to us to be one of the most important physical constants. Violle, Marks, Rowland, Anderson and Cowper, and Miculescu have made

Digitized by Google

fresh determinations, but there is little indication that confidence has been shaken in the well-known 772. The last of these determinations, as we observed in commenting upon it in a recent issue, rather tends to confirm JOULE's figure; being equivalent to 772·3, while Prof. MARKS obtained 772·81. In another column will be found an account of a determination by M. D'ARSONVAL, which is, perhaps, more interesting, on account of the details and methods employed, than important as throwing any fresh light on the accuracy of JOULE's value.

THE principle employed by M. D'ARSONVAL in determining the mechanical equivalent of heat was suggested some time ago by Prof. S. P. THOMPSON in his lectures, but has not been otherwise published. He proposed to hang a cylindrical copper vessel containing mercury by a bifilar suspension between the limbs of a magnet, which would be kept in rotation about a vertical axis. The magnetic field would drag round the cylindrical vessel through an angle which could be measured in the usual way, and the heating of the vessel and the mercury contained in it would be measured by fitting a glass tube to the top, thus making it practically the bulb of a thermometer.

THE reticence of lampmakers on the important question of the life of their lamps is very natural—they do not want to commit themselves to any rash promises. It is no use concealing the efficiencies, for these can be determined in a few minutes. But it seems that the Sunbeam Lamp Company might make some modest claim to a life for their lamps, for even a very short life would allow them to compete, much more favourably than is generally believed, with ordinary glow lamps. We have no definite information as to the life of Sunbeams; we made inquiries some months ago, and could only learn, what indeed is very apparent, that they are rather liable to blacken and thus to fall in efficiency. We have, therefore, reckoned up the comparative cost of these large lamps with ordinary glow lamps, with the view of finding out what length of life must be demanded of them if the total cost is to be the same in the two cases.

TAKING 500 c.p. for 1,000 hours, we should have, in the case of small lamps, to pay £59 for current (at 7d. per unit), and if 8-c.p. lamps are used the renewals, at 3s. 9d., would come to about £12, making a total of £71; or if 16-c.p. lamps are used—and this would be a more fair comparison—the renewals would come to £6, making a total of £65. Taking a 500-c.p. Sunbeam of the high efficiency class, at two watts per candle, the cost of current would be £29 for 1,000 hours, leaving £36 for lamp renewals, to bring the total to the same as that of the 16-c.p. lamps. This allows, at the price quoted in the list before us, 33 renewals, or a life of only 30 hours. But two watts to the candle is too good to be true, though it may represent the state of the lamp when new. Suppose, however, it falls from two watts to six watts, with a mean of four watts to the candle, the cost of current would be double the above figure, viz., £58, leaving £7 for renewals, in order to bring the total cost up to that of the 16-c.p. lamps. This would allow 6·35 renewals, or a life of 157 hours. We have only taken the 500-c.p. lamp at random, but it certainly leaves room for a modest claim on the part of the makers, who, strange to say, make no claim of the kind whatever.

Kilkenny.—At the last meeting of the Town Council it was resolved to introduce the electric light into the town.

Montreal.—The street lighting of Montreal, which already requires nearly 1,200 arcs, is shortly to be further increased.

The Faraday Centenary.—The Physical Society of St. Petersburg held a sitting on Tuesday evening last in honour of the centenary of Faraday.

Telephones in Winnipeg.—The town of Winnipeg possesses a telephone exchange which has now over 750 subscribers, being about one to every 36 of the population.

Metropolitan Electric Supply Company.—This Company now has its mains laid and ready to supply current in some 250 streets in the W.C., W., and N.W. districts.

Glasgow.—It is in contemplation to send a deputation from the Town Council to Frankfort to obtain information on the application of electricity to lighting and traction.

Sofia.—The tender of Ganz and Co., of Budapest, has been accepted for lighting Sofia by electricity. The installation, which will cost £80,000, is to be completed within two years.

The Oerlikon Works.—M. Emile Huber, of Zürich, has joined the Board of the Oerlikon Maschinenfabrik, and Mr. C. E. L. Brown will sever his connection with the firm at the end of the present month.

Bedford.—After a lengthy debate at a public meeting, convened last week by the Mayor, it was resolved that the Corporation should retain the power of carrying out the electric lighting of the town in their own hands.

Japanese Cables.—The telegraph cable between Nagasaki and Tsushima, in Japan, belonging to the Great Northern Telegraph Company, is about to be taken over by the Department of Communications of the Japanese Government.

Calcutta.—The Howrah Bridge, across the Hooghly, at Calcutta, has been lighted experimentally by the electric light. The effect is said to be most satisfactory. It is contemplated to extend the lighting to the docks at Kidderpore.

Canadian Electric Lighting Statistics.—There are at the present time in Canada some 150 central stations in operation, with about 12,000 arcs and 60,000 incandescents. Of these plants about 25 per cent. are operated by water-power.

Transmission of Power to Heilbronn.—Work was commenced on the installation for transmitting power from Lauffen to Heilbronn for the purpose of lighting the latter town on the 7th inst., and it is expected to be completed by December 1st.

The Telephone in Melbourne.—The City of Melbourne possesses a telephone exchange provided with a switch board capable of accommodating 2,600 subscribers. At present the number of subscribers to the exchange amounts to over 1,800.

Hanover.—The Municipal Central Station having now supplied current to private consumers for six months, a step is to be made towards lighting the public streets by electricity. Arc lamps are to be used for the purpose, the work being entrusted to the Allgemeine Elektricitäts Gesellschaft.

The Electrical Utilisation of Water-Power.—An Anglo-Swiss syndicate has been formed for the purpose of utilising the power of the Rhine near Laufenburg for the electrical transmission of power. It is intended to make a canal about one mile long, and it is estimated that some 7,000 H.P. will be available.

The Schuckert Trolley.—A very simple and apparently efficient trolley is used on the Schuckert overhead conductor electric tramway at the Frankfort Exhibition. It consists of an ordinary coiled conical spring, one end of which is fixed to the roof of the car, while the other end bears a socket for the trolley rod.

Digitized by Google

The Chicago Exhibition.—The Vienna Council of Ministers has refused to grant any subsidy to manufacturers who propose to show their goods at the Chicago Exhibition. On the other hand, it is stated that the Japanese Government proposes to spend the sum of £140,000 in connection with the Chicago Exhibition.

Telephone Trunk Wire Extensions in Germany.—The telephone trunk line connecting Ulm and Stuttgart (50 miles) has been completed, and will start working immediately. The line between Stuttgart and Rottweil is to be taken in hand at once, and that joining Tubingen to the general network will follow in the spring of next year.

The Salzburg Central Station.—From January 1st to August 31st of this year the Salzburg electric works supplied 1,386,252 lamp-hours, against 882,754 for the corresponding period of last year, an increase of 57 per cent. The electric lift at the Mönschberg, which completed its first year of working on August 9th, has carried up to that date 150,293 persons.

New Mexican Customs Tariff.—The Mexican *Diario Oficial* is publishing the new Customs tariff which is to come into operation on November 1st next, and from the particulars given it would appear that copper wires for electric lighting purposes will again be admitted into the country free as hitherto. Telegraph and telephone wires are also to be admitted free of duty.

The American Rubber Syndicate.—According to the financial papers, the great American rubber syndicate has failed, as so many previous combinations have done, from sheer inability to go on buying the quantities necessary to maintain its control. It was unable to borrow more money to purchase the new crop now coming into Para, and the great enterprise has proved a fiasco.

A Lead Alloy for Accumulator Plates.—The following lead alloy for accumulator plates is proposed by a M. Worms. It consists of 945 parts of lead, 22 of antimony, and 13 of mercury. The lead is melted first, and the antimony added, the mercury being introduced as the molten mass is run into the mould. The result is said to be an alloy of lead which can be easily split up into comparatively thin sheets.

Arc Lighting in Toronto.—The Toronto Electric Light Company was formed in September, 1883. It now lights the entire city, supplying current by means of 48 dynamos to 1,700 2,000 c.p. arcs, 1,500 of which are used in the streets. The steam plant consists of thirteen 100 H.P. Polson boilers, four 500 H.P. high-pressure condensing engines, and four 500 H.P. compound condensing engines, all of the Brown-Corliss type.

Cologne.—Distribution from the new central station is on the alternate-current transformer system, the cables being buried in asphalte poured into wooden conduits. Herr Hegener, the director of the Cologne station, is greatly in favour of transformers as against accumulators, and he asserts that the efficiency of the accumulators in the Darmstadt station has dropped from 62·1 to 57·8 per cent. within a year.

Church Lighting.—The London Electric Supply Corporation, who have gratuitously supplied St. Nicholas Church, Deptford, with the electric light for the last three years, have given notice that they can no longer do so unless arc lamps are substituted for incandescent lamps. As the electric light has been found preferable to gas in many ways, the churchwardens have resolved to make the change at a cost of 100 guineas.

The Cavalry Telegraph.—During the autumn manœuvres of the Austrian cavalry a telegraphic equipment, specially designed for field use, was tested, and gave complete satisfaction. The apparatus and batteries are placed in two small boxes, one of which can conveniently be carried on each side of a saddle. A line of 20 kilometres was laid in two hours. Each of the 41 regiments taking part in the manœuvres was provided with one of these portable sets of apparatus.

The Magnetic Survey of the United Kingdom.—In the last report of the British Association Committee on the Reduction of Magnetic Observations, it is stated that the magnetic survey of the United Kingdom, started on their own account by Profs. Rücker and Thorpe, proceeds rapidly under their superintendence. Messrs. Gray and Watson are at work in Ireland and Scotland respectively; and observations are made at more than 600 stations all over the British Isles.

The Bandsept Accumulator.—The accumulator invented by M. Bandsept is being introduced by the Franco-Belgian Lighting Apparatus Company. The electrodes are formed of a compressed powder, which is saturated during the process of compression by substances reduced to a gaseous state. The powder is thus impregnated, and becomes solid under continued pressure. The Company is about to carry out a system of electric lighting on the smaller lines of railway by means of this accumulator.

The Gutmann Electric Heater.—This heater consists of an electro-magnet whose laminated magnetic circuit is closed through a grate. The alternating current circulating through a coil wound round the laminated core establishes at its poles a field of rapidly varying intensity, which finds a path from one pole to the other through the grate, made of wrought or cast iron. The latter, not being laminated, becomes heated rapidly. The heat radiated is readily applied for heating or cooking purposes.

Dufftown.—At a public meeting recently held to consider the question of the Police Commissioners purchasing the present gas works and erecting new works, it was unanimously agreed to grant power to the Commissioners to employ a competent electrician to examine and report upon the practicability and probable cost of introducing electric light. It is understood that the waters of the Dullan or Fiddich would be used as the motive power for generating the electricity should the project be gone on with.

Gutta-Percha Forests.—The valley of the Orinoco, which is connected in such a peculiar manner to the River Negro by the Casicuiare, has been found to contain not only immense virgin india-rubber forests, the trees of which are said to yield a rubber superior to the best Para, but also trees of the order Sapotaceæ. Amongst the various gums obtained by explorers in the upper reaches of the river, some have been found by experts to be very similar, if not identical, with the product of the *Isonandra Percha* and *Dichopsis Gutta* of the Malay Archipelago.

Charterhouse Science and Art Schools.—The winter session of this, one of the largest science and art schools in the United Kingdom, will commence on Saturday, September 26, 1891, under the presidency of the Rev. Henry Swann, M.A. During the late session upwards of 1,100 students, mostly elementary teachers, availed themselves of the privileges afforded by this institution, and of this number nearly 800 presented themselves for examination, and were successful in obtaining a large number of certificates awarded by the Science and Art Department of South Kensington. Instruction of a practical character is given in most of the sciences at a very nominal fee.

The Electric Defences of the Thames.—The War Office authorities issued orders last week for an important series of combined artillery and submarine mining operations to be carried out at Sheerness to test the efficiency of the scheme of defence for the entrances of the Rivers Thames and Medway. The operations include night attacks on the forts. Telephonic communication has been established between Garrison Point and Grain forts for the purposes of the operations, and powerful electric search lights, to command the estuary of the Thames and Medway, have been erected on Fort Grain, on No. 1 Bastion, Sheerness lines, and at Barton's Point, near Sheerness.

The Frager Meter.—At the fortnightly meeting of the Lighting Committee of the Liverpool City Council, held on the 21st inst., the electric inspector (Mr. Yeaman) reported the completion of a series of tests undertaken with a view to the adoption of a standard meter with which to test the consumers' meters. The meters tested included those of the Hookham, Hartmann, and Braun, Frager, Richard Frères Laurence Scott and Co., Aron, and Ferranti types. The committee approved of the adoption of the Frager meter as supplied by Mr. R. P. Wilson, London, as a standard, and passed an order for the purchase of the instrument.

Hanover-square School of Electrical Engineering and Submarine Telegraphy.—The manager of this school, Mr. L, Drugman, M.I.E.E., informs us that as the result of the examination for the vellum certificate of the school, held in August. the following gentlemen have obtained the certificate in Electric Lighting and Power Transmission :—Messrs. G. Boa, J. L. Chambers, W. M. Hartin, G. Johnson, and W. B. Lock. This examination was conducted by Mr. Gisbert Kapp, M. Inst. C.E., M. Inst. E.E., and consisted of a Paper on Mechanical Engineering, a Paper on Electrical Engineering, a *viva-voce* and Practical Examination, and Drawing. All these students belonged to the advanced class. Instructor, Mr. Charles Capito, M. Inst. M.E., M. Inst. E.E.

Electric Traction on the South Staffordshire Tramways.—At a general meeting of the South Staffordshire Tramways Company, held at Darlaston on Thursday last week, the Chairman (Mr. Carruthers Wain) stated that arrangements were almost completed with a company to work the principal part of the tramway undertaking by means of overhead wires, the electric company to equip, work, repair, and renew the equipment, and to be paid partly in debentures and partly by annual instalments out of the earnings of the Company. A resolution was passed, with only one dissentient, authorising the Company to raise the balance (between £15,000 and £16,000) of a sum of £50,000 authorised some time ago. It was stated that a saving of about 3d. per mile would be effected in the working expenses.

Telephone Trunk Wire Extension.—The National Telephone Company has just completed an additional trunk wire between Perth and Dundee, to provide for the increased traffic between the former city and the towns connected by the Company's system. The new wire is specially intended to facilitate through communication between Perth, Glasgow, Edinburgh, and the South. The traffic from Aberdeen, Dundee, and towns in the division north of the Forth to Glasgow, Edinburgh, and the South has grown to such an extent that the Company recently decided to run additional trunk wires from Dundee to Glasgow and Edinburgh respectively, and these are now in course of erection. Of late several new trunk wires have been erected in Fifeshire to meet growing requirements there, and others are now in progress. Additional trunk communication between Dundee and Arbroath is about to be provided, and branch exchanges are proposed to be formed at Carnoustie and Brechin

Electric Lighting Shares.—A considerable amount of speculative activity, says the *Economist*, has recently been developed in electric lighting shares, due in part to the operations which are proceeding in the metropolis, and in part to the fact that the local authorities have, as a rule, shown little disposition to avail themselves of the powers conferred upon them by the Act of Parliament. It is difficult to see how the latter circumstances are to benefit the existing companies, unless it be that they are about to extend their spheres of operation. In the following table we give the quotations on Thursday of a few of the better known shares, contrasted with the prices at the end of August :—

	Price Sept. 17.	Price end of August.
Brush ordinary	2⅝	2½
Do. preference	2	1⅞
St. James's and Pall Mall ordinary	8	7
Do. preference	4⅞	4½
Swan	5⅝	4¾
Westminster	6	5½

The City Lighting.—At the meeting of the City Commission of Sewers on Tuesday, Mr. Baylis, the solicitor, reported that the chairman and he had satisfied themselves as to the position of the City of London Electric Lighting Company, to whom certain contracts for the electric lighting of the City were proposed to be transferred from other companies, and they recommended that authority for such transfer should be given, and the Board of Trade informed accordingly. This was agreed to. Mr. A. A. Wood hoped that the leading thoroughfares would not be closed by the electric lighting works during the busiest part of the autumn season. It was promised that this should be borne in mind. Mr. Ross, the assistant engineer, said the reason why the lighting of gas had been continued in streets where the electric light had been established was that certain risks and responsibilities had not been taken over by the electric lighting companies until a day or two since, but that in future in the streets in question, gas would no longer be used.

The Copper Supplies of the World.—Statistics just compiled show that in 1887 the total copper supplies of the world were estimated at 223,078 tons; in the following year they reached 258,026 tons; and in 1889, notwithstanding the depression which followed the collapse in copper speculation, the production of the metal further increased to 261,650 tons. In 1890 there was a still further jump to 269,685 tons. The most striking expansion has been witnessed in the United States, where the production rose from 25,010 tons in 1880 to 116,325 tons in 1890. During the same period the production of copper in Japan increased from 3,900 tons to 15,000 tons, and that of Spain and Portugal from 36,313 tons in 1880 to 52,335 tons in 1890. The Peninsula reached high water in copper production in 1888, when there was an aggregate of 56,450 tons. In Chili the production has greatly diminished. In 1880 the production of copper in that country reached a total of 42,916 tons, whereas last year it amounted to only 26,120 tons. With regard to the average prices realised for fine copper, in 1880 it was £63. 1s. 3d. per ton, in 1885 it had fallen to only £44. 1s. 6d., while in the following year it fell to the lowest point reached of recent years, viz., £40. 6s. In 1888 it sprang up to £76, and in 1890 it fetched £54. 1s. per ton.

Evening Classes at Finsbury Technical College.—We have been requested to mention that a new regulation has been adopted for admission to the evening laboratory classes at the Finsbury Technical College, in consequence of the overcrowding of applicants in past sessions. All applicants for laboratory work must previously fill up a form stating (*a*) the firm with whom they are employed, (*b*) the nature of their previous instruction in electricity, it being intended to reserve the laboratory places for those who are actually in the electrical industry, and for those who have previously mastered the elements of the science in one of the local science classes or Polytechnics. With the end of September the Finsbury lectures re-open. Prof. Perry will repeat on Tuesday evenings his course on the application of the differential and integral calculus to problems in mechanical and electrical engineering. Prof. Thompson will give a short course on telephones on Thursdays, commencing October 13th. On Mondays, beginning September 28th, he will occupy the advanced class with the subjects of motors and alternate-current work. On Wednesdays he will lecture on magnetism, electro-magnets, and measuring instruments. It is proposed later to have short courses of special lectures on electric locomotion and on the treatment of vector problems in the theory of electricity.

The Lake System of Electrical Conduits.—One of the first towns in the United States in which the running of wires underground was made compulsory was Washington, D.C. After protracted trials of various types of conduit, the United States Electric Lighting Company of that place finally settled upon the Lake underground system, a considerable amount of which, says the *Electrical Engineer* of New York, is now in operation and has proved eminently satisfactory. The conduit is composed of ducts built up in two tiers of terra cotta in the shape of double troughs, the bottom of the upper forming the top of the lower. These ducts are covered above and below by a cover. This is set in a bed of concrete, which also completely surrounds the ducts and keeps them firmly in position' The joints between the consecutive lengths are effected by bracket-shaped pieces, which clasp the conduits and which are held firmly in position by the concrete as it is rammed about them. This form of conduit has not only been used in electric lighting, but is now being introduced in Washington for telephone lines. The United States Electric Lighting Company, in Washington, has 30 to 35 miles of it with a cable capacity of over 500 miles. The Chesapeake and Potomac Telephone Company are now completing five miles with a cable capacity of at least 250 miles, and the same telephone company laid ten miles last year in Baltimore. The system is also coming into use in Chicago, St. Paul, Minneapolis, Cleveland, Louisville, San Francisco and Milwaukee.

ELECTROMAGNETIC THEORY.—XVI.

BY OLIVER HEAVISIDE.

(*Continued from page 495.*)

§ 86. From the last formula we see that to have moving force in a non-conductor (free from electrification, &c.) requires not merely the coexistence of electric and magnetic force, but also that one or other of them, or both, should be varying with the time. That is, when the energy flux is steady, there is no moving force, but when it varies, its vector time variation, divided by v^2, expresses the moving force.

The direction of **W** is a natural one to choose as one of the axes of reference of the stress, being perpendicular to both **E** and **H**, which indicate the axes of symmetry of the electric and magnetic stresses. The two lateral pressures combine together to produce a stress on the **W** plane

$$\mathbf{P}_{W1} = -\mathbf{W}_1(U+T), \quad . \quad . \quad . \quad . \quad (31)$$

where $\mathbf{W}_1$ is a unit vector parallel to **W**. (Take $\mathbf{N} = \mathbf{W}_1$ in the general formula (30) § 72 for $\mathbf{P}_N$).

If, further, **E** and **H** are perpendicular to one another, the stresses on the planes perpendicular to them are

$$\mathbf{P}_{E1} = \mathbf{E}_1(U-T), \quad . \quad . \quad . \quad . \quad . \quad (32)$$

$$\mathbf{P}_{H1} = \mathbf{H}_1(T-U), \quad . \quad . \quad . \quad . \quad . \quad (33)$$

which are also entirely normal. Here $\mathbf{E}_1$ and $\mathbf{H}_1$ are unit vectors. Thus, $\mathbf{W}_1$ is always a principal stress axis, while $\mathbf{E}_1$ and $\mathbf{H}_1$ become the other pair of principal axes when they are perpendicular, as in various cases of electromagnetic waves.

Thus when a long straight wire supports a steady current, or else is transmitting waves, the principal axes of the stress at a point near the wire are respectively parallel to it and perpendicular to it, radially and circularly. The first one has a pressure $(U+T)$ acting along it, the second (parallel to **E**) a pressure $(T-U)$, and the third (parallel to **H**) a pressure $(U-T)$. (This legitimate use of pressure must not be confounded with the utterly vicious misuse of pressure to indicate E.M.F. or voltage, by men who are old enough to know better, and do.) In general, U and T are unequal. But in the case of a solitary wave or train of waves with negligible distortion U and T are equal, and there is but one principal stress, viz., that with axis parallel to **W**, a pressure 2U or 2T. It is this pressure (or its mean value) that is referred to as the pressure exerted by solar radiation, and its space variation constitutes the moving force before mentioned. This matter is still in a somewhat speculative stage.

It is natural to ask what part do the stresses play in the propagation of disturbances? The stresses and accompanying strains in an elastic body are materially concerned in the transmission of motion through them, and it might be thought that it would be the same here. But it does not *appear* to be so from the electromagnetic equations and their dynamical consequences—that is to say, we represent the propagation of disturbances by particular relations between the space and the time variations of **E** and **H**; and the electromagnetic stress and possible bodily motions *seem* to be accompaniments rather than the main theme.

§ 87. In § 83 it was remarked that the flux induction due to an intrinsic magnetic forcive depends not upon itself directly, but upon its curl, and in § 84 a similar property was pointed out connecting the flux displacement and intrinsic electric force. That is to say, the fluxes depend upon the vectors $\mathbf{j}_0$ and $\mathbf{g}_0$, not upon $\mathbf{e}_0$ and $\mathbf{h}_0$. This remarkable and, at first sight, strange property, which is general, admits of being demonstrated in a manner which shall make its truth evident in a wider sense, and lead to a connected property of considerable importance in the theory of electromagnetic waves.

Let there be any impressed forcive $\mathbf{e}_0$ in a stationary medium. Its activity is $\mathbf{e}_0\mathbf{J}$ per unit volume, where **J** is the electric current, and the total activity is $\Sigma\mathbf{e}_0\mathbf{J}$, where the Σ indicates summation through all space, or at any rate so far as to include every place where $\mathbf{e}_0$ exists. Its equivalent is Q_0, the total rate of waste of energy, and the rate of increase of the total stored energies, say U_0 and T_0. Thus,

$$\Sigma\mathbf{e}_0\mathbf{J} = Q_0 + \dot{U}_0 + \dot{T}_0 \quad . \quad . \quad . \quad . \quad . \quad (34).$$

Now, the value of the summation is zero if $\mathbf{e}_0$ has no curl, or is irrotational—that is, an irrotational forcive does no work upon a circuital flux. This proposition may be rendered evident by employing a particular method of effecting the space summation, viz., instead of the Cartesian method of cubic subdivision of space, or any method employing co-ordinates, divide space into the elementary circuits belonging to the flux. (Here it is J.) Fixing the attention upon any one of these circuits, in which the flux is a constant quantity, we see at once that the part of the summation belonging to it is the product of the impressed voltage in the circuit and the flux therein. But there is no impressed voltage, because $\mathbf{e}_0$ has no curl; hence the circuit contributes nothing to the summation. Further, since this is true for every one of the elementary circuits, and inclusion of them all includes all space, we see that the summation $\Sigma\mathbf{e}_0\mathbf{J}$ necessarily vanishes under the circumstance stated of $\mathbf{e}_0$ being irrotational.

Now return to equation (34), and suppose that the initial state of things is absence of **E** and **H** everywhere, so that Q_0, U_0 and T_0 are all zero. Next start any irrotational $\mathbf{e}_0$, and see what will happen. The left side of (34) being zero, the right side must also be and continue zero. But Q_0, U_0 and T_0 when not zero are essentially positive. Now if (U_0+T_0) becomes positive, Q_0 should become negative, in order to keep the right number of (34) at zero. This negativity of Q_0 being impossible, these quantities Q_0, U_0 and T_0 must all remain zero. Consequently **E** and **H** must remain zero. That is, an irrotational forcive can produce no fluxes at all, if the flux corresponding to the force is restricted to be circuital.

It should be observed that this proposition applies not merely to the steady distribution appropriate to the given forcive, but to all intermediate stages, involving both electric and magnetic force, and flux of energy. Nothing happens, in fact, when any distribution of impressed force is made to vary in time and in space, provided it be restricted to be of the irrotational type, so that the voltage (or the gaussage) in every circuit is nil.

Notice further the dependence of the property upon circuitality of the factor with which the impressed force is associated (thus **J** with $\mathbf{e}_0$, and similarly **G** with $\mathbf{h}_0$), and the positivity of energy; and, more strikingly, the independence of such details as are not concerned in equation (34), such as the distribution of conductivity, permittivity, &c., or of the forces being linear functions of the fluxes.

§ 88. Returning to (34) again, we see that any two impressed forcives produce the same results in every particular, as regards

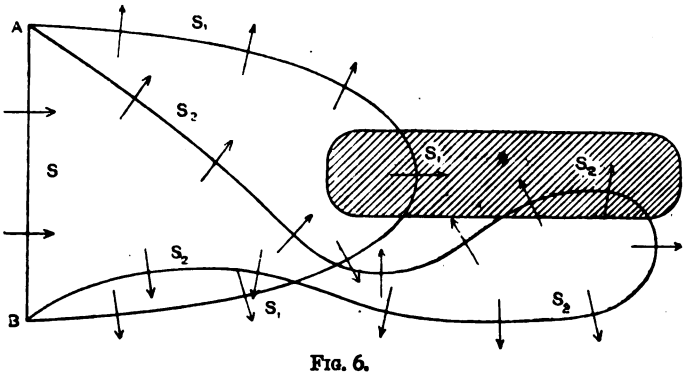

FIG. 6.

the varying states of **E** and **H** gone through, if their curl is the same. For the difference of the two forcives is an irrotational forcive, and is inoperative. Here it is desirable to take an explicit example for illustration of the meaning and effect. Describe a linear circuit in space, and a surface bounded by the circuit (Fig 6). Over this surface, which call S, let an impressed force V act normally, V being the same all over the surface. This system of force is irrotational everywhere except at the bounding circuit, where there is a circuital distribution of $\mathbf{g}^0$ the curl of $\mathbf{e}_0$, of strength V.

Digitized by Google

Now, our present proposition asserts that the disturbances due to V over the surface S are in every respect the same as those due to V (the same normal impressed force), spread over any other surface bounded by the same circuit. The comprehensiveness of this property may be illustrated by supposing that one surface is wholly in a non-conductor, whilst the other passes through a conductor; or that one surface is wholly within a conductor, whilst the other passes out of it and through another conductor insulated from the first. Thus, in the diagram, let S be the first surface (in section), and S_1 the second, passing through a conductor represented by the shaded region. The points A, B are where the common boundary of the two surfaces cuts the paper, whilst the arrows serve to show the direction of action of the impressed force. S_2 is another surface of impressed force, also reaching into the conductor. Now all these forcives (each by itself) will produce the same final state of displacement in the dielectric and electrification of the conductor, and will do so in the same manner; that is, the electromagnetic disturbances generated will be the same when expressed in terms of **E** and **H**. The distribution of energy, for example, and the stresses, will be the same.

But there must be some difference made by thus shifting the source of energy. Obviously the nature of the flux of energy is changed. This being

$$\mathbf{W} = \mathrm{V}(\mathbf{E} - \mathbf{e}_0)(\mathbf{H} - \mathbf{h}_0),$$

where we deduct the intrinsic forces to obtain the forces effective in transferring energy, we see that every change made in the distribution of the intrinsic sources affects the flux of energy, in spite of the independence of **E** and **H** of their distributions (subject to the limitation mentioned). In our example, however, the only change is in the sheet of impressed force itself.

§ 89. It may be readily suspected from the preceding, that, as far as the production of electromagnetic disturbances goes,

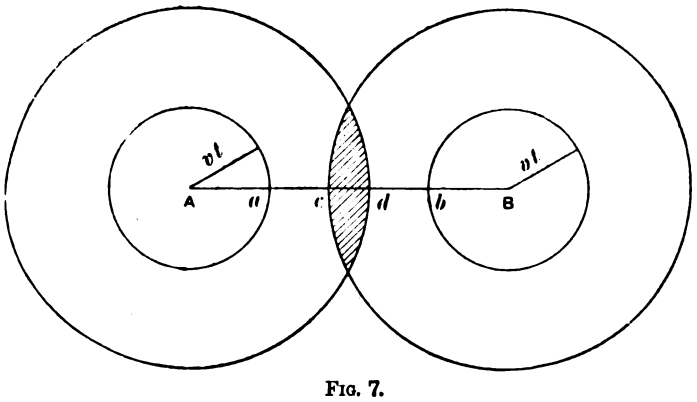

Fig. 7.

we may ignore $\mathbf{e}_0$ and $\mathbf{h}_0$ altogether, and regard the circuital vectors $\mathbf{g}_0$ and $\mathbf{j}_0$ as the real sources. This is, in fact, the case when ultimately analysed. In the example just taken the circuit ABA is the source of the disturbances. That is, they emanate from this line. If disturbances were propagated infinitely rapidly there might be some difficulty in recognising the property, because the steady state appropriate to the instantaneous state of the impressed force would exist (if the conductor were away); but, as we shall see later, the speed of propagation is always finite, depending upon the values of c and μ in the medium; and conduction does not alter this property, although by its attenuating and distorting effects it may profoundly alter the nature of the resultant phenomena. With, then, a finite speed of propagation, we have merely to cause the impressed force to vary or fluctuate sufficiently rapidly to obtain distinct evidence of the emanation of waves from the real sources of disturbance. Thus, let the source be circular in a plane perpendicular to the paper (Fig. 7), and A, B the points where it cuts the paper. When the source is suddenly started, the circle ABA is the first line of magnetic force. At any time t later, such that vt is less than the distance $\frac{1}{2}$AB, the electromagnetic disturbance will be confined wholly within a ring-shaped region having the circular source for core and of radius vt round A or round B. But when the distance vt increases to $\frac{1}{2}$AB overlapping commences, and a little later there is (as in the shaded part of the figure) a region occupied by two coincident waves crossing one another. Now, the union of these waves produces the steady state of displacement without magnetic force—that is, within the shaded region the magnetic force vanishes, and the displacement is that which belongs to the final steady state. As time goes on, of course the shaded region enlarges itself indefinitely, although outside it is still a region occupied by electromagnetic disturbances going out to infinity. This supposes that there is no conductor in the way. Should there be one, then, as soon as it is struck by the initial electromagnetic wave, it becomes and continues to be a secondary source of disturbance, and the final steady state, different from the former, now arises from the superimposition of the primary waves and the secondary.

It is, of course, impossible to go into detail at present, the object being merely to point out the difference between sources of energy and sources of disturbance. The source of energy only works when there is electric current at the spot, and this comes to it from the vortex lines (the circuital sources of disturbance). Thus, in the last figure, at time vt, when the ring of disturbance is of thickness $2vt$, if the impressed force be in a circular disc whose trace is the straight line AB, the force is working in Aa and in Bb, but inoperative elsewhere. Again, after overlapping has begun it is still working in Aac and Bbd, but is inoperative in cd, having done its work. Similarly when the sheet of impressed force has any other shape. The impressed force only works when it is allowed to work by the electromagnetic wave reaching it.

To emphasize the matter, take another case. Let the impressed force in any telegraph circuit be confined to a single plane section across the conductor, so that the vortex line is a line on its surface, going round it. If this be at Valencia, we may shift the "seat of the E.M.F." to Newfoundland, provided we preserve continuity of connexion with the vortex line, as before explained; for instance, by extending the sheet over the whole surface of the conductor between the two places. The sheet at Newfoundland and the surface sheet will together produce the same effects as the original sheet at Valencia. Or, we may have the sheet entirely outside the circuit, provided only that it is bounded by the original vortex line, in touch with the conductor.

What the practical interpretation of this extraordinary property is in connection with the "seat of E.M.F." of galvanic batteries and in electrolysis generally still remains obscure. All impressed voltages and gaussages are more or less difficult to understand. But there need be no doubt as to the general truth of the property if the circuitality of the current can be trusted.

(To be continued.)

THE DETERMINATION OF CURRENTS IN ABSOLUTE ELECTRO-MAGNETIC MEASURE.

BY G. F. C. SEARLE, M.A.

(Continued from page 555).

§ 14. **Equipotential Surfaces.**—An equipotential surface is one at all points of which the potential is the same. From this definition we see that no work is done in taking a unit pole from any one point on the surface to any other point on the surface. Taking two points, A B, close together on the surface, we see that since no work is spent upon the pole in moving it from A to B, the lines of force near A B must be perpendicular to the surface there, otherwise there would be a component force along A B, and work would have to be done. To draw the equipotential surfaces on the proper scale, they must be so drawn that, in going from one surface to the next, one erg of work is expended on the unit pole. If we do this then this set of surfaces may be used instead of the lines of force to indicate the state of the magnetic field at every point of space.

Digitized by Google

For if n (Fig. 14) is the normal to any equipotential surface at any point P, the force along n in the direction in which n increases is $-\frac{dV}{dn}$, and this is the resultant force experienced by the pole since the resultant force is perpendicular to the equipotential surface. Thus, if H is the resultant magnetic force at any point of the field, $\mathsf{H} = -\frac{dV}{dn}$. Now, taking $dV = 1$, which corresponds to a passage from one equipotential surface to the next, the surfaces being drawn in the manner just indicated, we have $\mathsf{H} = -\frac{1}{dn}$ where dn is the distance in centimetres from one equipotential surface to the next, measured along the normal. We now see how the set of equipotential surfaces maps out the field, for the normal to any surface at any point on it, gives the direction of the magnetic force, while unity divided by the distance, measured along the normal from

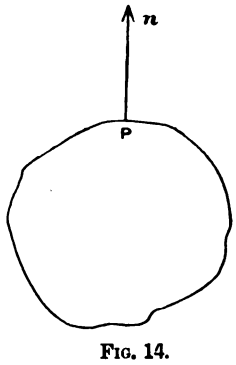

FIG. 14.

one surface to the next, is equal to the magnetic force. The curves in which the equipotential surfaces due to a magnet are cut by any plane can be found experimentally in the following way :—Place a magnet on a drawing-board covered with paper. Take a small compass, which has attached to its magnet a small brass cross-piece at right angles to the axis of the magnet. Place the compass on the board and make marks exactly opposite each end of the cross piece. Let A B be its two ends. Move the compass and place it so that the end A occupies the old position of B. By repeating this operation we shall obtain a set of points, and the curve drawn through them all will be a close approximation to the curve required. The same operation performed with the compass magnet itself instead of with its cross piece will plot out the lines of magnetic force. The paper will be divided up into small quadrilaterals, whose angles are right angles and whose sides are very slightly curved. Diagrams of this description will be found at the end of Maxwell, Vol. II.

§ 15. The system of tubes of induction, and of equipotential surfaces, divides up the whole field into a large number of cells.

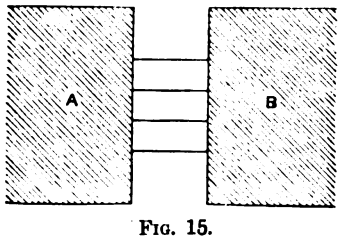

FIG. 15.

Let us inquire as to the size of these cells at a place where the magnetic force is H. We have seen that at such a place the cross section of a tube of induction is $\frac{1}{\mathsf{H}}$ square centimetres, while the distance from one equipotential surface to the next is $\frac{1}{\mathsf{H}}$ centimetres. Accordingly, the volume of each cell is $\frac{1}{\mathsf{H}^2}$ cubic centimetres, or there are H^2 cells per cubic centimetre of the field. These cells have a very deep significance on Maxwell's Theory. We will look a little more closely into the matter. Suppose we have two magnets, A B (Fig. 15), with large flat ends, uniformly magnetised. Let the ends A and B be placed very close together and parallel, A being a north pole and B a south one. Let H be the magnetic force at any point between A and B; this will be perpendicular to both of the faces and in the direction A to B. Then there are H tubes of induction proceeding from each square centimetre of the pole A, and ending on the pole B. If σ is the strength of the pole A per square centimetre, then since 4π tubes proceed from every unit pole, the value of σ must be $\sigma = \frac{\mathsf{H}}{4\pi}$ Now, a unit pole placed between the faces is acted on by a force H dynes from A towards B. But since the ends are very large indeed, compared with the distance between them, the force on the unit pole due to each end will be independent of the distance (always very small) of the pole from the end. Hence we see that each end produces by itself a magnetic force $\frac{1}{2}\mathsf{H}$. Now consider the magnetism on the face B. There are $\frac{\mathsf{H}}{4\pi}$ units of south magnetism per square centimetre. This is acted on by a magnetic field whose strength is $\frac{1}{2}\mathsf{H}$, due to the opposite pole. Thus each square centimetre of the face B is attracted to the face A with a force $\frac{\mathsf{H}^2}{8\pi}$ dynes. Now separate the two poles slightly further by a distance x. The work done is $\frac{\mathsf{H}^2}{8\pi}x$ ergs per square centimetre of face. By the movement we have increased the volume between the poles by x cubic cm. per square cm. of face. Each cubic cm. contains H^2 cells, so that the number of cells in the field has been increased by $\mathsf{H}^2 x$ per square cm. of face. Comparing the work done and the number of cells formed, we see that the formation of one cell has involved the expenditure of $\frac{1}{8\pi}$ ergs of work. Maxwell supposes that the energy of all electrical and magnetic systems is really distributed throughout the field. We may accordingly suppose that each cell contains $\frac{1}{8\pi}$ ergs of energy. The above demonstration is hardly exact unless the size of the ends of A and B is infinite compared with the distance between them, but it seems to put the matter in a fairly clear light. Although we cannot assert definitely that each *cell* does contain $\frac{1}{8\pi}$ ergs of energy, yet we can show by a more elaborate process that we are always able to assert that the whole potential energy of the magnetic system is equal to the whole number of cells in the field divided by 8π.

§ 16. The attraction of the two ends A and B is brought about, according to Maxwell, by a stress in the medium between the poles. There must be a tension $\frac{\mathsf{H}^2}{8\pi}$ dynes per square centimetre in the direction of the magnetic force, since this is the force per square cm. which either face experiences. The energy per cubic cm. is also $\frac{\mathsf{H}^2}{8\pi}$ ergs, since there are H^2 cells per cubic cm., so that the tension per square cm. and the energy per cubic cm. are equal. It is very instructive to compare the case we have been considering with that of a soap film. Suppose we have a wire framework, A C D (Fig. 16), the side A being l centimetres long, and a bar, B, sliding on the sides C D. Let a soap film be placed on the space A B. It will endeavour to pull the bar B towards A. Let B be pulled further from A through a distance x. Let T be the surface tension, *i.e.*, the pull across each centimetre of the surface. The force exerted on B by the film is then Tl dynes, and the work we do in displacing B through x centimetres is Tlx ergs. But lx square cm. is the increase in the surface of the film, so that we have done T ergs per each square centimetre increase of the film, and we are, in consequence, led to suppose that the soap film contains T ergs of energy per square centimetre of surface.

Maxwell (Vol II., ch. XI.) has shewn that if in addition to the tension $\frac{\mathsf{H}^2}{8\pi}$ along the lines of force there is a pressure in

Digitized by Google

the medium at right angles to the lines of force equal to $\frac{H^2}{8\pi}$ dynes per square cm., then all the forces experienced by magnets and currents can be accounted for. We have here merely put into a quantitative form the conception of Faraday that the lines of magnetic force tend to shorten themselves, and that they repel each other when placed side by side. When the medium with which we are dealing can become magnetised the expressions for the stresses become rather more complicated. For this case we must refer the reader to Maxwell.

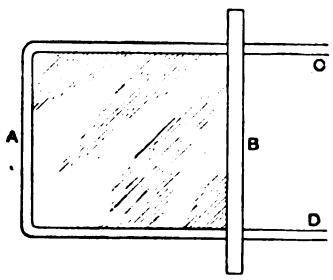

Fig. 16.

§ 17. We will now find the magnetic potential due to a single pole of strength m placed at O (Fig. 17). The force experienced by the unit pole at P is $\frac{m}{OP^2}$. If we supposed that this remains constant while we move the unit pole from P to a very near point Q, then the work spent upon the pole would be $\frac{m}{OP^2}(OP-OQ)$. If we supposed the force remains the same as it is at Q, the work would be $\frac{m}{OQ^2}(OP-OQ)$. The first expression is larger and the second smaller than the true amount. But we get a very close approximation by putting for the work done the expression $\frac{m}{OP\cdot OQ}(OP-OQ)$. But this is equal to $V_Q - V_P$. Hence

$$V_Q - V_P = \frac{m}{OP\cdot OQ}(OP-OQ) = \frac{m}{OQ} - \frac{m}{OP}.$$

Fig. 17.

Going from Q to the near point R, we have in the same way $V_R - V_Q = \frac{m}{OR} - \frac{m}{OQ}$, and, therefore, by addition, $V_R - V_P = \frac{m}{OR} - \frac{m}{OP}$. By proceeding in this way we see that if A and B are any two points $V_A - V_B = \frac{m}{OA} - \frac{m}{OB}$. Now we consider the magnetic potential at infinitely distant points to be zero. Take then B to be infinitely distant, then $V_B = 0$ and $\frac{m}{OB} = 0$, and we thus find $V_A = \frac{m}{OA}$, or simply $V = \frac{m}{r}$ when r is the distance of the point at which we require the potential from the pole. In other words, the work spent upon a unit magnetic pole in bringing it from an infinite distance to within a distance r from a pole of strength m is $\frac{m}{r}$ ergs. This is the potential energy of the system of the two poles. If we had brought up a pole of strength m' the potential energy of the system would have been $\frac{mm'}{r}$ ergs.

Erratum.—In the issue for September 11th the last formula of § 6 should read $T = 2\pi\sqrt{\frac{K}{MH}}$, *instead* of $T = 2\pi\sqrt{\frac{MH}{K}}$.

(To be continued.)

THE VELOCITY OF LIGHT REGARDED AS A VELOCITY OF MATTER.

BY S. TOLVER PRESTON.

If we accept the conclusion as axiomatic that matter alone can possess velocity, still some may find a difficulty in conceiving, even in its most ultimate form, the objective existence of a velocity equal to that of light.

But if there be no "Force" (spiritual) in the domain of Physics—"action at a distance" (assumed *instantaneous*) being supposed rejected—then surely something must move at not less* than the velocity at which light is propagated. It may be all very well to say light is propagated in the form of a wave. But what is the mechanism which propagates the wave, if there be no (spiritual) "Force?" Something material must get across space at the speed of a wave of light. We cannot traverse space without matter by the aid of a wave.

In a somewhat parallel way in principle, at least (without knowing whether light is carried forward in a succession† of curved or straight lines), if the molecules of *air* exert no "Force" or distant influence on each other, these molecules can obviously have no means of acting on each other, excepting by direct impact, and, therefore, they must possess normally a velocity not less than that of the wave which they propagate—a wave of sound in this case.

If, then, the reality of the existence of a velocity of matter not less than that of light can be inferred, the question may be how to facilitate the conception of it. The fact may be cited that it has been demonstrated mathematically that according to the modern kinetic theory of gases, the velocities of the molecules of the atmosphere (in continual interchange of motion among themselves), vary within an *indefinitely* great range. We cannot imagine an infinite velocity; but the theorem that the velocities of the molecule of a gas "vary between zero and infinity," must at least imply that there is no assignable limit to the velocities attainable by molecules in the accidents of their encounters, provided the number of molecules be not limited. The number of molecules in the atmosphere is great enough to allow enormous velocities at times according to the above mathematical theorem, which would entail, perhaps, speeds in excess of that of light, now and then.

But I have pointed out (*Phil. Mag.*, May, 1891, p. 441, "Some Remarks on the Kinetic Theory of Gases") that the friction in the ether and other causes would tend essentially to curtail the speed which molecules might otherwise accidentally acquire. But if a molecule of air can (in the contingencies of its encounter with others) perhaps attain a speed equal to that of light occasionally, though rarely, and certainly would exceed this speed sometimes but for the friction in the ether, how simple is it to conceive what must be very much smaller portions or particles of matter in the form of ether, possessing normally a velocity not less than that of light. For such particles of ether have nothing comparable to the friction of passage to surmount, which the relatively big molecules of the atmosphere have, moving in ether. We have spoken of "particles" of ether, which, of course, involves the assumption that the ether is of some sort of *molecular* constitution. The idea of a *non*-molecular ether can‡ scarcely be called a conception, and has gained no real ground.

As regards visible velocities capable of being acquired by matter, we may observe that even the relatively gross masses constituting comets are seen to traverse the ether at speeds of 300 miles per second or more. So that to imagine particles of matter moving without friction, and so minute as those constituting the ether must be, to possess normally the speed of

* This is, perhaps, only approximately true (?) in the case of a fluid theory of matter into the consequences of which I do not presume to enter; but in any case this Paper may awaken thought and be useful to publish, especially on account of the practical interest now attached to the ether.

† It is not implied, of course, that light is propagated like sound; all that is contended is that a velocity cannot get across space without matter accompanying the velocity—no consequence what direction the velocity takes or how it varies.

‡ We have elsewhere laid stress on the fact that, according to the vortex atom theory, the ether would be necessarily atomic or molecular; but it is doubtless best to be independent of particular theories of the nature of matter generally.

Digitized by Google

light, is easy enough. The remarks apply practically to the tentative calculations (as rough limiting values) for stored-up energy, pressure, &c., illustratively offered in a former article, "On the Energy capable of being Stored in the Matter of Space or Ether," in *The Electrician* of June 12th, when this natural velocity unit was taken, not merely as a vague conception, but as representing a velocity of matter, from which we may derive approximate estimates of the energy silently stored in the material body, concealing this velocity within itself.

It must surely, after all, be an axiom that "velocity" can only be applied to matter, for "force" is assumed (not conceived) to be *instantaneously* propagated; so that it appears questionable if we can apply the term "velocity" here. Even if this assumption of "action at a distance" be encouraged as a speculative possible truth (although admittedly inconceivable), yet this, obviously, should not hamper independent inquiry. If, on the other hand, "action at a distance" be dismissed from the thoughts entirely, then the mere admission that a velocity of matter, not less than that of light exists, must deductively have vast consequences in regard to the ether, which then presents itself to us as the prime source of motion and storehouse of energy.

ELECTRIC LIGHT IN HOLLAND.

In a country where so curious a mixture of imperturbability and enterprise, of thrift and luxury, is to be found, it seems to be a mere chance whether electric light will spread rapidly or struggle ineffectually. It happens that what little electrical work there is has been put down by Germans, and though it is spreading on its own merits, it is not likely to be taken up so well as if some Dutch engineers could be found to turn their attention from canal cutting and dyke building. Numerous factories are provided with their own electric light plants here, as all over the world; but, as far as we are aware, there are only two public supply stations, the one at the busy capital, Amsterdam, and the other at the fashionable residence of the Court at the Hague.

On a recent occasion we took the opportunity of visiting these two stations, tracking them down in each case by the chimney shafts and their exhalations; for the Dutchman is justly proud of the picturesqueness of his streets, and allows no overhead wires. With praiseworthy impartiality, Holland has adopted alternate currents in one station and low-pressure with batteries at the other, and as far as the light is concerned, both glow lamps and arcs are thoroughly first class, the former being well up to colour, the latter steady and silent, both giving general satisfaction and not known to fail.

At the Hague we found the *Centraal Station voor Electrische Stroom levering*, a substantial building consisting of a commodious engine-room and "kettle-house," surrounded by and overlooked by a glazed corridor communicating with the various offices of the supply company. The whole of the plant, from the dynamo to the lamps themselves, including the mains, is supplied by and is the design of Messrs. Siemens and Halske, who are represented by the chief engineer, Mr. N. J. Singels. A pair of horizontal engines had been at work, but are now dismantled, and are being moved to allow for extension of the plant, on account of the increasing demand for light. The three-wire low-pressure system with batteries is employed, and the load last month was equivalent to rather more than 3,000 16-candle lamps. The engines are of an inverted marine type, and drive two dynamos, one at either end of the shaft, the driving of course being direct. There are two of these sets, and there is plenty of room for two or three more. We do not like to criticise the dynamos, the fact that more of them are being built is some proof that they are satisfactory, even if the eulogistic account which was given to us is put down to enthusiasm and pride in the work of so well-known a firm. They are of the inside-pole, outside-commutator pattern, as described and illustrated in our issue of August 28, p. 461. The stationary magnets are like those of the Jablochkoff dynamo; and the armature wound Gramme-ring fashion, with bar conductors, is overhung. The outer surface of the armature acts as a commutator; and although the machine appears to be very expensive to build, it must be admitted that the trouble of attaching the sections of a separate commutator is thus avoided. It was pointed out to us that the centrifugal force in such an armature is balanced by the pull of the field-magnets; but the only advantage that we can see in this type of machine is the reduction of angular speed of the armature and shaft, at the cost of considerable mechanical stress and very large peripheral speed of commutator. It is rather remarkable that while the English firm of Siemens Bros. have put down a set of dynamos at the Naval Exhibition of the largest and most substantial character, and of a design and workmanship that cannot fail to please the eye of an English engineer, their German allies should deliberately build such strange machines. There is no reason why the efficiency should not be excellent, and the only points about which we are inclined to be sceptical are the cost and the durability.

Only a small battery capacity is provided at the Hague station, and it is employed in much the same way as at Kensington and Knightsbridge. An all-day supply is provided, all the private houses and smaller customers being charged by meter, while the hotels and large establishments are charged by contract. A large switchboard, placed in a gallery overlooking the engine-room, controls the various feeders and mains, voltmeters with pilot wires from the ends of the feeders and ammeters being provided, while an attendant controls the pressure by means of resistances. In the *ketel-huis* large locomotive boilers are used, and, the remaining space being limited, a water-tube boiler is being put down. The economy of this station appears to be remarkable, but the figures which we saw cannot be compared directly with those of our London stations, though we hope that the Chamber of Commerce scheme of gathering statistics will enable a just comparison, in such a case as this, to be made. Load diagrams are taken every day, and among the various analyses which are made is one which gives the "ampere-hours per kilogramme" of coal. This appears to vary from 2·8 to 3. There being, say, 110 volts, this gives 308 to 330 watts for 2·2lb., or 5·33 to 4·97lb. per E.H.P. Siemens' armoured cable is used, many of the feeders being concentric conductors.

At Amsterdam a beginning was made in the centre of a large block of houses in the busiest part of the city, and overhead wires were run to various shops and hotels. The light being appreciated, more plant was put down, and permission was granted for running underground conductors. Alternating currents are used, one dynamo running direct on the mains, and the other on alternators. The high-pressure service is at 2,000 volts, and is transformed to 72 volts for the glow lamps and to 36 volts for the arcs. The dynamos are of Ganz's make, and resemble the Siemens' continuous-current dynamos at the Hague, in having overhung ring-armatures with fixed internal magnets, and are direct driven by horizontal engines. The space in the engine-room is very limited, and the supply company hope to remove shortly to larger premises. The underground conductors are made by Felten and Guilleaume, the larger ones being concentric; they are lead covered, and are laid in wooden troughs, filled in with asphalte and covered with stone flags. The supply is not maintained all day, but the whole of it is charged by meter, considerable abatement being made to large consumers. Frager and Aron meters are used, and a meter of Messrs. Ganz and Co. made by the Helios Company. The transformers, arc lamps, and many of the accessories are of Ganz's design, but manufactured by the Helios Company.

The price charged at Amsterdam is 8d. (40 cents) per 1,000 watt hours; and lamps are to be bought, having a life of 1,000 hours, and an efficiency of 3½ watts per candle, for 1s. 8d. to 2s. The price of current compares well with that which is charged in London, when it is remembered that while the gulden (100 cents) is worth 1s. 8d., it only goes as far as a shilling in most purchases; and the price of 8d. may, for practical comparison, be reduced to less than 5d. It is a pleasure to find such good results, and that the work is well and carefully carried out, with no unsightly temporary makeshifts. On a future occasion we hope to describe an equally satisfactory specimen of accumulator traction in Holland.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

Advertisement Rates, &c., forwarded on application as above.

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday. Renewals of expiring advertisement orders and alterations to standing advertisements should be in Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday.*

SMALL PREPAID ADVERTISEMENTS *accepted up to 4 p.m. Thursday.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, 1891, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with well-written Biographical Notices of leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1891 should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Prospectuses free.

ELECTRICAL BOOKS AND PUBLICATIONS

All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad*

"THE ELECTRICIAN" *Series at present consists of—*

THE ALTERNATE CURRENT TRANSFORMER IN THEORY AND PRACTICE. By Dr. J. A. FLEMING. Vol. I. Price 7s. 6d., post free.

THE ART OF ELECTROLYTIC SEPARATION OF METALS (Theoretical and Practical). By Dr. GEORGE GORE. Price 10s. 6d., post free.

PRACTICAL NOTES FOR ELECTRICAL STUDENTS. By A. E. KENNELLY and H. D. WILKINSON. Vol. I. Price 6s. 6d., post free.

THE STEAM ENGINE INDICATOR AND INDICATOR DIAGRAMS. Edited by W. W. BEAUMONT. Price 3s. 6d., post free.

ELECTRO-CHEMISTRY. By Dr. GEORGE GORE. Price 2s., post free.

Several Further Volumes in Active Preparation.

NOW READY, IN TWO VOLUMES.

"THE ELECTRICIAN" PRIMERS.

Fully Illustrated.

Price: Stout paper covers, 2s., post free, 2s. 2d. each; strong cloth, 2s. 6d., post free, 2s 9d. each. Single Primers, 3d., post free, 3½d. Abroad postage extra.

CONTENTS OF THE CURRENT NUMBER

NOTES 569
Electromagnetic Theory.—XVI. By Oliver Heaviside. Illustrated. Continued 573
The Determination of Currents in Absolute Electro-Magnetic Measure. By G. F. C. Searle, M.A. Illustrated. Con. ... 574
The Velocity of Light Regarded as a Velocity of Matter. By S. Tolver Preston 576
Electric Light in Holland 577
GAS-ENGINE SUB-STATIONS 578
The Frankfort Congress of 1891. By Prof. S. P. Thompson, F.R.S 579
Alternating-Current Electric Supply Stations. By Dr. J. A. Fleming, M.A. Illustrated 582
Magnetism in Iron and other Metals.—LL. By Prof. J. A. Ewing, F.R.S. Illustrated. Continued 584
The Frankfort Exhibition.—XI. Illustrated 586
On an Electrical Method of Determining the Mechanical Equivalent of Heat. By M. D'Arsonval. Illustrated 588
Electric Mining Machinery, with Special Reference to the Application of Electricity to Coal Cutting, Pumping, and Rock Drilling. By Llewellyn B. Atkinson and Claude W. Atkinson, Assoc.MM. Inst. C.E. Illustrated. Continued 590
Tests of the Tudor and Correns Accumulators 592
American Notes 593
Scandinavian Notes 594
CORRESPONDENCE—
The Correction for "*g*" in connection with Sir William Thomson's Standard Balance Instruments—Andrew W. Meikle 594
The Determination of Currents in Absolute Electro-Magnetic Measure.—J. D. Hamilton Dickson 594
Smoke Annihilation.—W. Geipel 594
Trade Notes and Notices 595
New Companies, Statutory Returns, &c. 595
City Notes, &c. 596
Companies' Share List 596

GAS-ENGINE SUB-STATIONS.

The proposal which has been made by the Gas Company of Cork to generate and supply electrical energy by means of scattered stations worked by gas engines, offers a very interesting problem to the engineer, and is a matter of considerable importance to many others than the inhabitants of the town in question. Taking the price of electric supply on the one hand at 7d., or even the 6d. which is talked about but not frequently found in practice, and reckoning the cost of generating a unit by gas engines at less than 2d., there is something very tempting in the idea. It is obvious that this scheme not only makes use of the existing gas mains instead of expensive conductors, but does away with the necessity for a special staff of clerks and collectors, to say nothing of directors. We have alluded more than once to the subject in these columns, and have commented on the policy and the cost of such a scheme, our attention having recently been called to it by the leading gas journal. On the latter occasion it was proposed to use this system in Glasgow, and there it would have had a more satisfactory field than at Cork; but it would be interesting to see the system tried on a fair scale, and our gas friends must excuse us if we venture to prefer that the cost of such an undertaking should fall upon them. For the electrical industry has sunk too much money in pioneer work which has turned out to be more useful as a lesson than profitable as an investment.

There are a good many different points requiring careful consideration; for while the principle of feeding a low-pressure network by separate dynamos avoids the use of mains and feeders, the generating stations cannot be multiplied without serious increase of capital expenditure and cost of labour. We may take for an example a station capable of running 500 16-candle lamps, say 32 kilowatts. The slow speed of gas engines makes direct driving out of the question, and belting would have to be used; so that a commercial efficiency of more than 86 per cent. could not be expected, thus demanding 50 horse-power, or 1,250 cubic feet of gas per hour. Taking gas at 3s. per thousand, we consume 45d. worth per hour, getting

Digitized by Google

a unit of electrical energy for 1·4d. It is this figure, so easy to calculate, which is at first so encouraging. But, after all, this only represents the consumption of fuel; and this we know, from Mr. CROMPTON'S last Paper, may be put, under favourable circumstances, at a slightly lower figure. When we say "favourable circumstances" we refer to existing stations and not to ideal ones. If it were not for the unfortunate waste in the boilers we might approach the 2½lb. of coal per unit, which ought to be sufficient, and which is amply sufficient when the plant is subjected to a regular test. This would bring down the fuel to 0·275d. per unit, and gas would have to make up the difference between this and 1·4d. in other directions if it ever has this price to compete with. It is, however, to be remembered that in the case of gas supplied by a gas company to its electrical department, the actual cost of production of the gas would probably be charged, so that the cost per electrical unit generated would be less than the 1·4d. worked out above, though how much so would depend upon the manner in which the accounts of the electrical concern were entered in the Company's books.

The cost of plant and, therefore, the upkeep, must necessarily be dearer under this system of distribution by gas engines. A reserve must be kept at almost every station; and not only do two 50 H.P. dynamos cost more than one of 100 H.P., but gas engines are very expensive machines for their output when all the tanks and fittings are included, and the cost of the several buildings must be added. The boilers of a steam station must not be taken together with the engines in making a comparison with gas engines, since the gas company practically throw in the cost of generation in the price of the gas. If it is proposed to use even a small battery reserve, the cost of labour in attending to a number of scattered accumulators would be very appreciable, and it is not easy to see how light loads could be met satisfactorily unless by using two gas engines to each dynamo. If, however, there is one member of the gas industry who is better able than another to plan and to develope such an undertaking, Mr. DENNY LANE, the secretary of the Cork Gas Company, is the man.

THE FRANKFORT CONGRESS OF 1891.

BY PROF. SILVANUS P. THOMPSON, F.R.S.

Electrical Congresses are not held with the recurrent regularity of the meetings of the British Association. That which has been held this year at Frankfort differs from its predecessors in Paris in many ways, most of all in that it did not profess to be representative of the abstract science at all, being avowedly of an electro-technical character. The absence from such a gathering of such leaders as Sir William Thomson, Prof. H. von Helmholtz, Monsieur Mascart, and Prof. Rowland, is quite sufficient in itself to mark the difference. In the proceedings of the Congress itself there were no discussions on matters of refined theoretical importance; the Congress bore a strictly matter-of-fact aspect, and confined its attention to questions of practical interest. Further, the Congress was not official in the same sense as the Paris Congress of 1881, which was got up under the direct patronage of the Government of the French Republic, and to which most of the delegates were officially designated by their respective Governments. It is true that the opening session of the Frankfort Congress was honoured by the presence of the ever popular Postmaster-General of the German empire, his Excellency Dr. von Stephan. But the delegates present were mostly chosen—so far as they had any standing at all to distinguish them from the crowd of members who became such by purchase of a ticket—by the various electro-technical societies, not by the Governments of their respective countries.

The Congress began on the evening of Monday, September 7th, in the large restaurant of the Electrical Exhibition, with a "greeting," or informal reception, the homely Teutonic heartiness of which stood out in strong contrast with the frigid ceremonial of the corresponding function at the British Association Meeting at Cardiff, from which several of the English party had gone almost direct to Frankfort.

On Tuesday, September 8th, the work of the Congress began with a general assembly in the Victoria Theatre in the Exhibition grounds. The members were welcomed by Privy Councillor Heldberg, honorary president of the Electro-technical Society of Frankfort, to the initiative of which body both the Exhibition and the Congress owe their origin. Then followed an introductory oration by his Excellency Dr. von Stephan, who announced the interest taken in electrical matters by the German Kaiser, reviewed the progress of electrical science since the Paris Congress of 1881, touched on the commercial questions relating to the development of the industry, referred to the alarming rate at which our coal supplies are being used up, expressed the hope that electricity would enable us to utilise other natural forces, deprecated undue speculation, and ended by declaring the Congress open. Then followed the election of Dr. Werner von Siemens as president, and of the five vice-presidents, Mr. Preece of London, M. Hospitalier of Paris, Prof. Ferraris of Turin, Prof. von Waltenhofen of Vienna, Prof. Carl Hering of Philadelphia, and Prof. Kohlrausch of Hanover; and as secretaries, Herr Uppenborn of Berlin, Prof. Heim of Hanover, Herr Hartmann, and Postrath Ebert of Frankfort. As secretaries of sections, Dr. Epstein, Dr. O. May, Dr. von Nordheim, and Prof. Lepsius. Some words of welcome were also spoken by the Burgomaster Adickes, in the name of the city of Frankfort, and by Herr Sonnemann in that of the Committee of the Exhibition.

Formalities having been concluded, the Congress settled down to hear a Paper by Prof. Kohlrausch on the topic, what is the fittest way of training a technical electrician? The formidable array of studies which, according to Prof. Kohlrausch, the budding electrical engineer must follow, would result in a four or five years' course in the technical college. He must necessarily postpone all practical experience in the industry until he is 22 or 23 years of age, if he would master all the studies of the programme. The various problems in such a career were very cleverly stated by Prof. Kohlrausch with a sincerity and an earnestness that disarmed criticism. In the debate which followed Prof. Slaby, of Berlin, urged that the young electrician would be better if a year in the factory were intercalated in his five-year course of study, a view which the octogenarian, Prof. Rühlmann, supported in his inimitable style. Dr. Werner von Siemens declared that electrotechnics as a single science did not exist, and that there was a much greater demand for practical engineers than for technical electricians, who were the special products of the technical high schools. It did not seem to occur to any of the speakers that there was current in England a wholly different mode of producing an electric engineer, or that there could be any advantage in a course of five years' training in the industry, with, perhaps, a year in a technical college intercalated in the time of pupillage. This debate having come to an end, the assembly was pleased to listen for forty minutes to the reading of a Paper on the new domain of alternating currents by the writer, and then adjourned for lunch. Amongst other matters of business, it appointed a committee, under the presidency of Prof. Kittler, of Darmstadt, to discuss certain propositions relating to the legal questions arising from the interference with telegraphs and telephones of the strong currents used in lighting and tramway work. This matter, indeed, appeared to be the one burning question brought before the Congress. Whenever the topic was approached it aroused the attention of a large number of engineers present at the Congress. Petitions to the Reichstag, prepared for signature, and drafts of Bills to be presented, were freely handed about. The committee held several lengthy sittings during the following days, but finally presented to the Congress a report, which was accepted unanimously without amendment. This report leaves matters very much where it found them. Its elaborate propositions virtually declare that there is no scientific neces-

Digitized by Google

sity for such interference between different electrical systems, and that where such interference arises the common law provides a sufficient remedy. Further, that it is impossible to set up a valid distinction between strong currents and weak currents, or to restrict the use of earth returns to either class of circuit. It is doubtful whether English electricians would acquiesce in so vague a settlement of the question.

The sectional meetings into which the Congress resolved itself were held in various localities, and usually simultaneously, so that it was impossible to get an adequate notion of the proceedings of them all; and in some cases the long time occupied by some one speaker caused a dislocation of the programme. Thus, for example, an extremely interesting Paper by Dr. Holborn, of Charlottenburg, on the magnetic properties of steel hardened and tempered under various precise conditions, was listened to by a comparatively small audience, owing to the time of its reading having been changed. To the sectional proceedings of Tuesday and Wednesday further reference will be made later. The evening of Wednesday closed with a banquet in the hall of the Palm Garden, Dr. Werner von Siemens presiding. This banquet, which was attended by about 500 persons, was noticeable for the warmth of welcome accorded to the speeches of foreign visitors, notably that of Prof. Ferraris in proposing the toast of the City of Frankfort.

The second general assembly was devoted to Papers on a standard gauge for screw threads by Dr. Löwenherz, Director of the Imperial Institute for Physical Research at Charlottenburg, and on Notations and Symbols, by Monsieur Hospitalier. The work accomplished in England, by Whitworth, in heavy engineering, and by the Royal Microscopical Society, in unifying the screw thread used for microscopes, is regarded in Germany as of enormous value. The Sellers thread used in America does not appear to be acceptable on the Continent, where Whitworth gauges are preferred. But for fine screws there is no accepted gauge; and Dr. Löwenherz's proposition was to found a new scheme on the basis of the metric system, apart from which he declared no gauge to be acceptable. Monsieur Hospitalier advocated the adoption of a system of symbols, formulæ, and nomenclature which should have international validity, and made several suggestions towards such a system. In the discussion which followed, Mr. Uppenborn referred to the difficulty created by the difference in value between the British horse-power as defined by James Watt and the metric horse-power which had been devised as a Continental equivalent. The playful explanation of an English member that a British horse could work harder than a metric horse was received in good humour; and the subject of notations was then by common consent referred to a committee, with Prof. Ferraris as chairman, to bring up a report. At this sitting a formal proposition was circulated by the American delegates, proposing the adoption of the name of "henry," in honour of Prof. Henry, for the practical unit of coefficient of self-induction, which has hitherto been known as the "secohm" or the "quadrant." This proposition was also remitted to the consideration of the Sectional Committee. Another discussion arose upon a Paper by Dr. Oscar May on the proper regulations about electric conductors from the point of view of the fire insurance companies. For English electricians the debate on this question had little interest in the absence of the ever vigilant engineer of the Phœnix Fire Office, without whose opinions no discussion on fire regulations can be considered complete.

At the third and final general meeting on Saturday, 12th inst., reports were received from the Sectional Committees and discussed. If it were permitted to raise the veil from the meetings of these committees, much might be told of the extraordinary and lively spirit of good fellowship which pervaded even the most animated discussions. When a dozen eager electricians come together from various nations, and insist on making their opinions known in half-a-dozen different languages in rapid succession, and each harangues and expounds in his own and other languages in turn, the result becomes at times indescribable. The Committee on Notations, while not accepting the whole of M. Hospitalier's suggestions, found themselves able to agree upon a report which was eventually passed by the general assembly *nemine contradicente*. Translated into English it runs as follows:—

I. The Congress decides that—

1. Physical quantities are to be denoted by italic letters;
2. Units are to be denoted by Roman letters;
3. Physical constants (coefficients relating to specific properties of materials) and angles are to be denoted by Greek letters.

II. The Congress decides: That whilst it recognises the following names, "joule" for the volt-ampere-second, and "watt" for the volt ampere—names fixed by the International Paris Congress in 1889—the practical electrical units shall be represented by means of the Roman capitals which constitute the initial letter of their respective names, viz.:—Ampere, A; coulomb, C; farad, F; joule, J; ohm, O; volt, V; and watt, W.

III. Whereas M. Hospitalier has elaborated a system of notation which, in his opinion, is capable of designating all the physical quantities which are of any practical importance (without introducing any needless change), we recommend to the members of the committee named by the Congress that they should kindly put to practical test the system (which the committee considers of material value), and at the end of the present year publish in the technical journals the results of their examination, in view of arriving at a common agreement; and we leave to the next Congress the definite adoption of these symbols.

On the American proposal to adopt the name of "henry" for the unit of self-induction no conclusion was arrived at by the committee. Though a majority appeared to be in favour of the proposal, it was strenuously resisted by Prof. H. F. Weber, of Zürich, who did not seem to be aware of the magnitude of Henry's researches of 1831. He proposed instead the name of Neumann, who in 1845 did so much to perfect the theory of variable currents by introducing the expressions for the self-potential of a circuit into the differential equations. Neither did the committee agree upon another proposal to adopt as the practical unit of magnetic flux the "gauss" equivalent to 10^8 C.-G.-S. magnetic lines.

After disposing of these matters the assembly listened to Herr Zipernowsky's project for a rapid-transit electrical railway between Vienna and Buda-Pesth, a distance of 200 miles, to be run in less than two hours. No one seemed to doubt the electrical arrangements, but wind-friction seemed to be a bugbear. The last Paper was by Dr. Epstein, of Frankfort, on "Institutions for Research and Standardising, similar to the Reichsanstalt at Charlottenburg," and was followed by a discussion as to the character of certificates which such establishments should issue.

In the Sectional proceedings many interesting and valuable communications were made. Unfortunately, most of these were given *viva voce*, printed copies of them not being obtainable. A notable exception occurred in the case of the Paper read by Mr. Preece on the progress of telegraphy and telephony in England, printed copies of which (in German) were handed about at the time of reading.

The first section was devoted to instruments for measurement and theoretical matters. Dr. Koepsel, one of the staff of Messrs. Siemens and Halske, discussed existing modes of measuring currents. Dr. Lindeck, of the Imperial Research Institution of Berlin, narrated his experiences with standard cells of various types. Professor Quincke, of Heidelberg, described and showed a very simple and cheap form of instrument, which could be used either as a magnetometer or as a galvanometer of various degrees of sensibility. It consisted, briefly, of a light magnet attached to a mirror of rather larger size than is usual in mirror galvanometers, suspended by a cocoon fibre in a circular hole cut in a vertical glass disc about a foot in diameter. A paraffin lamp threw a spot of light upon a scale. Various coils could be used with the apparatus. To those accustomed to the many patterns of mirror galvanometer used in English laboratories the apparatus presented little novelty save in the extreme simplicity of its parts. But to German electricians, accustomed to the cumbrous "subjective" mode of reading by means of an observing telescope, the apparatus afforded a rapturous delight, increased doubtless by the delicate sarcasms at the ways of professional instrument makers, which Prof. Quincke interwove in the most

Digitized by Google

charming manner with his description. Other contributions to the topic of instruments were made by Dr. Bruger and Prof. Feussner. The latter has been doing good work on the subject of some new alloys for resistance coils, and their various temperature co-efficients.

Dr. Du Bois described a most elegant magnetic balance for weighing, by a species of steelyard, the magnetic permeabilities of pieces of iron; and he showed how to discriminate between the reluctance arising from shape, and that due to specific properties of the material. Dr. Holborn spoke of his researches on steel for magnets, which led him to the conclusion that even the best sorts of steel will not make good retentive magnets unless particular care is taken to harden the steel at the temperature proper to each brand, and to temper it in a sufficiently precise mode. Prof. H. F. Weber gave a long and most elaborate account of his researches on the general theory of incandescent lamps, and described the results of an exhaustive examination of a large number of lamps manufactured by different makers. He finds the temperature of the radiant filament to be nearly always about 1570° C.; a lamp which when shining with 1 candle power had a temperature of 1400° only rose to 1600° when it was over-run to 32 candle power. Lamps with black filaments showed a slightly higher radiation coefficient than those with grey graphitic filaments. It was a comfort to learn finally that the economy of all lamps—apart from their length of life—is the same for all, and depends in nowise on their mode of manufacture. One of the most interesting of all the communications was by Dr. Voller, of Hamburg, upon the propagation of electric waves in conductors. He has followed up the experimental work of Hertz, and extended it in a series of beautiful demonstrations, in which using exhausted tubes, which become luminous so that a whole audience can see them, he showed the existence of nodal points in the electric waves.

The second section, to which was allotted the topics dealing with strong currents, met in an annexe of the restaurant at the Exhibition, a room almost unendurable by reason of heat and noise. In this section Herr Geist spoke of dynamometric apparatus, and Herr Baumgardt discussed the relative advantages of compressed air and electricity for transmitting power. Mr. Kapp explained the method of measuring the various losses in armatures due to hysteresis, friction, and eddy-currents, which was simultaneously worked out a few months ago by him and by Mr. Housman. It appeared to be novel to our Continental brethren. Even the jury of the Exhibition did not propose to apply this simple method to testing any of the dynamos. But the main interest in this section, as indeed of the whole Congress, centred in the topic of the multi-phase alternate current, or *Dreh-strom*, as it is familiarly called. Herr M. von Dolivo-Dobrowolsky (who is associated with Mr. Brown, of Oerlikon, in the Lauffen-Frankfort transmission of power) spoke of his work with alternate-current motors, and explained the principle of his rotary-current motors, the largest of which, of nearly 100 H.P., receives the current from Lauffen, and pumps water for an artificial waterfall. He based his explanations respecting phase-differences of the alternations of voltage and current upon the device of supposing the actual current to be split into two currents, one in precise phase with the voltage (which he termed a "working" current) and the other in quadrature with it, which he termed a "watt-less" current. In the discussion Messrs. Déri, Korda, and Kapp, and also the writer, took part. Other distinct communications on the topic of alternate-current motors were made by Herr Goerges, of the firm of Siemens and Halske, and by Herr W. Lahmeyer, of Frankfort. It should be mentioned that polyphase motors (or rotary-current motors) are shown in the Exhibition by all the firms represented by these gentlemen, and also by Schuckert, of Nürnberg; and that there was quite an *embarras de richesses* of rotatory transformers for changing alternating currents into continuous, and *vice versâ*. Mr. Lahmeyer diverged from alternate-current topics into the transmission of power by continuous currents. His firm is showing in Frankfort how power may thus be transmitted from the suburb of Offenbach, some eight miles away. Mr. Lahmeyer proposes to obviate sparking in dynamos by introducing resistance in the connections between the sections of the armature windings and the bars of the commutator. Mr. Guttmann, of New York, described the success which had attended the introduction of Tesla's motors on the rotary-current principle.

In the third section, dealing with telegraphic and telephonic matters, there was the Paper of Mr. Preece, already referred to, and a brief but interesting communication by Geheimer Postrath Grawinkel, of the Berlin Post Office, on the use of Tudor accumulators for telegraphic purposes. He found the average current to be but one milliampere per line. Dr. Strecker, also of the Berlin Telegraph Department, described a telephone time recorder to enable the department to charge the users of telephones in proportion to the time that they used the instruments. Dr. Julius Maier, of London, read a Paper on "The State Control as contrasted with Private Control of Telephones;" and the author described the Phonopore of Mr. Langdon Davies, which on this occasion was connected up from the Exhibition to Homburg on the ordinary telegraph lines simultaneously with the ordinary telegraphs. It appeared that the phonopore telegraph was making its way as a useful adjunct to railway telegraphs, converting omnibus lines into trunk lines without interfering with ordinary working.

The fourth section dealt with electro-chemistry and miscellaneous applications, such as the adaptation of electric appliances to mining machinery. It appeared that Mr. Van Depoele and Mr. Atkinson had independently devised reciprocating rock drills by the combined use of continuous and alternate currents on a plan published some years ago in an elementary form by Dr. Werner von Siemens.

Dr. Zerener discussed the processes of electric tanning, and Mr. Pfutzner the process of electrolytic refining of copper, as used by Siemens and Halske.

One of the most memorable features of the Congress was the subsequent excursion to Lauffen to view the turbines, dynamos, and transformers, by means of which the current is transmitted to Frankfort over a line 108 miles long. As the line runs for almost its whole length along the railway, the excursionists had abundant opportunity for observing the manner in which the three wires are carried on oil-insulators on lofty poles. The interest of the occasion was enhanced by the presence not only of several members of the Prussian Ministry and of State officials from Switzerland, Würtemberg, Baden, and Hesse, but also of M. Marcel Deprez, Prof. Ayrton, Prof. Ferraris, Colonel Huber, Director of the Oerlikon works, Herr Rathenau, Director of the Allgemeine Company, Postrath Ebert, who superintended the erection of the line, Oscar von Miller, who engineered it, Baurath Lindley, of Frankfort, and of Messrs. Dolivo-Dobrowolsky and C. E. L. Brown, who designed the motor, the dynamo, and the transformers. The party admired the generating dynamo designed by Mr. Brown and constructed at the Oerlikon works, the most mechanical, surely, of all dynamos hitherto put together. They looked at the transformers and inspected the testing laboratory erected for Prof. Weber and his assistants. Then they enjoyed the hospitalities of the two Companies—the Allgemeine Elektricitäts Gesellschaft, of Berlin, and the Oerlikon Maschinenfabrik, of Zurich—who have collaborated in this intensely interesting experiment; and returned in their saloon carriages to Frankfort, conscious of having visited the scene of the most remarkable electrical experiment of the century.

If the Congress of 1891 had had no other result than to bring together so many electricians and engineers to discuss, day by day, the progress of their common science, and to learn to esteem and value one another, it would have done a useful service. But it did more than this: it showed how an important scientific experiment can be carried out on a large scale by the co-operation of public authorities with private industrial bodies. The Lauffen-Frankfort transmission would have been simply impossible but for the enlightened and spirited way in which the German Postal Telegraph Department lent its powerful aid to forward a scheme requiring the assent not only of various local bodies, each exercising local government in the territories traversed by the line, but also of the railway companies and other corporations. The success of this enterprise is a lesson in many ways, not only to the electricians, but to the telegraph departments of other countries.

ALTERNATING CURRENT ELECTRIC SUPPLY STATIONS.*

BY DR. J. A. FLEMING, M.A.

§ 1. **The General Design of Alternating Current Stations. Motive Power. Selection of Unit.**—In the general design of a system of electric supply by alternating currents, as at present carried out, many considerations have to guide the engineer in the selection of a suitable site, and in the choice of the motive power and the arrangement of the generating plant. At the present time (1891) the selection of a system of electric supply to be adopted for electric lighting of towns is practically limited to one of two systems. First, the system of direct supply, with or without secondary batteries, on the two, three, or five wire systems; and, secondly, the system of alternating current supply, including the so-called rotary field (Drehstom) systems, on the general lines of one or other of the plans described in the previous chapter.

The system of two-wire direct current low-pressure supply is one that is suitable for small districts in which the lighting is dense, and in which the supply station can be placed approximately in the centre of the district to be lit. Experience shows, however, that the economical limits of such a system are reached when the mean length of the feeders is some 300 or 400 yards. By the three-wire system, as developed by Mr. Edison and Dr. Hopkinson, the system of low pressure supply can be economically conducted when the mean length of the feeders is from half to three-quarters of a mile. The five-wire system is applicable up to a mean distance of one mile. Beyond this distance, we are practically limited to a system of supply based upon alternating currents and transformers. Assuming, then, that the case to be dealt with is one in which the above facts point to the employment of the alternating current system, the first consideration to which the engineer has to address himself is the selection of a suitable site for the station. It will generally be found that the choice is limited to two or three positions, and that questions of convenience, price of land, access, nuisance, and other circumstances bind down the engineer to the selection of one out of a small choice of possible sites. Assuming, however, that an option exists between one or more positions for such an "eccentric station," then the following considerations should have due weight in determining the exact choice to be made.

In the first place, the selection ought to be governed by the consideration of convenience of access for coal and of freedom from creating nuisance by smoke, steam, or vibration. At the outset, when the supply from such station is small, the amount of coal and other stores to be brought into it, and of ashes, &c., to be removed, will not present formidable difficulties, but as the station grows in magnitude this will prove to be one of the most serious items in the economical management of such a station; hence, wherever a river-side or water-side site can be procured, by which coal can be received and ashes removed by water, a great advantage is secured, even omitting, for the moment, the advantages of condensation of exhaust steam.

As every thousand units of electric energy sold involves a combustion of from 4 to 10 tons of coal according to the system of alternating current supply adopted, it is obvious that convenience for handling coal and discharging ashes is of paramount importance, and that interruptions of this work by any conditions of weather ought to be practically impossible. With this object the engineer will naturally provide, under these circumstances, for convenient access by road; also, if possible, a connection with a railway siding, and will see that, in addition, a storage for coal is provided, to render it feasible to purchase and store two or three months, supply of coal, thus rendering the station independent of strikes or trade complications. Assuming that such water-side site is procurable, the next question is the general design of a station. In this matter the greatest possible mistakes have been made in many existing stations, either in designing them on too small a scale at the beginning, without sufficient provision and arrangements for extension or else in designing them at first on too large a scale. The object to be aimed at should be to lay down the station on such general lines that it is capable of considerable extension, as required, without in any way interfering with the existing plant or interrupting the current supply, but at the same time not to involve the enterprise in its initial stage in too large a capital outlay in buildings, on which at first no adequate return can be made. In many cases electric lighting stations have been put up in a small and temporary manner, resulting in the necessity for entire rebuilding at great cost and inconvenience when the demand for current passes a certain limit. Accordingly, the best general design, wherever it is possible for such stations, is an arrangement in which the building is gradually extended from one end as required. If space is limited, this building may take the form of a single building of several stories, engines being placed on the ground floor, dynamos on the floor above, and boilers on the second floor, stores and offices on the third floor. If ground space permits, a cheaper building can be constructed, taking the form of two sheds, lying alongside or in line with one another, one forming the boiler house and the other the engine and dynamo room, arrangements being made at one end for stores, offices, fitting-shop, &c. The general design of such a station calls for great forethought in all the arrangements, in order to reduce in every way the amount of labour required. Want of prevision in this matter results very often in the erection of a station in which there is a considerable waste of labour, and this is an important item in proportion as the station grows in magnitude. Assuming that a careful choice has been made as to site, having regard to the considerations above mentioned, the next matter which demands careful forethought is the choice of the size of the unit of power and of the unit of steam generating plant, in other words, the sizes of boilers and the engines. On this question, there is at present considerable diversity of opinion. Some engineers prefer to select a large engine unit, guided apparently by the notion that such a large engine unit is more economical than a number of smaller ones of equal total power. This, however, has by no means been demonstrated to be the case. Apart from any other reasons it is clear that if the current supply to any one section of a district is wholly dependent upon one large engine, it is obvious that another of equal size, or equivalent, must be provided as a reserve, and hence 50 per cent. of the plant is always idle. If the unit selected is a smaller one then, provided that the alternators can be worked in parallel, it is possible to have a much smaller fraction of the engine and dynamo plant kept idle as a reserve. Moreover, a break-down throws out of use a much smaller proportion of the total power. The same, of course, applies to the boilers. Owing to the general nature of the load diagram of the ordinary electric lighting supply station, the maximum demand for current is very many times greater than the mean demand, and moreover the maximum demand from most supply stations exists only for a very small fraction of the whole 24 hours. The ratio between the total number of units sent out from the station in the 24 hours to the amount which would be sent out if the plant were working at its full capacity for the whole 24 hours is conveniently called the *diurnal load factor* of the station; and the ratio between the units sent out from the station in one year, and the total amount which would be sent out if the machinery worked always at its full power, is called the *annual load factor*. Experience shows that the annual load factor for an electric supply station, sending out currents for lighting purposes alone, is not more, in general, than eight or ten per cent. Accordingly, as is now well known, the great difficulty that the electric engineer has to contend with is the fact that for large periods of the 24 hours the generating plant is very lightly taxed, and under these circumstances, unless it is properly subdivided, the efficiency of generation will be very small.

In the selection of boilers the choice lies either between the boilers of the water-tube type, one of the locomotive forms, a modified marine boiler, or the well-known Lancashire boiler. The general cause of the small average net evaporative duty of boilers in stations having a small load factor is the necessity for lighting and firing up the several boilers for only short periods during the evening, so that there is an immense waste

* These articles form part of Vol. II. of "The Alternate Current Transformer in Theory and Practice." All rights reserved.

Digitized by Google

of heat from radiation and conduction as the boilers cool down after having been thrown out of use; such losses are of course increased when there are large masses of brickwork in direct contact with the fuel which have to be heated up. For this reason many engineers give the preference to forms of internal firing boilers, such as the locomotive marine boilers or the Lancashire. The use of the ordinary return-tube marine boilers has been limited, owing to the difficulty experienced in transporting them by rail when of large size. A modified form of marine boiler has been constructed by Davey-Paxman (*see* Fig. 1) for use in electric lighting stations. This boiler is known as the dry-back boiler; it is not more than 9 feet in diameter, and the furnaces are contained in two cylindrical flues crossed in advance of the firing bridge by a Galloway tube. The products of the combustion pass right through the back, are thrown upwards, and made to return to the front

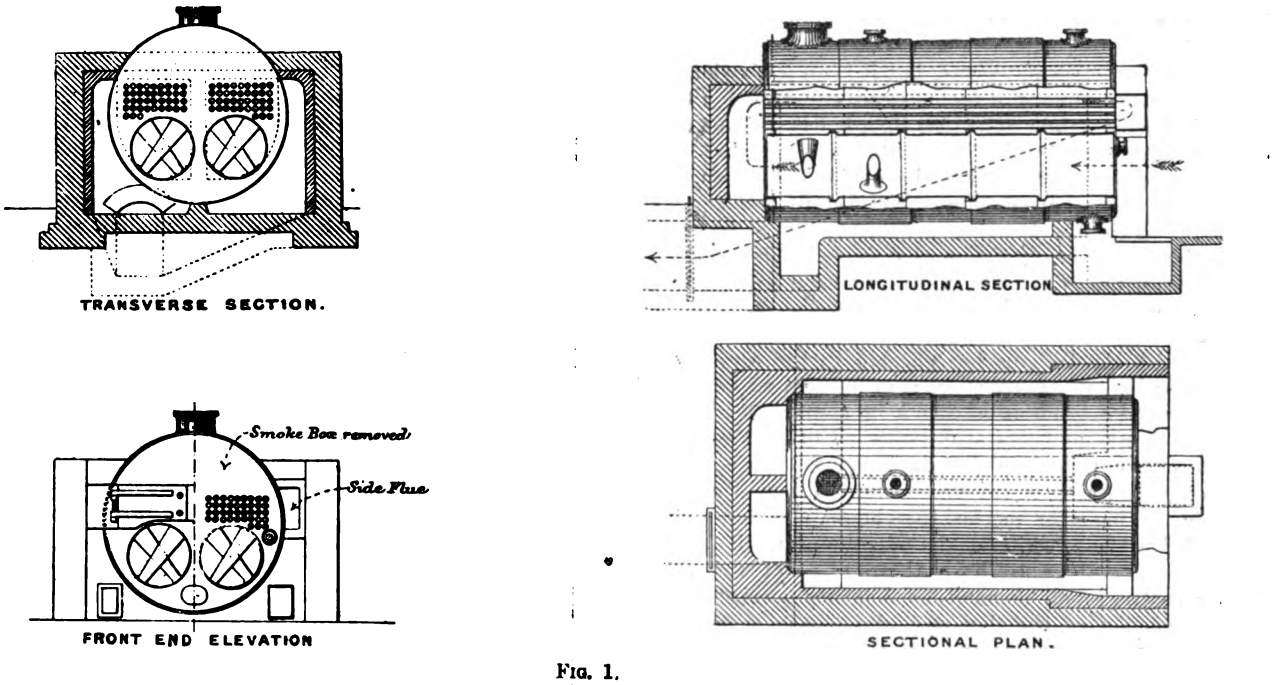

Fig. 1.

through the tubes by means of the refracted fire-brick dry-back. Mr. Crompton and Mr. Longridge have modified this form of boiler by placing the tubes below the furnaces. The products of the combustion, after passing to the end, are thrown downwards by the fire-brick dry-back, and then passed back to the front of the boiler through tubes placed below the

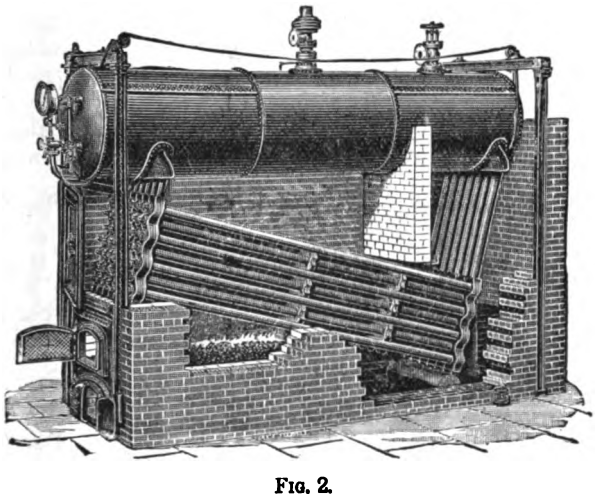

Fig. 2.

furnaces to the smoke-box or chamber formed beneath the fireman's feet, from whence they pass under the bottom of the boiler on their way to the chimney stack.

Other engineers prefer, where space permits, the employment of the ordinary Lancashire boiler. Formerly difficulty was experienced in making flues of sufficient strength to withstand the high pressure now required; but as this difficulty can, and has been, overcome, this objection is not now valid. On the other hand, the length of this boiler is an insuperable objection to its use in many cases. Amongst well known water-tube boilers used in electric lighting stations, the Babcock and Wilcox water-tube boiler, a section of which is shown in Fig. 2, is extensively employed. The great recommendations of this boiler are the rapidity with which it can make steam, and the fact that the limit of its evaporative power is only found in the ability of the grate to burn fuel. From its tubular construction it is very free from risk of dangerous explosion, and can easily be transported in sections and erected *in situ*; moreover, it is exceedingly economical as regards space, and from its rectangular form and great vertical height is specially adapted for batches of boilers in central station work where floor space is limited and costly. An objection which has been urged against it is the fact that there are considerable masses of brick-work to be heated up, and which, therefore, absorb and dissipate a sensible amount of heat. On the other hand, for central station purposes, where the demand for steam may, owingto fogs, suddenly become very considerable, it is of the greatest possible advantage to have a boiler which can be suddenly called upon for a considerable delivery of steam, and in which there is great safety and freedom from risk by explosion. Both these qualities are possessed by the Babcock boiler.

Mr. Raworth has suggested an arrangement intended to reduce the enormous waste of fuel in getting up steam in boilers which are used only during the maximum hours of demand. The boilers are erected in groups of three, with flues and condensers so arranged that when the central boiler is being used the products of combustion may be diverted through the furnaces and flues of one or both the other boilers. During the hours of light demand when the middle boiler alone is being used, the exhaust steam from the pumps and supplementary engine is turned into the idle boilers, until the water in them attains a temperature of 212°F., the additional heat required to raise steam being supplied by the products of combustion taken from the central boiler. When the steam in the idle boilers has risen to working pressure, they may, when required, be put into use and fires lighted; the gases from the central boiler being taken direct into the chimney. The method of applying the exhaust steam from the supplementary engines is as follows:—The supplementary exhaust pipe is carried across the whole range of boilers and a branch provided to each boiler, governed by a cock or screw valve. An outlet from the supplementary exhaust pipe is provided into the atmosphere covered

Digitized by Google

by a mushroom valve of considerable size, weighted to 11b. to the square inch, and provided with an arm by which it can be raised to give free exit. The branch pipe to each boiler is attached to a block on the cover of the shell, and an internal pipe is carried down in continuation of the external pipe to about one foot below the working water level, where it turns at right angles to the vertical pipe, and is furnished with a circulating nozzle. When it is desired to heat up any boilers, the valve between the supplementary exhaust pipe and the boiler is opened, the exhaust valve to the atmosphere is closed, and the exhaust steam from the supplementary engines will be condensed in the boiler. As the water in the boiler increases in temperature the back pressure will increase, but will never exceed the 11b. to the square inch. In the case of water tube boilers, it is necessary to attach a distributing box to the discharge orifice of the nozzle, and to take from it pipes leading to each of the tubes in which the natural circulation is downwards. This is necessary to set up the circulation of the whole of the water tubes in the boiler. We are not aware that this plan has been put in practice anywhere, but it is an indication amongst others that the economy of fuel in steam generating is beginning to receive more serious attention than it has done at the hands of electrical engineers.

In the selection of engines the choice of the engineer lies between dynamos driven direct coupled to the engines, and those in which the dynamos are driven by belts or by rope gear, the latter being either the single endless rope-gearing with jockey pulley, or the multiplex rope gearing with the usual groove pulleys and grooved fly wheel. The direct driving has been considerably assisted of late years by the improvements which Mr. Willans has effected in the high-speed compound engine. Wherever space is of importance, direct driving by high-speed engines is almost a necessity. Where space is available many engineers still prefer to drive the dynamos in groups either from the fly-wheel of the engine or from a counter-shaft, owing to the lower engine speeds which are then possible. Whichever method be chosen, the first question to be settled is the selection of the dynamo unit. It is not necessarily an advantage to have these units of the same size. Owing to the small demand for lighting current during the greater portion of the day and night, it is generally best to select one pair of units (one being a reserve on the other), of such a size that one of them will be fairly well loaded during the greater portion of the day, and to select the other dynamo units of such larger size that the output of each machine is from one-sixth to one-tenth part of the full output of the station at its hour of maximum load during the winter.

The very poor economy which some stations exhibit in the matter of coal consumption may be also often attributed to the selection of too large an engine or dynamo unit. It must be borne in mind that compound non-condensing engines are not economical in steam consumption at low loads. It is found that at low loads indicator diagrams taken from high and low pressure cylinder show that the low-pressure cylinder is contributing very little to the total work of the engine, and under some circumstances the diagram of the low-pressure cylinder may even be a negative area, indicating that part of the power of the engine is being used to drive the low-pressure cylinder as a pump. It is, therefore, of great importance to select the engine and dynamo unit of such size that, under any circumstance, the generating plant in actual use is fairly well loaded. The theory that large engines essentially have a greater economy than small ones is not by any means generally true; and on the other hand, owing to the variation in the load, large non-condensing compound engines will often exhibit a relatively very much lower economy at the low loads in weight of steam used per indicated horse-power than smaller and well-designed high-speed high-pressure engines. Engines used for electric light work are under the great disadvantage that they must run at the same speed whether doing much work or little, and hence the only way in which the low station load factor can be neutralised is to give each engine individually as large a load factor as possible.

(To be continued.)

MAGNETISM IN IRON AND OTHER METALS.*—LI.

BY PROF. J. A. EWING, F.R.S.

(Continued from page 547.)

§ 176. **Retentiveness and Residual Magnetism.**—An equally satisfactory agreement is found when the results of experiments on retentiveness are examined in the light of the molecular theory. We shall take advantage of the opportunity which this discussion of the theory affords to describe some of these results more fully than has yet been done.

In the first stage of the magnetising process, as has been already remarked, there is no retentiveness: the magnetism that is initially induced, under very weak forces, disappears entirely when the inducing force is removed. This accords with the view that the molecular magnets are then being as it were elastically displaced from a position of stable equilibrium, without rupture of the ties by which the initial grouping maintains itself, so that each molecule simply returns to its primitive position when the displacing force is withdrawn. Theory and experiment alike show that this condition persists only so long as the susceptibility is very small.

In the second stage the susceptibility has become much increased as a consequence of the large deflection the molecular magnets suffer in breaking away from their original grouping to form new combinations. The movements they then accomplish are in great measure irreversible, that is to say, they are not undone as the magnetising force is being withdrawn. We may therefore expect to find a rapid development of residual magnetism during that part of the magnetising process in which the susceptibility is high. The theory shows that in favourable cases nearly the whole of the magnetism acquired during that stage will persist as residual magnetism. Experimental instances of this are given below.

The third stage, on the other hand, contributes little to the residual magnetism, for the molecular deflections that occur in it are for the most part undone as the magnetising force is withdrawn. A result of this is that the residual magnetism approaches saturation sooner (that is, under the action of weaker magnetising forces) than does the induced magnetism.

Another result is that the residual magnetism has a saturation value which is definitely less than the saturation value of the induced magnetism. It is indeed possible to imagine a molecular structure such that all the magnetism of saturation would be retained on the withdrawal of the force. This would be the case in a cubical formation if the lines of centres were parallel and perpendicular to the direction of the field throughout the whole piece. But the imperfect homogeneity of any actual piece of iron puts such a conception out of court, and when any of the lines of centres are inclined to the field, it is clear that the saturation value of I_r is less than that of I. It will be shown presently that a continuous cubical formation with lines of centres uniformly distributed as regards inclination is a structure which gives more than sufficient possibility of residual magnetism. The value of I_r, which the theory shows to be possible in such a structure, is in fact greater than the values which are found in experiments with even the most retentive metal.

The molecular theory makes it easy to understand the difference between retentiveness and what may be called coercive capacity, by which is meant the quality that the coercive force (§ 47) measures—the quality in virtue of which a substance holds its residual magnetism so strongly that a large magnetic force, acting in the reversed direction, is necessary to remove it. Retentiveness, on the other hand, is the quality in virtue of which much residual magnetism is held, though it may be held very weakly. Probably no magnetic substance has so much retentiveness as soft annealed iron, and probably none has so little coercive capacity. Retentiveness, by the molecular theory, is the result of a regular molecular structure of such a kind that the molecules readily arrange themselves in lines which are but little inclined to the direction of the applied force. The molecular ties may, however, be extremely weak. Coercive capacity is a result of strong ties, such as might be formed by reducing the distances between the mole-

* All rights are reserved.

Digitized by Google

cular centres or between some of them, and this condition may very well exist in a structure where the lines are unfavourably arranged for retentiveness.

§ 177. **Experiments on Residual Magnetism in Iron.**—The following experimental results* were obtained with straight iron wires, 400 diameters long, using the direct magnetometric method. The magnetising force was gradually raised to an assigned value, then gradually withdrawn, to allow the residual magnetism to be noted; then raised to a slightly higher value, again withdrawn, and so on; so that the values of I and I_r were ascertained, corresponding to successive steps in the magnetising process. The results will be seen to bear out what has just been stated, and to furnish strong evidence in favour of the theory that the constraint of the molecular magnets is due to their mutual magnetic forces.

45·51	1230	933	0·76				

Table XXX. gives the results of an experiment† in which an iron wire, 1·58mm. in diameter, was tested, first in the annealed state, and then after being hardened by stretching beyond its elastic limit. Inspection of the figures will show that the ratio of residual to induced magnetism, which is at

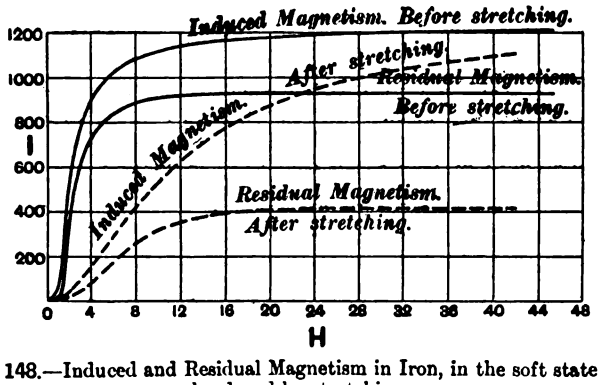

Fig. 148.—Induced and Residual Magnetism in Iron, in the soft state and hardened by stretching.

first small in both cases, rises to a maximum. This maximum, in the annealed wire, is so high as to imply that the rate of increment of residual magnetism is then not far short of the rate of increment of induced magnetism. The ratio afterwards falls off as the magnetising process passes into its third stage.

Fig. 148 is drawn to exhibit the same results. It shows well how the residual magnetism approaches its maximum faster than the induced magnetism, notably in the hardened wire.

* *Phil. Trans.*, 1885, Part II., pp. 556 *et seq.* † *Loc. cit.*, § 41, pp. 559-60.

This mode of representing the results, where I and I_r are given in terms of H, is not, however, well adapted to show what is the saturation limit towards which I_r is tending, nor what is the relative rate of increment of the two at various stages of the magnetising process. To bring these points out we may draw a curve showing I_r in relation to I (Fig. 149). We already know the saturation value to which I tends, namely, about 1,700 C.-G.-S. units (§ 98), and it is not difficult, by extrapolation of the curve in this new figure, to deduce an approximate value for the saturation limit of I_r.

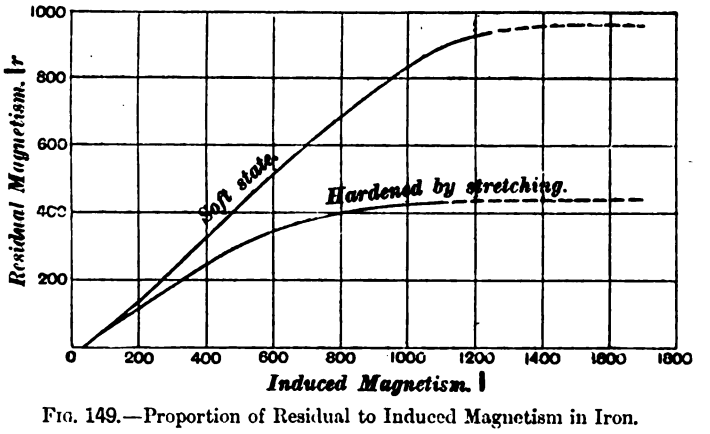

Fig. 149.—Proportion of Residual to Induced Magnetism in Iron.

This is done in Fig. 149, where the broken lines form a conjectural extension of the curves, beyond the range of the experiment, up to the saturation value of 1,700 for the induced I. It appears from these that the saturation values of the residual magnetism in this specimen are approximately 970 when the metal is annealed, and 430 when it is hardened by stretching.

An inspection of the curves in Fig. 149 will also show that after the initial stage in parts, in which the residual magnetism is acquired less rapidly, the proportion which the increment of I_r bears to that of I becomes nearly as possible constant, and remains so (in the annealed wire) throughout a large part of the whole process of magnetisation. From the point I = 150, or so, up to 800 the curve is practically straight, and during that part of the process nearly the whole of the magnetism that is acquired goes to form residual magnetism. By Table XXX. we have

H	I	I
1·30	140	85
3·16	764	650
Difference.....	624	565

So that, during this time, $\frac{565}{624}$, or quite 92 per cent. of the magnetism that is being induced contributes to the residual magnetism. After this the curve bends over rather quickly and $\frac{dI_r}{dI}$ becomes much reduced. In other specimens of annealed iron the value of $\frac{dI_r}{dI}$ during the steep stage was even more nearly unity.

This was the case in the experiment of Table XXXI., made with a piece of annealed iron wire 0·72mm. in diameter.* In this case a supplementary experiment was made to determine the influence of longitudinal pull on the residual magnetism. After the test made in the ordinary condition of no load, a steady load of 4 kilos. or 9·76 kilos. per sq. mm., was applied (a load well within the elastic limit), and the observations in the second portion of the Table were made. The proportion of I_r to I in each case is shown in Fig. 150, where the dotted line refers to the experiment in which wire was in a state of longitudinal tension. The full curve for no load is conjecturally extended to find the saturation value of I_r, which is higher in this specimen than in the last, namely, 1210. The rate of increment of I_r, relatively to I during the steep part of the curve is also greater, and the curve is prac-

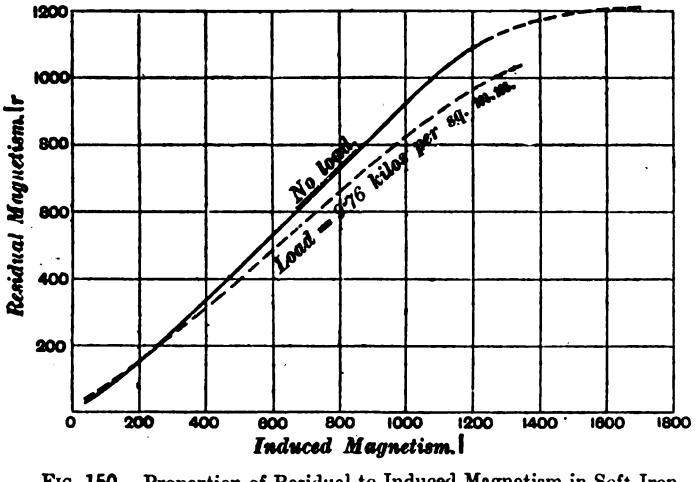

FIG. 150.—Proportion of Residual to Induced Magnetism in Soft Iron Wire.

It appears from these that in the stage lying between I = 300 and I = 1,100, or so, nearly 99 per cent. of the induction of magnetism was taking place by the turning round of the molecules into new lines, in which they remained when the magnetising force was withdrawn. Scarcely any of the induced magnetism was then being contributed by quasi-elastic deflections. After 1,100, the part played by quasi-elastic deflections began to be considerable.

In the test made while the wire was loaded the limit to which the residual magnetism apparently tended was about 1010. A feature to be remarked is that in the earliest stage the curve taken with load lies above the curve taken without load, crossing it when I is about 200. The presence of longitudinal pull, though unfavourable to the retention of magnetism by annealed iron when the magnetisation is strong, is favourable to it when the magnetisation is decidedly weak

Experiments made with other specimens gave results which agree well with these. With another piece of annealed iron wire 0·78mm. in diameter the following (amongst other) readings were taken :—*

* *Loc. cit.*, p. 559, § 40. Reference to the same Paper should be made for similar experiments with steel in the soft and hard states.

H	I	I_r	H	I	I_r
0·86	26	6	5·40	991	898
1·98	164	96	6·81	1,067	946
2·66	478	378	11·20	1,166	1,014
3·78	806	696	17·24	1,212	1,042

In this case between H = 2·66 and H = 6·81 the increment of I is 589, and that of I_r is 568 or 96 per cent. of the other.

One more experiment of the same class may be referred to in further illustration of the influence of longitudinal pull on the retentiveness of iron.† In this instance the piece tested, a wire, 0·72m. in diameter and 30·5cms. long, had been hardened by stretching beyond its limit of elasticity before the observations were made. Its retentiveness was then examined when without load and also when various amounts of steady pull were in action. The curves of I, also of I_r, each in relation to H, have already been given in Figs. 105 and 106 respectively; but the points to which attention is now directed may be better seen by reference to Fig. 151, where curves of I_r in relation to I are drawn for no load and for two values of the load. These show that a moderate amount of pull is very favourable to retentiveness in hardened iron, and greatly augments the saturation limit towards which I_r tends. A stronger pull, on the other hand, is less favourable, though under the greatest pull that was used in these experiments the wire continued to be more retentive than it was in the unloaded state. In a similar experiment made with steel wire, the amount of pull was further increased, and was then found to have an unfavourable effect, that is to say, it reduced the retentiveness in the upper range of the process below the value possessed by the unloaded wire.

In Fig. 151 the apparent saturation limit of I_r is about 460 when there is no load, and this is raised to 860 by the presence of a load of 12·2 kilos. per square mm. It is, of course very possible that a slightly greater or slightly less load than this would produce a still more favourable effect on

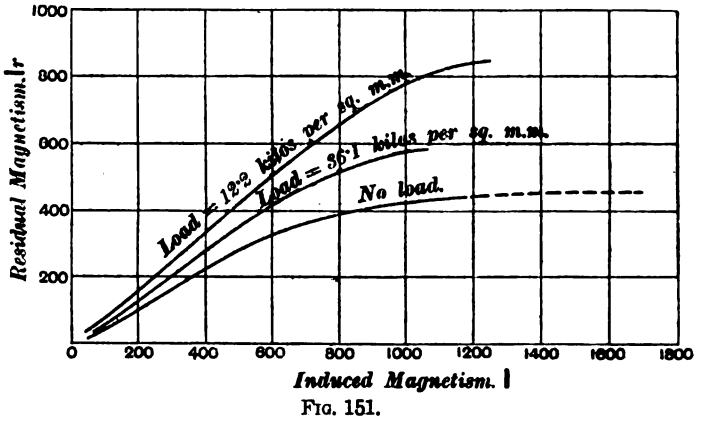

FIG. 151.

the saturation value of the residual magnetism. When there is no load the rate of increment of I_r with respect to I at the steepest part of the curve is about 0·7; but the presence of a suitable amount of load raises that to at least 0·85.

(To be continued.)

THE FRANKFORT EXHIBITION.—XI.

(FROM OUR SPECIAL CORRESPONDENT.)

The only two large alternating-current machines at the Exhibition are the 600 H.P. Helios machine and that of Messrs. Siemens and Halske. We give some details of the latter together with an illustration (Fig. 1), showing also the steam engine driving it. The machine is wound for 2,000 volts when running at 100 revolutions, and a maximum output of 330 kilowatt. The construction is very similar to that of the former machine of this kind built by the firm, the chief thing which strikes one about it being its enormous size. The

* *Loc. cit.*, pp. 625-8, § 110.

Digitized by Google

armature is fixed and the magnets revolve within it. The armature is built up of sixty coils, wound on pieces of laminated iron and bolted to the frame. Each separate coil can, on removal of the machine casing, be unbolted, and easily taken away for repairs when necessary. The sixty magnet coils are wound on radial inwardly projecting teeth. All the conductors are stranded and pressed into a square shape, the copper wires being lightly insulated from each other by paraffin and varnish, the outer insulation consisting of paraffined fibre.

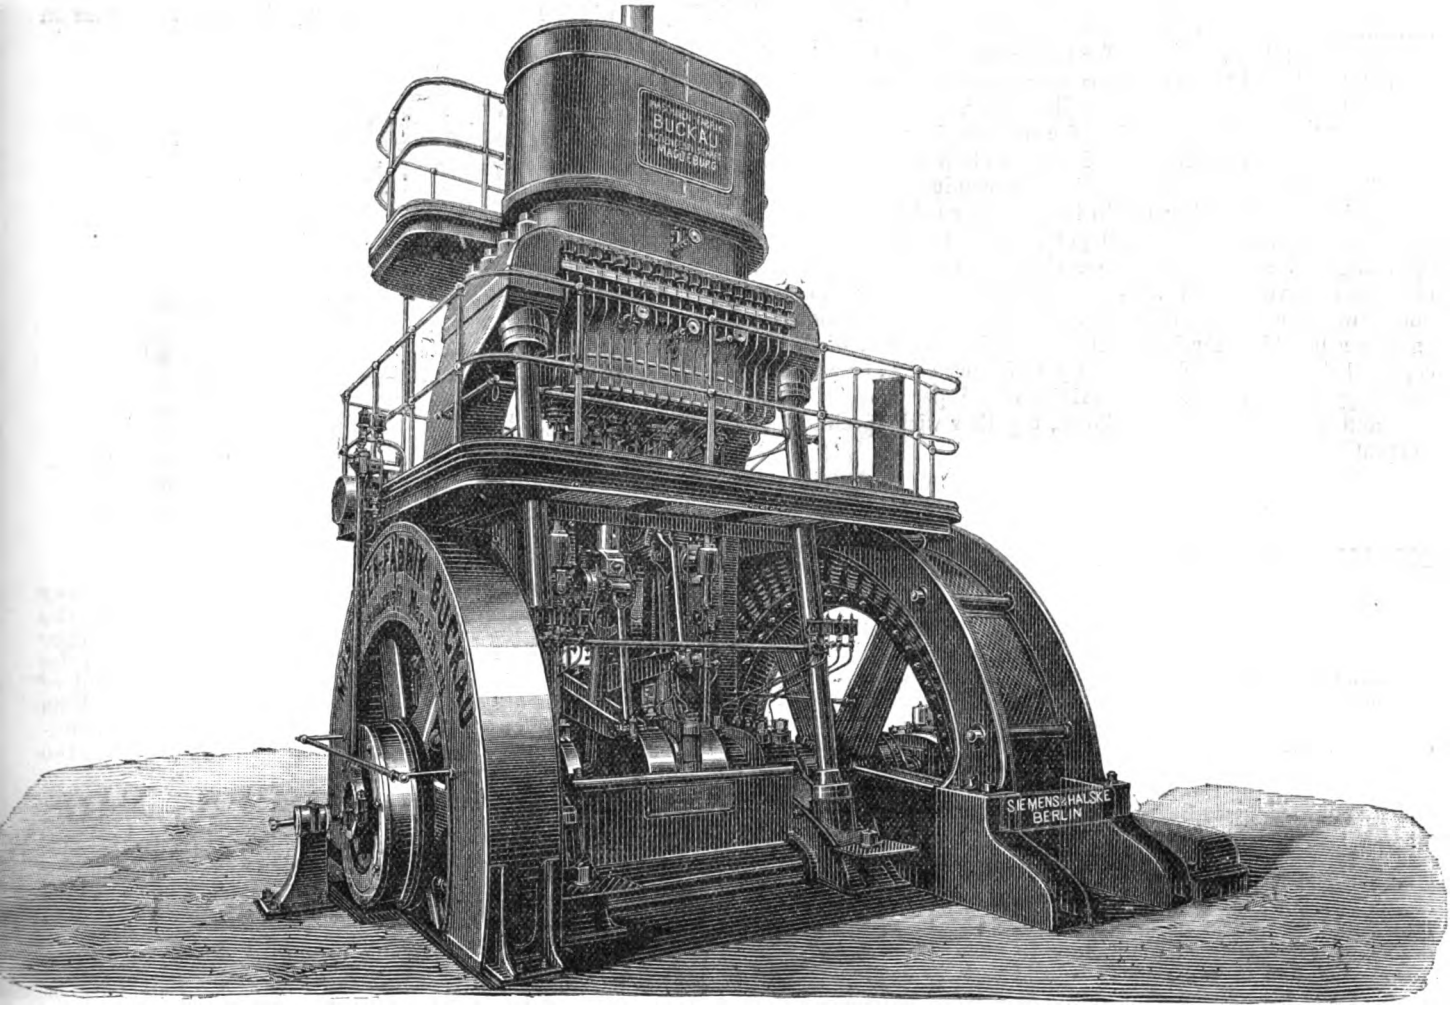

FIG. 1.

The alternator is coupled direct to the engine, and the lower part of the armature has a fairly deep space dug out in the ground for it, and sufficient room is left for the men to get down and clean or examine it. The diameter of the armature over all is nearly 15ft. 2in., while that of the magnet wheel is 8ft. less. The machine is chiefly used for motor-driving, the motors being used as transformers from alternating to direct current, the direct current being used chiefly to charge accumulators.

The 450 H.P. steam engine from the Maschinenfabrik Buckau-Magdeburg, driving the dynamo was not originally constructed for this particular machine. It was intended to run at 160 revolutions, and takes up comparatively small space. As will be seen, the two piston rods are very close together as also the cranks, and the effects of the ascending and descending masses of piston rod and cranks very nearly neutralise and balance each other, so that there is very little pressure indeed on the bearings. Thus comparatively high speeds are permissible. The cylinder diameters are 24·6 and 37·4 inches, and the length of stroke is 27·6in. The initial steam pressure is about 150lbs. per square inch, giving the engine 450 H.P. Grooves are cut on the flywheel to allow of it being levered into a favourable starting position.

The second illustration (Fig. 2) shows one of the three dyna-motors set up by this firm. The motor is of exactly the same construction as the generator just described, although on a smaller scale, and the continuous-current machine coupled to it is an interior four-poled machine of the type already described in these articles (*The Electrician*, August 28th). The usual apparatus is provided to show the right moment to put the load on to the motor, consisting of a small transformer with three windings, one to the generating machine, one to the motor, and the third to a glow lamp. In order to speed up the alternating motor, a battery of accumulators is connected to the continuous-current dynamo, which thus acts temporarily as a motor.

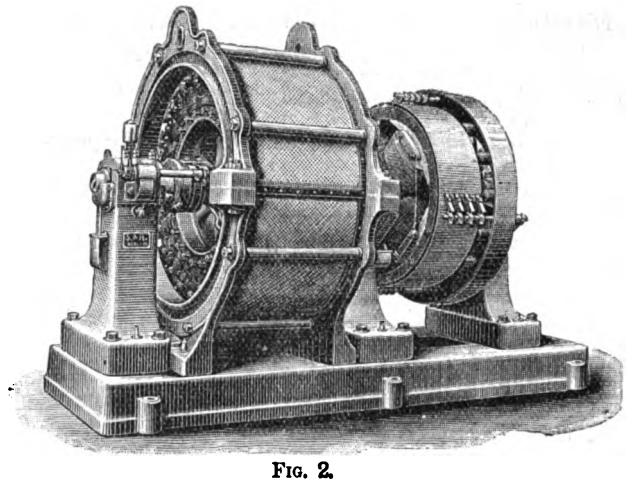

FIG. 2.

A very fine exhibit of wires, cables, and conductors of every kind is shown by Messrs. Felten and Guilleaume. Several examples of distributing boxes for the attachment of feeding

Digitized by Google

and distributing cables on both two-wire and three-wire systems are shown, set in brick foundations, and finished with masonry setting; these are filled with insulating material, poured in hot, where the box is liable to be flooded. Several patterns of cast-iron joint-boxes and branch-boxes, both for ordinary and concentric cables, are exhibited. Lead-covered cables, with single and with concentric conductors, are made by this firm, who have provided for the latest requirements by manufacturing "biconcentric" cables for multiphase currents. A double covering of lead, put on by hydraulic pressure, is generally provided, and the lead is again protected, if necessary, by an armouring of round or flat iron wires, or iron tape. Numerous specimens of telegraph cables for underground and tunnel work are exhibited, and these are, in some exceptional cases, provided with a lead tube as well as iron sheathing. A new quality of their well-known bronze wire for telegraph and telephone purposes has been produced by Messrs. Felten and Guilleaume, who have succeeded in maintaining a conductivity to 60 per cent., while the breaking strain is as high as 44 tons to the square inch, allowing some 30 per cent. to be saved in weight by using a lighter wire having the same conductivity as the older and heavier quality. This firm are introducing the compound wire, having a steel core and copper sheath. The steel enables a breaking strain of 40 tons to be attained, while the copper brings the conductivity up to 55 per cent., or a 35-ton breaking strain with a conductivity of 75 per cent. Copper tape and wire of all sizes is shown, together with specimens of Ferranti cable and locked wire rope.

ON AN ELECTRICAL METHOD OF DETERMINING THE MECHANICAL EQUIVALENT OF HEAT.*

BY M. D'ARSONVAL.

I have the honour of describing to this Society a series of experiments undertaken by me to determine the mechanical equivalent of heat by transforming work into thermic energy by means of electricity. The heat liberated by an electric current, itself generated by a known amount of mechanical work, furnishes a simple means of measuring the mechanical equivalent. This method has already been employed by Joule at the commencement of his remarkable investigations in thermodynamics, and more recently still by M. Violle.† My work has, therefore, no other aim than to point out new devices permitting of a more accurate measurement of the power absorbed on the one hand, and on the other of the heat liberated by the disappearance of this energy. I have endeavoured more especially, in order to eliminate causes of accidental error and to avoid lucky coincidences, to devise a method permitting of the indefinite *accumulation* of the heat produced, and subsequent measurement of it by means of the balance. I have been able to attain this result by the calorimetric method communicated by me in 1877 to the Société Biologie, a method I have constantly employed since then in my researches on animal thermodynamics. In order to make clear what follows I will recall, in a few words, the principle underlying the method.

(i.) *My calorimeter does not heat, during the experiment it remains constant at the surrounding temperature.* I have, therefore, no correction to make, and I need not fear loss of heat by radiation.

(ii.) *The heat generated is automatically carried off, as its production goes on, by a stream of water, which flows into the apparatus at zero temperature and leaves it at the surrounding temperature of* T *degrees.*

To measure the heat produced it is, therefore, only necessary to weigh the water passed through the apparatus. Let P be this weight in kilogrammes, the number of Calories produced will then be given by the equation

$$C = P \times T.$$

We thus see that it is the compensating effect of the cold source which is the ultimate measure of the calories.

In another arrangement I have employed as the compensating source of cold the latent heat of volatisation of some liquid. In this the heat evolved distils the liquid *at the surrounding temperature*, and the change of state is not accompanied by any variation of temperature. I described this method to the Société de Biologie in 1878, and to the Société de Physique in 1880. I have, however, preferred the first method, because it answers in a more direct way to the very definition of the caloric, which is the raising of one kilogramme of water at 0°C. to 1°C. Moreover, the second method involves the previous determination of the heat of volatisation of the liquid, and in this method also a small error in weighing is more serious. The sensitiveness of the first method is, it will be understood, the greater the nearer the surrounding temperature T approaches to zero; while that of the second is almost independent of this. Moreover, the liquid does not always vaporise regularly. All these reasons induced me in the present case to measure the heat produced by the rise in temperature of a stream of water admitted at the temperature of melting ice.*

The various conditions are fulfilled in the calorimeter illustrated in Fig. 1, which I have employed in my different researches on

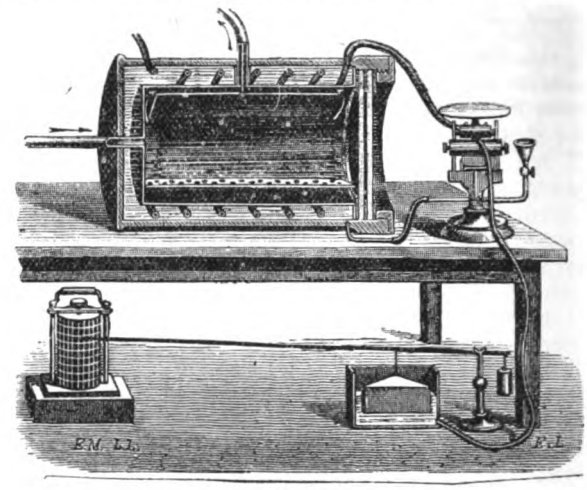

FIG. 1.

animal heat. The apparatus consists of two concentric copper cylinders enclosing two cavities; the central one containing the animal under test, the outer annular cavity containing a copper coil pipe, the left-hand end of which is in communication with the reservoir of water at zero temperature, and the right-hand end of which is in communication with the outflow regulator. This annular cavity is filled with a dilatable liquid which is in communication with the temperature regulator, which in turn regulates the flow of water through the coil.

The regulator (Fig. 2) consists of an india-rubber membrane, fixed horizontally on a block of metal by means of a ring provided with screws. The lower surface of the membrane is placed in communication with the dilatable liquid (petroleum) in the calorimeter by means of a metal tube, B, filled with water and terminated by a tap, C. On the upper surface of the membrane rests a metal piston,

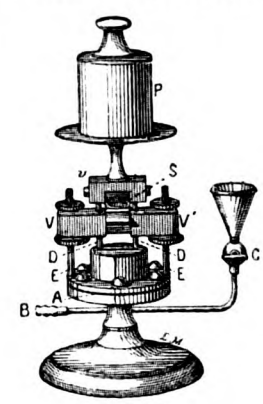

FIG. 2.

connected by the two vertical rods D D to a cross-piece surmounted by a tray, P, which can be weighted. These two rods pass through a second horizontal cross-piece, V V', which can be displaced vertically along the rods E E' and fixed in any required position by screws. To the top of the cross-piece, V V', is secured the thin india-rubber tube, S, which is in communication with the free end of the cooling coil.

* Paper read before the Société Internationale des Électriciens, March 4, 891.

† *Comptes Rendus*, 1870 and 1871.

* I have lately gone back to the distillation calorimetric method, substituting ethyl chloride for the sulphuric acid I used at first. The results obtained with this substance are very satisfactory. Ethyl chloride boils regularly without bubbling, its latent heat of volatisation is low, and its boiling point differs but very little from the average surrounding temperature. It is a very manageable substance, and has yielded good results in animal calorimetry, and is one which I hope to use also in the determination of the mechanical equivalent of heat.

Digitized by Google

The working of the apparatus is easy to understand. The annular cavity of the calorimeter being well filled with petroleum, without air bubbles, the tap C is then opened so that the calorimeter may be in equilibrium with the temperature of the surrounding air, and the tube S closed by the weight P, so as to arrest all outflow. This done, the tap C is closed. If a source of heat is then introduced into the calorimeter, the temperature of the apparatus tends to rise, consequently the liquid (petroleum) expands slightly. This expansion causes the india-rubber membrane of the regulator to lift, raising the piston and slightly opening the india-rubber tube S. This allows a cold stream to flow through the coil, which carries off the heat given out by the source to be measured. This opening is effected gradually, without jerks, and the quantity of liquid which is flowing away at any instant is proportional to the heat given out. You can see by the illustration (Fig. 1) the simple method I employ to record the volume of water which has flowed, or rather to record the phases of the flow. This method of registration has no *raison d'être*, when, as in the present instance, it is a constant source of heat which we are concerned with.

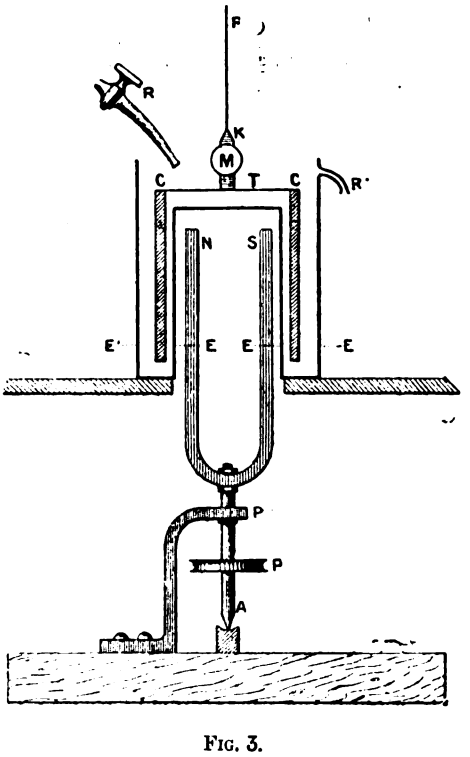

FIG. 3.

This method is accurate to a degree one cannot grasp at first glance. With the apparatus described, I can account for all but $\frac{1}{250}$th of the heat supplied. I may remark also that *the absolute error of the apparatus remains sensibly constant, while the relative error becomes smaller and smaller the longer the experiment is continued.* That is one of the great advantages of the method.

The method of measuring the heat having been described, I now pass on to the means employed to determine the power absorbed. The first idea of it occurred to M. Marcel Deprez, and is described in an account of a projected experiment communicated in our joint names to the Congrès de la Rochelle. The projected experiment was not then carried out, and in order to realise it I was obliged to completely alter the original arrangement, which did not permit of an easy measurement of the heat evolved.

The first apparatus I employed consisted of a thick seamless copper tube C C (Fig. 3), of ·06m. interior diameter, and ·15m. high, suspended vertically by the clip K from a steel wire. In the *interior* of this tube revolves a horse-shoe magnet, N S, which generated Foucault currents in the tube, tending to rotate it in the same direction as the magnet. The torsion of the steel wire, F, enabled me to measure at any instant the torque, that is to say, the energy absorbed by the tube; energy which is entirely transformed into heat in the tube itself, as has been well shown by the experiments of M. Violle with the Foucault disc. We can by this device measure the energy absorbed with extreme precision, since a mirror, M, allows us to see from a distance that the torque is constant by the lamp, scale, mirror method employed by Sir William Thomson in reading galvanometer deflections. The copper tube is plunged into an annular trough, E E, of ebonite, which forms the calorimeter, and which possesses the advantage of shielding the tube from the draught caused by the rotation of the magnet. It is possible to reinforce the magnetic field by placing an iron tube outside the copper tube, but inside the ebonite trough. This, however, is not necessary. I prefer to reinforce the field by substituting an electro-magnet of the Siemens shuttle-wound armature type for the permanent magnet, the coil being energised by a continuous current derived from a constant source (accumulators).

In order that the power absorbed may remain constant it is necessary (the magnetic field being constant) that the permanent magnet or Siemens coil should revolve at a constant speed. To attain this I employ the following mode of regulation:—A Gramme dynamo carries on the end of its armature spindle P (Fig. 4), a flat spring, R, bent into a circle.* This circular spring is fitted with two equal weights, M M'. A point, V, which is situated on the prolongation of the axis of the motor on the opposite side of the spring R can be screwed in and out as required. The current enters at V, and goes round the spring R to the motor. The armature revolves at an accelerated speed until the centrifugal force developed by the weights M M' flattens the spring sufficiently to break the circuit. To overcome the spark on breaking, I interpose a variable resistance, L, between B B'. If one likes one can send nearly the whole current through the shunt, and only send sufficient through the spring to regulate the small irregularities of speed due to irregular friction; the power demanded from the apparatus remaining constant in the present case. A machine developing 1 H.P. will not under these circumstances give the slightest spark when the circuit is broken at V. The screw, V, allows one to regulate the speed very accurately *during running*, and to promptly bring the torque exerted on the copper tube to a decimal value of a kilogrammetre.

The heat produced in the copper tube being a constant quantity, the calorimeter can be considerably simplified. It is, in fact, only necessary that the water which flows in at zero temperature should constantly flow out at the surrounding temperature. This can be ascertained by merely putting a thermometer at R' (Fig. 3), and regulating the influx accordingly by the tap R, which is in connection with a reservoir containing water at the temperature of melting ice and maintained at a constant level. The water flows

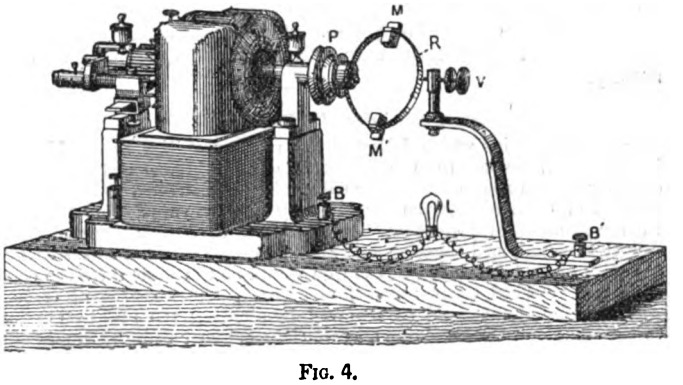

FIG. 4.

into the inside of the copper tube and goes round under it to flow out. The tube, being very thick and a very good conductor of heat, rapidly brings the temperature of the water inside the ebonite calorimeter to uniformity.

To eliminate the parasitic heating due to the friction of the air and the current in the Siemens coil, it is only necessary—the apparatus being at work—to take away the copper tube, keeping the current in the coil at the same time. A certain quantity of ice-cold water is found to be warmed up in a given time. The weight of this water is noted, and the experiment is recommenced with the copper tube. A different weight of water is now obtained, from which the first must be deducted. The difference gives the exact amount of heat absorbed by the copper tube.

The apparatus which I employed could absorb 3 to 5 kilogrammetres per second.† I worked in a basement, where the temperature during winter remained very nearly constant at 10°C. I obtained for the mechanical equivalent values which varied from 419 to 427 kilogrammetres.‡ I only regard these values as a first, though satisfactory, approximation to the truth. I intend to continue these researches with a somewhat different arrangement, capable of absorbing 4 to 5 H.P., and I am in hopes of eliminating, by the large scale of my operations, certain causes of error which I was unable to avoid with the first apparatus.

To obtain regularity of speed I also tried the following arrangement, which might be useful in chronographic experiments. A

* The idea of regulating the speed of an electric motor by making use of a centrifugal governor to break the circuit is due to Helmholtz. Since 1843 it has been applied in different ways by a number of people. The method I propose here has in its favour its great simplicity, and above all the possibility of regulating while running.

† 1 kilogrammetre = 7·2331 foot-lbs.

tuning-fork (50 double vibrations) is placed in connection with the middle N (Fig. 5) of a battery of primary or secondary cells through an alternate current motor M. The ends of the battery are joined up to two adjustable screws, V V', placed exactly opposite each other. The tuning-fork is fitted with an elastic strip L, which, while the fork vibrates makes contact alternately with V and V'. A small electromagnet, E, keeps up the motion. It is easy to see by the diagram that the motor M will be traversed by absolutely regular alternate currents, with which it will synchronise. The whole trick (*tout l'artifice*) consists in having converted the electrical tuning-fork into a current reverser by merely connecting it to the middle of the battery. As to the motor one can use a Siemens alternator with shuttle-wound armature, although it would be better to use one without iron in the armature similar to the commercial type of machine. In the research we are now concerned with I preferred the apparatus with the circular regulator

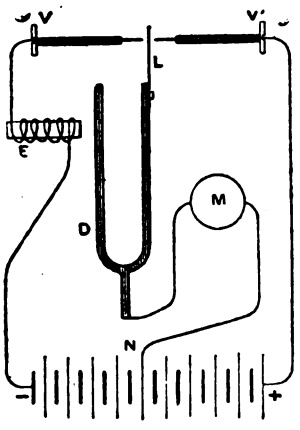

FIG. 5

shown in Fig. 4, owing to the large power which it can regularly develop. I am continuing this experiment with much greater forces, and I shall hasten to communicate my results to this society.

DISCUSSION.

In the discussion which followed the reading of the Paper, M. CARPENTIER referred to the Foucault currents developed in the iron cylinder placed round the copper tube. It did not seem to him that the method of determining the parasitic heating by suppressing the copper tube was altogether correct. The Foucault currents generated in the copper tube modified the magnetic field, and one could not assert that the quantity of heat developed in the iron would be the same *after* the copper tube was replaced as it was before. This possible source of error M. Arnoux pointed out could be removed by securing the said iron cylinder to the spindle of the revolving magnet; the cylinder being then stationary relative to the revolving magnet, there would be no generation of the Foucault currents in it. If at the present moment the mechanical equivalent of the calorie was only known accurately to two places of decimals it was, said M. Arnoux, due in a large measure to the fact that its determination had always been carried out by means of diminutive apparatus, mere scientific toys, which only absorbed one or two kilogrammetres per second; apparatus in which losses by radiation attained a high figure. With large apparatus the losses by radiation became negligible, since the volume of the calorimeter increased as the cube and its radiating surface increased only as the square of its linear dimensions. With appliances capable of transforming into heat not merely a few kilogrammetres, but a few hundred kilogrammetres per second, we ought to succeed in determining the mechanical equivalent to three or four places.

ELECTRIC MINING-MACHINERY, WITH SPECIAL REFERENCE TO THE APPLICATION OF ELECTRICITY TO COAL-CUTTING, PUMPING, AND ROCK-DRILLING.*

BY LLEWELYN B. ATKINSON AND CLAUDE W. ATKINSON, ASSOC. MM. INST. C.E.

(Continued from page 560.)

Turning to the application of electricity to movable machinery, the authors have for the last four years been constantly engaged in the design of electric coal-cutting plant, and the results of the work done in this direction will now for the first time be published.

Although this use of electric power has only recently become an accomplished fact, it is interesting to note that the idea presented itself to Mr. Henry Wilde, F.R.S,, of Manchester, one of the earliest pioneers in the development of the dynamo machine, as long ago as 1873, when he described the application of electric power to coal-cutting machines of various forms, in a provisional patent taken out by him in that year.

It was in 1887, so far as the authors know, that the first machine was built for the purpose of cutting coal by electricity. It had a cutter of the bar type revolving on its own axis, a form which it appears was first introduced by Mr. Grafton Jones, and was driven by a motor designed for the purpose, and made by Messrs. W. T. Goolden and Co. The original experiments were conducted at the collieries of Messrs. T. and R. W. Bowers, and the conception of thus employing electricity is due to Mr. F. Mori, electrician, of Leeds, and Mr. J. Blackburn, manager to Messrs. Bowers. Considerable difficulties were, as was natural, found in adapting power to conditions so novel, and so outside all ordinary experience; and, in order to obtain full information as to the obstacles to be overcome, the authors devoted a good deal of time to practically working at the coal-face the various machines that have been constructed. These difficulties have been twofold: namely, electrical and mechanical. The original machine designed by Mr. J. Blackburn was provided with a motor arranged to fit it. This was a three-coil vertical motor, adapted to work in a horizontal position. It was of 6 H.P., and was driven by a dynamo having a normal output of 10 H.P., the motive power being the engine of a hauling-machine, situated at the bottom of the shaft. The distance between the dynamo and the motor was about a mile.

The original dynamo and original motor were both compound-wound, the series-coils on the motor consisting of sufficient turns of thick wire to nearly saturate the magnets with the large current developed on first closing the switch; but when running at a normal load this series-coil had little influence on the magnetisation, which was then affected by the shunt-winding; so that the regulation as to speed was almost as good as if the winding had been simply shunt. This arrangement is convenient as giving a good starting power, and at the same time ensuring satisfactory speed regulation; but in the case of coal-cutting machines the authors have a preference for a series-wound dynamo and series-wound motor, for reasons previously described, namely, that when the motor is being stopped, by the insertion of a proper resistance, the electromotive force may be reduced nearly to zero before breaking the circuit; and further, if it is desired to handle the cables or to disconnect them, or to handle any part of the circuit of the machine after it is stopped, there is no liability to a shock should the insulation at any other point be defective. This is of great importance in a motor intended to be used by inexperienced miners, who are easily frightened, even by a moderate shock, so that they neglect to adjust the brushes, &c., even if they are not so far afraid that they will not work the machine at all. This first plant, which is still working satisfactorily, was, it will be noted, practically unprotected from dirt, dust, or explosive gases, and it was in connection with this that the authors first devised their system of enclosed motors.

With the next machine, built by Messrs. Goolden, as it was desired to cut into the coal at a height which was suitable for using direct driving without the intervention of gearing, the armature-shaft itself was made to carry the cutter-bar. The opinion, however, which the authors now hold is, that although this method of working is quite feasible, it is on the ground of expediency not desirable. It is difficult to construct armatures with shafts large enough to carry the strain put upon them by a cutter bar of the description used without cramping the space for wire and insulation.

Figs. 3 and 4 show still later developments of this class of machinery, in which the cutter-bars are mounted on a separate shaft, and driven by steel double helical gear-wheels. The point to be noted is the combination of the electrical structure with the more strictly mechanical framework, thus providing the greatest amount of strength and electrical power with minimum weight and size. The dimensions of the heading along the coal-face are generally so small that it is only by great compactness that the use of these coal-cutting machines is rendered possible.

Fig. 5 shows in plan the general method of working. The machine, mounted on its wheels standing on the rails laid along the face, is adjusted by means of a turn-table and worm-gear, so that the cutter-bar points along the heading; the current is switched on, and the bar, revolving rapidly on its axis, is turned through an angle of 90° so as to enter the coal. The worm-gear and table being then locked, the machine is drawn along, by means of a winch and wire-rope, cutting its way as it goes. Automatic methods of winding have been devised, but that of pulling in by hand is probably the simplest in the end, and has the advantage of enabling the man at the winch to tell whether the machine is cutting in hard or soft material, and accommodate the rate of movement accordingly. Automatic winding-gear is usually arranged to work at a fixed speed, which must necessarily be that at which the machine will cut in the hardest material to be dealt with, so that with softer material the progress is obviously less than it need be.

The authors have suggested an automatic winding-gear intended to obviate this objection. It consists of a ratchet-and-pawl motion,

* Abstract of Paper read before the Institution of Civil Engineers.

Digitized by Google

the pawl being under the control of an electro-magnet. Since the load on the motor is accurately measured by the current flowing through it, the magnet can be so adjusted that if the load should exceed the desired limit the pawl would be lifted out of gear, and the feeding stopped until the machine had eased itself again to its normal load, when the pawl would commence to feed it forward.

All the motors used for these coal-cutting machines are entirely enclosed as to every working part. The field magnets are lagged in steel coverings, the switches, with their resistance frames, are placed in iron boxes, and from the outside it would be difficult to see that the machine was an electric motor. Furthermore, precautions have been taken to thoroughly enclose the gearing, and all bearings and their parts into which grit can obtain access, and the system of lubrication is such that the oil passes from the armature-shaft to the cutter-shaft, and thence is drained into the gear-box, which has an oil-tight joint, so that the gear eventually revolves in oil.

A particular arrangement of machine was shown which was required to cut at any height from 9in. to 33in. from the road-level. This was effected by bolting to one of the pole-pieces a casting with two segmental slots. The cutter-bar was carried in a support moving on these slots, and by these means could be raised and lowered to any height, remaining at the same time in fixed relation to the armature shaft from which it is geared. It is interesting to point out to electrical engineers how the somewhat difficult problem of arranging this machine, so as to avoid the magnetic short-circuiting of the poles, has been met. The leakage from such extended pole-pieces is considerable, but not nearly so excessive as might at first sight be thought.

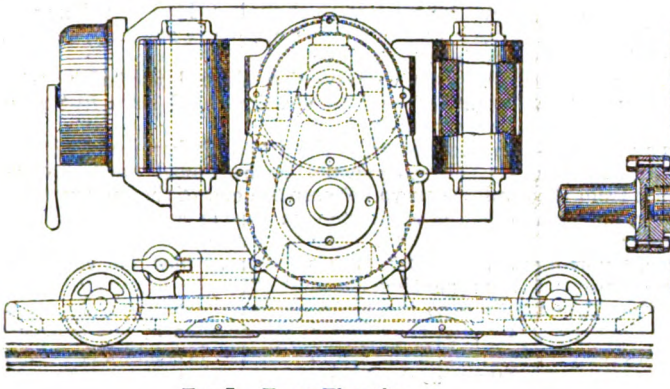

FIG. 3.—Front Elevation.

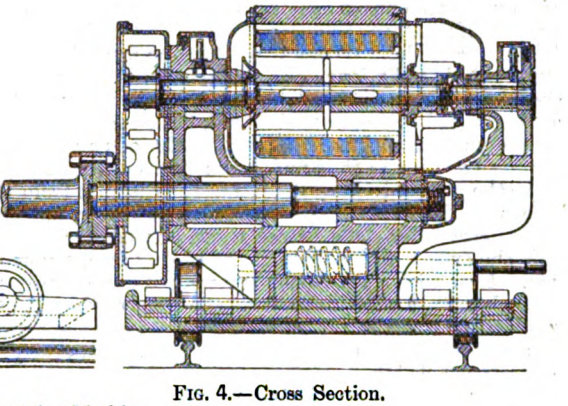

FIG. 4.—Cross Section.

Goolden Coal-cutting Machine.

Several forms of armature have been tried in these machines, with both "drum" and "gramme" windings; and the authors are of opinion that on the whole the "gramme" armatures are best adapted for the work, the reason being that it is very difficult to secure the wire across the ends of a drum-winding in such a manner as to ensure their being positively driven; and in the absence of such positive driving it seems only to be a question of time when the insulation will become abraded by the excessive vibration. One form which has been much used in these machines was illustrated. The armature core is deeply notched to receive the coils, and when these have been wound in place the whole is covered with a layer of annealed charcoal-iron wire. By this means a notched armature, giving a low magnetic resistance in the air-space, is obtained, whilst the production of eddy-currents and consequent heating of the polar horns is avoided, and the armature is of a form which can be handled and laid on the ground, if necessary, without any damage occurring to the wire or its surface.

It soon became evident that the ordinary brushes used on dynamos and fixed motors were useless, owing to the excessive vibration to which the machines were subjected, whilst various forms having butt-contacts, in which the brush was pushed forward by springs, gave rise, both with metallic and with carbon blocks, to excessive heating, due, as far as can be ascertained, partly to the friction on the commutator, and partly to the inferior electrical contact thus obtained.

Brushes of a type which has been successfully used in launch and tramway work, and was originally designed by Mr. Holroyd Smith, composed of blocks of metal carried by light steel fingers or springs, were also tried with similar results, and finally the authors have adopted various forms in which the necessary elasticity is given either in the brush itself, or in a light steel back, there being, however, no movable hinge or knuckle which would allow it to chatter as a whole on the commutator.

The chief mechanical problem in connection with these coal-cutting machines has been: First:—What is the best form of gear to use? and secondly, What is the best form to give to the cutter-bars and cutters? As to the gear, the authors have tried chains of every description and strength, and have had to abandon them all; they have also tried phosphor bronze gearing of ordinary forms, but have finally adopted, as working more smoothly and with less noise, and giving a maximum of strength, cast steel double helical wheels, shrouded nearly to the pitch line. By mounting one of such a pair of wheels in a manner free to slide to a small degree upon its shaft, the perfect alignment of the wheels is secured and the running leaves little to be desired.

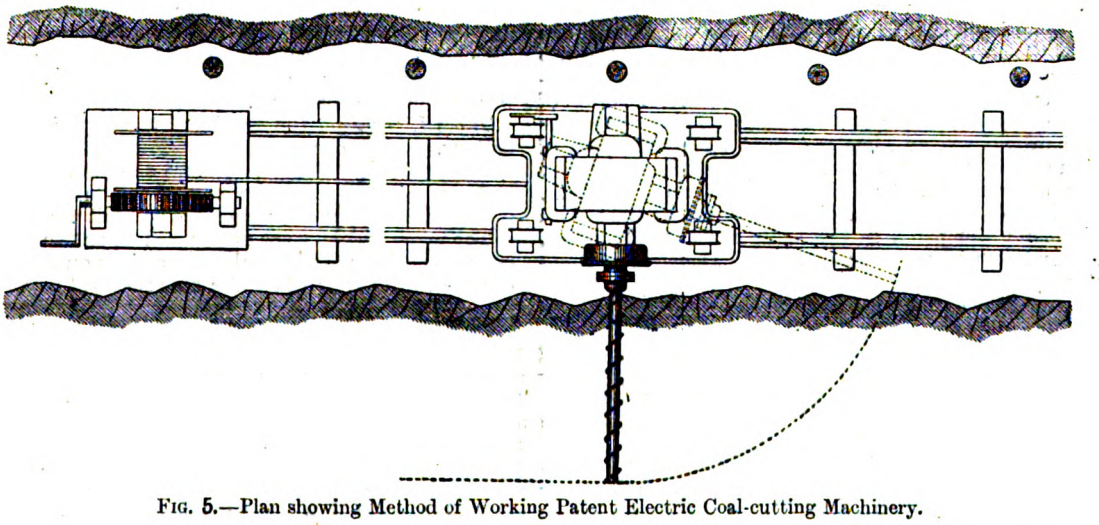

FIG. 5.—Plan showing Method of Working Patent Electric Coal-cutting Machinery.

Although the several machines illustrated in this Paper have been made to cut above the floor level, at heights specially suited to each particular case, so as to work in the bands of shale or dirt and thus save the coal, yet the form with a bar-cutter is eminently suitable for cutting at the level of the floor itself, and the authors have designed machines for this purpose, the rails being laid directly on the surface thus formed. The form of cutter most usually adopted in such cases is that of a large disc or wheel with

Digitized by Google

the tools fixed into its periphery. This disc is carried on a bracket projecting from the side of the machine, and is caused to revolve by a pinion gearing into teeth either cut in its horizontal surface, or into teeth formed on its periphery, the teeth of the pinion being then made sufficiently long to allow the tools to cut clear at the bottom. The tools are spread out so as to cut the material clear of the disc.

Machines on this principle have been used with considerable success in several places, but the authors consider the bar cutter is to preferred for several reasons.

First, there is a considerable amount of difficulty in making a machine with a disc cutter to turn round so as to cut its own way under the coal, and in fact in most cases this is done by hand.

Secondly, when the tools are blunt, they have to be taken out and replaced by sharp ones while the disc remains in the coal, a matter of some difficulty in the confined space and with the small amount of light available. With a bar-cutter, on the other hand, since the bar is only held by four bolts at the coupling, it is turned out of the coal and a fresh one with a complete set of new cutters substituted, the other being sent to the bank to be reground.

Thirdly, if the coal or roof is at all tender there is a great tendency for it to fall as soon as it is undercut; to avoid this, wedges are inserted in the groove to keep it up, but the distance from the front of the cut to the back of the disc is considerable, and as a consequence the coal often falls before it can be wedged; this, of course, jambs the cutter, which then has to be dug free, involving a loss of time. Now with a bar-cutter the wedges can be inserted close behind the bar, only a few inches from the front of the cut, and the coal supported, so that even if it falls it cannot jamb the cutter.

Fourthly, a bar-cutter can be made to bare to a greater depth, as much, for instance, as 5ft.

Fifthly, in order to make an electric motor of sufficient power while the weight is kept small, it is necessary to run it at a fairly high speed, and therefore, to keep the gearing compact, the cutter must also run at a high speed. This is easily attained without any disadvantage with a bar cutter, but is quite impossible with a disc cutter, where the speed of the tools would be so great as to seriously heat and soften them. In practice the authors run the motors at about 700 revolutions per minute, while the cutter makes about 500 revolutions per minute. On the other hand, the disc cutters will draw more of the fine coal out of the groove than the bars will; but this advantage is not sufficient, in the authors' opinion, to compensate for the disadvantages enumerated above.

(To be continued.)

TESTS OF THE TUDOR AND CORRENS ACCUMULATORS.*

In response to an invitation issued by the Berliner Electrische Beleuchtungs-Aktiengesellschaft parallel series of tests on the two above accumulators were undertaken by Dr. Heim and Prof. Kohlrausch, of Hanover, Prof. Peukert, of Brunswick, and Dr. Voller, of Hamburg, as theoretical experts; and Messrs. Otto Berner, Gustav Conz, and Richard Seifert, of Hamburg, and Germershausen, of Berlin, as commercial engineers. Dr. Classen, of Hamburg, also assisted at the measurements. The tests took place on the 11th, 12th, 13th, and 14th of July, on batteries laid down by the Berlin Correns Accumulator Company, in the Wilhelmshalle, Hamburg, and by the Hagen Accumulator Company, in the Thalstrasse, Hamburg, respecti vely.

The object aimed at was to submit both batteries to a series of similar tests, under, as far as possible, equivalent conditions. Voltage measurements were accordingly taken with batteries of 50 cells of each kind, which had not recently been put in or out of circuit by the switch, from which it may be concluded that they were under as nearly identical conditions as they can be when in actual work. Further, since the voltages of the cells themselves must exceed those found for a coupled-up battery, the losses occurring in the connections, as determined during charging, were added to the values obtained during the discharge, so as to arrive at the actual voltages of the cells. The instruments belonging to the central stations were not used for measurements of current and voltage, a torsion galvanometer and resistances from the Hamburg City Physical Laboratory, and from the Electrical Institution of the Technical High School at Hanover, being employed instead. The instruments were compared carefully, and the means of several readings were taken.

Tests as to insulation showed no faults which, on account of "earths," or short circuits, could have had any appreciable effect on the results.

With regard to the limits of charge and discharge, it was agreed that charging should be continued until the turning point in the voltage curve between the end of the final rapid rise and the subsequent gradual increase during an overcharge should clearly have been reached. The discharge was to be stopped when the voltage showed a fall of 10 per cent. below the value at which it remains for some time constant after the commencement of the discharge. Since at the close of the discharge the pressure falls off very rapidly, the effect on the amount of the discharge is not very important if the fall in pressure is somewhat greater or less than this 30 per cent. The current was kept constant as far as practicable.

The tests made on the two batteries were as follows:—

(*a*) 1, charge; 2, discharge; 3, charge at a current of about ·5 ampere per square decimetre.

(*b*) 4, discharge at about 1 ampere per square decimetre.

(*c*) 5, charge; 6, discharge; 7, charge at from ·6 to ·7 ampere per square decimetre.

(*d*) 8, discharge; 9, charge; 10, discharge at about 1 ampere per square decimetre.

The Correns Battery.

The Correns battery tested started working at the beginning of May, that is about 2½ months before the time at which the experiments were made. The type was their H_{21} C, 924 ampere-hours capacity, charging current, 154 amperes. The charge thus occupied about 5 hours. Each cell contained 21 negative and 22 positive plates, the total surface of each electrode being 300 square decimetres.

According to the statements of the men in charge, the battery had been regularly charged according to their instructions, and discharge had not been carried lower than to about 1·83 volts per cell. Mr. Correns, a few days previous to the experiments, had had the cells emptied, and had superintended the filling of them with acid. Consequently, during the course of the experiments, the battery, as far as can be the case with one in regular work, was in a normal condition.

Table I. contains the results of the experiments on the Correns battery. The observers were Messrs. Germershausen, Heim, Kohlrausch, and Seifert. Before the first measured charge, the battery was charged at the normal current until gas was copiously given off, and then discharged to the limit arranged upon.

Too much weight must not be laid upon the values for the efficiency found from the several tests, as it is only after a large number of such equivalent tests that a true result at a given current can b$_e$

obtained. The full capacity of the battery at the current indicated by the maker's 155 amperes (discharge 2) is given. A current strength 1·3 times as great as this gave 97 per cent., and a current strength twice as great (discharges 4, 8, and 10) gave at the mean 85 per cent. of this capacity.

As the result of all the tests an efficiency of 93 per cent. in ampere hours and 81·5 per cent. in watt hours was obtained. The mean current (reckoned from all the tests) at charging was 1·28 times, and at discharging 1·68 times, those indicated respectively by the makers; the current density during charging averaged ·69 amperes per square decimetre, and during discharge ·9 amperes per square decimetre.

The Tudor Battery.

The Tudor battery had been at work since November, 1890—that is to say, for about eight months, at the time it was tested. The type was No. XX. of the price list for April, 1889. Capacity, 660 ampere hours; charging current, 165 amperes; discharging current, 198 amperes, and so made for charging in three hours. Each cell contained 16 negative and 15 positive plates, the total surface of each electrode being 288 square decimetres. According to the men who had been running the battery, it had been up to six or seven weeks before the tests fully charged or overcharged. During these six or seven weeks, however, the charge had, without exception, been too small. More exact information could not be obtained, as no books were forthcoming; but it may be considered probable that during this time the Tudor battery had only received too small charges, and that, consequently, it was not quite in a normal condition. The battery was not overhauled by the contractors previously to the tests. Unfortunately, the Accumulator Company refused to take any part in the tests. Table II. contains the results of the tests on the Tudor battery. The observers were Messrs. Berner, Conz, Peukert, and Voller.

Before the first measured charge the battery was charged at normal current until gas was freely given off, and then discharged down to the arranged limit.

The figures clearly show that the behaviour of the battery improved during the tests. This is evident from the fact that in Tests 6 and 7, and particularly in the three last tests at about 300 amperes, the capacity and the efficiency in ampere hours come out strikingly high in comparison with the three first tests at about 150 amperes. These results are, thefore, in accordance with the statements of the attendants, since, if the Tudor battery during the six or seven weeks preceding the tests had not been fully charged, its action, which had deteriorated owing to the small charges, would naturally have improved during the complete charges and discharges it was subjected to during the tests.

As mentioned above, no great weight must be attached to the values found for the efficiency from the several tests. The full capacity of the battery at the current indicated by the makers, 195 amperes (discharge 6), is given. A current strength 1·6 times as great as this (discharges 4, 8, and 10) gave on an average 91 per cent. of this capacity.

As the result of all the tests, efficiencies of 87·5 per cent. in ampere hours and 68·8 per cent. in watt-hours were obtained. The mean current from all the tests in charging was 1·12 times, and in discharging 1·29 times those indicated respectively by the makers. The current during charging averaged ·61 amperes per square decimetre, and during discharge ·85 amperes per square decimetre.

The above results do not allow any conclusion to be drawn with regard to the superiority of either kind of accumulator in reference to efficiency or the relation between capacity and current strength, nor could the question have been settled if the Tudor accumulator had been regularly charged before the tests were made. Such a general conclusion could only be drawn after tests on a large number of batteries of both kinds. The tests also would have had to be more exact and more complete than those now made. It may also be remarked that the circumstance that the Correns battery is constructed for a five-hour discharge, whilst the Tudor completely discharges in three, could hardly be taken into consideration.

The results actually obtained prove that the particular Correns battery tested considerably surpasses the particular Tudor battery tested as regards efficiency both in ampere hours and watt hours. The Correns battery showed efficiencies which have never yet been surpassed by any kind of accumulator.

No tests were made as to the influence of over charging or over discharging. Obviously, moreover, no conclusion can be drawn as to the lives of the two accumulators.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *September* 15, 1891.

The Montreal Meeting of the National Electric Light Association.—The meeting of the National Electric Light Association at Montreal may be counted as a grand success. The Convention was remarkably well attended, and something like 200 delegates had assembled as early as Sunday night, September 6th. A special train came through from New York bearing more than a hundred people, and was joined at Rutland, Vermont, by a special train from Boston bearing fifty more. The headquarters of the Association were at the Windsor Hotel, where the accommodations were for such a gathering of the very best. The citizens of Montreal had made most elaborate preparations for the thorough entertainment of their visitors, and there was a constant round of entertainments of one sort or another all the time the Convention was in session. The business meetings were held in the morning, and the afternoon was given up to miscellaneous work and entertainments. The exhibition of electrical machinery and appliances held in the Victoria Rink, closely adjoining the headquarters, was probably the finest ever held in the country. There have been more pretentious exhibits partaking of a spectacular nature, but nothing anything like so complete a collection of working machinery. Of course, the Thomson-Houston and Edison companies were in the front rank of exhibitors; in fact, to a certain extent, the Convention was made the field of a tolerably sharp cross-fire between these two great rivals, and a vigorous effort was made in certain quarters to utilise the National Electric Light Association for pulling Edison chestnuts out of the fire. This inner history in the political economy of the Convention, however, did not appear in any disagreeable way, and produced no serious result on the Convention as a whole, although the existence of such an undercurrent was quite obvious. The Westinghouse Company was conspicuous by its absence.

Power for the use of the exhibitors was kindly furnished from the dynamo room of McGill University; the Edison Company receiving it on a gigantic railway dynamo used as a motor, and the Thomson-Houston Company on a similar large machine. One of the most interesting exhibits was that of Mr. H. Ward Leonard, who, as I have before mentioned, recently severed his connection with the Edison Company, like

Digitized by Google

so many others of the well-known electrical engineers of this country. Mr. Leonard showed a new device of his invention for regulating motors, the fundamental idea being to run a given motor at any desired speed and any necessary torque, the velocity of rotation being independent of the load. The motor employed was operating an electric hoist, and picked up its load at any desired speed within a very wide range and was under the most perfect control; the suspended weight could be brought down with great rapidity to a point close to where it was to be placed, and then lowered far more gently than could be accomplished by any other means, or its motion reversed if necessary. It was something unique among motors of any sort in its extremely perfect regulation, retaining meanwhile a surprisingly high efficiency. Its only inconvenience was that it required a control of both the motor and the generator, so that in case of deriving the power from a central station it becomes necessary to transform by a generator on the spot, as was done in this particular instance, the current operating an Edison motor being used to drive a dynamo, which in turn was used to drive a dynamo to supply the working motor. Another exhibit that attracted a great deal of attention was the Thomson-Houston reciprocating rock drill, shown in actual operation gnawing its way into a block of stone.

During the Convention, the Governor-General of Canada was a visitor at the Exhibition, and was present at the banquet given by the citizens of Montreal on Friday evening, September 10th.

The Papers read at the Convention were of a high order of merit. Perhaps the most important work accomplished was the formulation, by the Committee on Safe Wiring, of a set of standard wiring rules, to supersede the diverse regulations now enforced by the insurance companies. The committee that was appointed for the purpose of working up this Report contained two practical insurance inspectors, and with their co-operation a set of provisional regulations of a very complete and valuable character was drawn up and presented to the Association. A permanent committee to take charge of the matter was appointed; and at the next Convention the rules, with slight modifications, will doubtless be adopted. Other valuable Papers were those by Mr. Jas. J. Ayer, Mr. C. J. Field, and Captain Eugene Griffin. The discussions contained much that was of interest, but were less vigorous than at any preceding Convention.

Too much cannot be said for the hearty welcome given the Association by the citizens of Montreal, who extended every possible courtesy, and gave to their friends from the States as warm a reception as could have been desired. The members of the Association will carry away with them the warmest regard for their Canadian hosts, and most pleasant memories of an unusually successful and agreeable Convention.

SCANDINAVIAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

COPENHAGEN, *September* 21, 1891.

The Copenhagen Telephone Company intend to introduce several facilities for its subscribers from the beginning of next year. Night service will be introduced at the Copenhagen head station, and the Company offers cheaper rates for connections in the interior of the town.

The principal square of Copenhagen, the "Kongens Nytorv," a large and handsome square, will probably soon be lighted by electricity; whether electric lighting will be adopted for other public places or streets remains to be seen.

The laying down of the State telephone cables in Stockholm has now been going on for some time. The so-called American system is adopted. The cables are placed in blocks of cast cement, each block calculated for 36, 18, or 15 cables, as the requirements of the locality may be. These blocks are firmly attached to each other by the Hultman patent method, and are laid in connected lengths of 120 metres. At every 120 metres there is a manhole, serving the double purpose of hauling in and connecting house wires. Each cable contains enough wires for 100 subscribers. The getting of the cables through the ducts in the cement blocks has in some places caused some trouble, and various devices have been tried, among which may be mentioned the one used in America of employing rats, a plan which was, however, soon abandoned. In Stockholm it is proposed to fasten together a number of one-metre wooden rods by iron hooks, and then to push these through from manhole to manhole. In order to facilitate the passage of the cable and reduce the friction the ducts will be greased with a mixture of vaseline and paraffin.

CORRESPONDENCE.

THE CORRECTION FOR "g" IN CONNECTION WITH SIR WILLIAM THOMSON'S STANDARD BALANCE INSTRUMENTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR,—In your issue of the 18th inst. you say "Sir William Thomson appears to have overlooked the correction for 'g' in connection with his Standard Balance instruments." As a matter of fact this has not been done. The current on these instruments varies as the square root of the weight used; and consequently, though the variation of "g" between Glasgow and London is about $\frac{1}{25}$ per cent., the error so introduced into the indications of a standard electric balance would be only $\frac{1}{50}$ per cent., while the error introduced into an instrument removed from Glasgow to the Equator would be $\frac{1}{7}$, if no correction were made. A correction is, however, made whenever a standard is being sent from Glasgow to a place where the difference in "g" would produce any appreciable error. The amount of this correction is determined by data from tables of variation for "g", and when no data are available for the particular place, "g" is calculated from the well-known formula

$$g = G\,(1 + \cdot00513 \sin^2 \lambda).$$

(See Thomson and Tait's "Elements of Natural Philosophy," § 187.)

Where G is the apparent force of gravity upon unit mass at the Equator, and λ is the latitude of the place.—I am, &c.,

Physical Laboratory, ANDREW W. MEIKLE.
The University, Glasgow, Sept. 23, 1891.

THE DETERMINATION OF CURRENTS IN ABSOLUTE ELECTRO-MAGNETIC MEASURE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the excellent series of Papers by Mr. Searle now appearing in *The Electrician*, he refers to the well-known theorem "$\Sigma F \alpha = 4\pi \times$ (quantity of north magnetism inside)" as due to Prof. Stokes. The fact is, the theorem is due to Gauss, who published it in 1839. His Paper containing it was translated, and appeared in "Taylor's Scientific Memoirs," Vol. III., pp. 153-196. It is the theorem of section 22 of that Paper. In 1849 Prof. Stokes published a Paper on Clairaut's theorem in the "Cambridge and Dublin Mathematical Journal," Vol. IV., pp. 194-219. For convenience he collected a number of "propositions respecting attractions," of which proposition VII. is the one above referred to. In a footnote to p. 195 Prof. Stokes says, "not one of the 'propositions respecting attractions' is new, although now and then the demonstrations may differ from what have hitherto been given. With one or two exceptions, these propositions will all be found in a paper by Gauss, of which a translation is published in the third volume of 'Taylor's Scientific Memoirs,' p. 153. The demonstrations here given of propositions VI. and VII. are the same as Gauss's."

Trusting that you may regard the above correction as deserving of insertion,—I am, Sir, &c.,

J. D. HAMILTON DICKSON.

Peterhouse, Cambridge, September 22, 1891.

SMOKE ANNIHILATION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The system alluded to in your issue of September 18th, under the above heading, of supplying hot air behind the bridge of the furnace to assist the complete combustion of the fuel, though old, is a good one, judging by its extensive use; but it is difficult to understand how it can account for the

Digitized by Google

analysis of the fuel and results as quoted by you from the *Chemical Trade Journal*. The analysis of the fuel used gave 28·35 per cent. of volatile matters, chiefly hydrocarbons; and that of the flue gases gave 100 per cent. of nitrogen, oxygen, and carbon oxides, but *hydrogen absent* in all forms; while it goes on to state "that economy is effected by thus obtaining more perfect combustion, this is proved by the fact that the hydro-carbons, usually allowed to escape unburnt, contain three-tenths of the heat of the original fuel."

It would be interesting if the Gaseous and Liquid Fuel Supply Company would explain how their tests can be reconciled with the laws of the conservation of energy, for, with the system employed the hydrogen cannot have "gone off in smoke."—I am, Sir, &c., W. GEIPEL.

TRADE NOTES AND NOTICES.

TENDERS WANTED.—The Common Council of Pisa announce that they are prepared to receive tenders for the supply and distribution of electricity for public purposes within the city. Further particulars may be obtained from Signor A. Nardi-Dei, dal Palazzo Comunale, Pisa, to whom tenders are to be sent by December 15th.

——— The Town Council of the Borough of Eastbourne are prepared to receive tenders for a "Westminster chiming clock" for the Town Hall, to be fitted for illumination with all the necessary appliances. Further particulars may be obtained on application at the Borough Surveyor's Office, Town Hall, Eastbourne. Tenders supplying full particulars must be sent to Mr. H. West Fovargue, Town Clerk, Town Hall, Eastbourne, on or before October 13, 1891. Further information will be found in our advertisement columns.

——— The Taunton Town Council desire tenders for the supply and erection of electrical fire calls within the borough. Plans, specifications, and other information may be obtained at the office of the Water Works Manager, Municipal-buildings, Taunton, and tenders are to reach Mr. T. Meyler, Town Clerk, by October 5.

MESSRS. BENHAM AND FROUD'S NEW CATALOGUES.—Messrs. Benham and Froud (Limited) have forwarded us advance copies of their new catalogues of electric-light fittings and wrought-iron work. The former contains some very handsome examples of the manufactures for which this firm are justly celebrated; every design in the book is original, and the whole of the work has been made at the factory in Chandos-street, Strand, London, W.C. Included in the designs shown are electroliers, brackets, ceiling lights, church fittings, floor and table lamps, pillars, glass and silk shades, standards, lanterns, pendants, &c. Some of the designs are especially handsome, and suitable for use in the most artistic installations of the electric light. All are carefully marked and priced, and Messrs. Benham and Froud notify that specimens of most of the fittings shown can be seen in their show rooms. The catalogue of wrought-iron work, although containing no specimens of electric-light fitting work, is full of new and original designs, many of which could be readily adapted to the electric light if required.

MESSRS. BALDERSTON AND CO.—We have received from this firm a little treatise on machine-belting, issued by Messrs. Fayerweather and Co., of New York, for whom Messrs. Balderston and Co. are agents for the United Kingdom.

MR. WILSON HARTNELL.—We are informed by Mr. Farrar, the London agent for Mr. Wilson Hartnell, of Leeds, that he has secured the order for the electric lighting of the new flour mills for Messrs. James Tucker (Limited), Cardiff, which, when complete, will rank amongst the largest in the country.

SUNBEAM LAMPS.—The Sunbeam Lamp Company send us a price list of their lamps, which are made in sizes varying from 150 c.p. to 2,000 c.p., and are suited for pressures from 50 to 110 volts. They are made in two classes, the one for high efficiency, and the other for longer duration. There is an undoubted saving in first cost by using these lamps instead of groups of small lamps. The efficiency of the first class appears, by the figures given in the price list, to be 2 watts per candle, and the second class 2½ watts per candle. These probably refer to the initial candle-power when new. No information is given as to falling off of candle-power or life. These factors will not, we believe, allow them to compete with arc lamps, and it is difficult to estimate the economy compared with small lamps.

RANSOMES, SIMS, AND JEFFERIES.—This firm sends us a new catalogue and price list of their steam engines, boilers, and other machinery. They illustrate among their boilers a multitubular externally fired cylindrical boiler, requiring a limited space for setting.

PHOTO COPIES OF TRACINGS.—Messrs. Bemrose and Sons, of 23, Old Bailey, E.C., send us specimens and a price list of their papers for white line, black line, and blue line prints; together with particulars of printing frames, dishes, and other accessories.

WOODHOUSE AND RAWSON UNITED (LIMITED).—This firm have opened a branch office and sample room at 89, Bothwell-street, Glasgow, which is under the management of Mr. B. F. Howard, who has been appointed agent for Scotland.

THE CRYSTAL PALACE AND DISTRICT ELECTRIC LIGHTING.—We learn that Messrs. J. E. H. Gordon and Co., of 11, Pall-mall, who have secured the order for the central station and mains for the supply of electricity to the Crystal Palace Exhibition, and afterwards to the Sydenham district, are making rapid progress with their works, and will have their station of 20,000 lights capacity in full work on the opening of the Exhibition on January 1st next.

ELMORE COPPER.—The Elmore Patent Copper Depositing Company send us facsimile copies of fourteen testimonials as to the excellence of their copper tubes. We are requested by the Secretary to notice these testimonials, "as statements have occasionally appeared raising the question as to whether the process can be relied upon to produce uniformly good articles at a reasonable price." We have never questioned the quality of these goods, but have doubted whether the advantages would be so great, and the price so low, as the promoters have loudly proclaimed. We are glad to learn that, at all events, fourteen firms—apparently customers—are satisfied as to quality.

NEW COMPANIES, STATUTORY RETURNS, &c.

BROWN'S ENGINE COMPANY (LIMITED).—This Company has been registered in Scotland, with a capital of £15,000 in £5 shares. Object:—To adopt and carry out an agreement with Mr. Alexander Francis Gordon Brown, Swindridgemuir Dalry, and William David Russell, of Maulside, Ayrshire, to acquire the invention for an expansion rotary engine, described in letters patent of February 2, 1888, and also the patents therefor in Great Britain, Austria, Belgium, Germany, France, Italy, Spain, and the Spanish Colonies, New South Wales, Queensland, South Australia, Victoria, New Zealand, India, Canada, the United States of America, and Brazil; to take out patents, British, foreign, or colonial, for the invention; to acquire other inventions and work these; and to carry on the business of engineers, mechanical engineers, machine and engineering tool makers, boiler makers, ironfounders, brass founders, millwrights, metal workers, and steel converters; and to buy, sell, manufacture, repair, convert, let on hire, and deal in engines, machinery, rolling stock, metals, metal implements tools, and utensils of all kinds. The office of the Company is in Glasgow.

PARTINGTON CYCLE COMPANY (LIMITED).—This Company was registered on September 19, 1891, with a capital of £10,000 in £1 shares, by S. S. Seal, 7, Serjeants' Inn, Temple. The objects are:—To carry on the business of mechanical and electrical engineers, machinists, cycle manufacturers, and all or any of the businesses connected therewith. Office, Mill-street, Middleton, Lancaster.

J. CAWTHRA AND COMPANY, LIMITED (Manufacturers, Merchants, Suppliers of Electricity, Gas, &c.).—The statutory return of this Company, made up to July 7, 1891, was filed on July 13th. The nominal capital is £120,000 in £10 shares, all of which are taken up, and £107,450 paid in respect of calls, while the remaining £12,550 is considered as paid. Office, 7, Swaine-street, Bradford.

COLLIER AUDIBLE TELEPHONE SYNDICATE (LIMITED).—The statutory return of this Syndicate, made up to September 1, 1891, was filed on the 7th following. The nominal capital is £9,000, in £100 shares, all of which are taken up. The full amount has been called upon 30 of the shares, and £2,860 paid, leaving £140 unpaid 60 shares (of which 30 belong to A. T. Collier, of 38, Gray's Inn-road, W.C., and 30 to the London and Colonial Finance Corporation (Limited), are considered as fully paid. Office, 5A, Coleman-street, E.C.

CUTTRISS, WALLIS, AND COMPANY (LIMITED).—An agreement made April 20, 1891, between T. Cuttriss and S. W. Cuttriss (trading as Cuttriss and Co., of the first part, E. C. Wallis of the second part, and R. W, Graham (on behalf of the above Company), of the third part, states that the Company intend to take over the business of Cuttriss and Co., of the Elmwood Electrical Works, Leeds, and also that of E. C. Wallis, electrician, of 1, Bond-place, Leeds; and in full satisfaction for the said businesses 420 fully paid-up shares will be allotted to the vendors or their nominees, which shares, however, will not rank for dividend during the first year unless 10 per cent. is paid on the paid-up capital. S. W. Cuttriss and E. C. Wallis are appointed Managing Directors for five years, from November 1, 1890. Remuneration for such services will be at the rate of £150 per annum each, for the first two years, and £200 per annum each for the remainder, and in addition the sum of £25 per annum for each £1 per cent. over 6 per cent., provided that the additional remuneration do not exceed £150 per annum each. The statutory return, made up to August 14, 1891, was filed on the following day. The Company, which was registered on April 22, 1891, has a capital of £10,000, in £5 shares, 736 of which have been taken up. Upon 316 shares £3 per share has been called, and with the exception of £10 paid, while the remaining 420 have been considered as fully paid. Office, Elmwood Electrical Works, Camp-road, Leeds.

FROUDE-HURRELL TORPEDO COMPANY (LIMITED).—The statutory return of this Company, made up to Aug. 14, 1891, was filed on the 21st following. The Company, which was registered on the 24th March last, has a capital of £10,000 in £10 shares; 121 of the shares have been taken up, the full amount called, and £760 paid, leaving the remaining £450 unpaid. Office: 3, Broad-street Buildings, London, E.C.

Digitized by Google

WEYBRIDGE ELECTRIC SUPPLY COMPANY (LIMITED)—The statutory return of this Company, made up to August 8th, was filed on September 3, 1891. The Company was incorporated to take over the Electric Lighting Depôt, Weybridge, carried on by the Laing, Wharton, and Down Construction Syndicate (Limited), and had a nominal capital of £15,000 in £5 shares; seven shares have been taken up, but no calls have been made, and the present shareholders are the original subscribers. No agreement for the taking over of the business has as yet been filed. Office: Thames-street, Weybridge.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the past week were £4,849.

CITY AND SOUTH LONDON RAILWAY COMPANY.—The traffic receipts of this Company for the past week amounted to £684.

CITY OF LONDON ELECTRIC LIGHTING (PIONEER) COMPANY (LIMITED).—Notice is given that the transfer books and register of members of this Company was finally closed on the 18th inst.

EASTERN TELEGRAPH COMPANY (LIMITED).—This Company announces the payment, on October 15th next, of interest of 3s. per share, less income-tax, being at the rate of 6 per cent. per annum, on the preference shares of the Company for the quarter ended September 30th, and the usual interim dividend of 2s. 6d. per share on the ordinary shares, free of income-tax, in respect of profits for the quarter ended June 30th. The register of transfers will be closed from Oct. 7th to 14th, both days inclusive.

EASTERN EXTENSION, AUSTRALASIA AND CHINA TELEGRAPH COMPANY (LIMITED).—The Directors have declared an interim dividend for the quarter ended June 30th last of 2s. 6d. per share, payable on the 15th prox.

GLOBE TELEGRAPH AND TRUST COMPANY.—The Directors of this Company have declared an interim dividend of 2s. per share.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended September 18th, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £3,780.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The receipts of this Company for the two weeks ended September 15th show a decrease of £591 as compared with the corresponding period last year.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 698.—Vol. XXVII. FRIDAY, OCTOBER 2, 1891. Price Fourpence.

NOTES.

In many respects it is to be regretted that there is nothing in this country to correspond with the National Electric Light Association of the United States. The members represent the class which attend, or ought to attend, the meetings of the London Chamber of Commerce; in the holiday aspect of the Convention it resembles the British Association; and for carefully prepared papers and practical discussions it may be compared with our Engineering Institutions. The papers are limited in number, they are printed beforehand, and in the hands of the members, and they are of a solid and representative character. Some of the topics, such as arc-light supply and street railways, do not at present largely concern us on this side of the Atlantic; but they were dealt with in a practical way, which must have been appreciated by the American audience. The zone system advocated by the President is open to the criticism that if it be admitted that distribution at high electrical pressure is satisfactory and advisable, it may as well be used for the centre of the town as well as for the outlying districts.

It is easy to see the advantage of throwing out high-pressure feeders to the suburbs of a town, while no such feeders are required for the streets neighbouring on the supply station. But to use two systems concurrently, to say nothing of the multiplication of different voltages for different distances, reminds us of the hole which Sir Isaac Newton made in his door for the kitten, alongside the one provided for the cat.

Fortunately for us in this country we know little of the tyranny of parent companies over supply companies, and it is difficult to realise the serious complaints which are made against them by the supply companies in the United States. This appears to be an outcome of the American "electric light systems." An Edison Supply Company uses everything of the Edison brand, and a station fitted by the Brush Company has not a single article in common with the Edison. Our American friends seem to suffer particularly in the measuring instruments thus supplied to them.

The remarks which were made at the meeting of the National Electric Light Association about measuring instruments ought to encourage our manufacturers to brave the McKinley tariff, and show what can be done in the way of ammeters and voltmeters for station work. We would call attention to the observations of Dr Louis Bell, which will be found in our abstract of the fifth day's proceedings, and recommend those of our readers who are specially interested in the matter to read the remarks of Mr. Ayer and of Mr. Scott, in the full report which appears in the *Electrical World* of New York for September 19th. We need not go so far as Montreal to hear grumbling about the accuracy of instruments. Prof. Kennedy, in the discussion on Mr. Crompton's Paper before the Institution of Civil Engineers, said that he had been scoffed at because he wanted a voltmeter to be right to a volt, and was told that he should not expect it. This sounds rather like the "parent company" tyranny. We hope that before long we shall have reports of the work done by the Electrical Standardising Laboratory, giving details, like the Kew report, of the accuracy attained and the number of instruments examined. Such information is much needed by instrument makers who really try to turn out good work. We shall not be surprised to learn that voltmeters may be purchased for five pounds which will read to a quarter of a volt.

In our leading article of March 20th we discussed the alleged decrease of hysteresis in the iron core of a transformer under heavy loads. To be more accurate, we did not discuss the question itself, but the way in which it had been handled. The position was very disappointing. Mr. Mordey, by a method of doubtful accuracy, had detected it, and Prof. Ayrton confirmed it, but without giving any clue whatever to an explanation. We felt confident that either an explanation or a refutation would soon turn up; but six months have elapsed, and the electrical world has since then been busy with Dr. Fleming's explanation of the Deptford phenomena (if this expression is better than Ferranti effect), with Electrical Standards, with Faraday centenaries, and with multiphase motors, and the matter has been almost forgotten. We had secretly hoped that the explanation would sooner or later be found in the course of articles on Magnetism by Prof. Ewing, which are now drawing to a close; and this week we have the pleasure of pointing it out on page 602, section 181, of the present issue.

The explanation of the decrease of hysteresis with heavy load is as simple as the molecular theory of Prof. Ewing, and is "one of those things which anybody could have thought of." Of course, we are quite ready to hear of all the previous publications, and are prepared to learn that it is a very old story, and all that; but of one thing we are quite certain, that no explanation of such complete simplicity has been offered before. Prof. Ewing treats the secondary of the

Digitized by Google

loaded transformer, not as a conductor carrying a larger current than at other times, but merely as one which has less resistance than when lightly loaded. Most of our readers are familiar with old alternate current dynamos which took more power to run them idle than when loaded; and this has been explained, with more or less lucidity, as being due to the wasteful production of eddy currents in the one case, and the useful expenditure of the same currents in the external circuit in the other case. Prof. EWING simply shows that the magnetic molecules, instead of vibrating independently and thus setting up eddy currents, have their vibrations damped by the conductor of low resistance, and tend to move in unison, so that such currents as are produced, do not occur in the iron, but in the secondary circuit itself.

PROF. EWING'S explanation will doubtless be criticised. Shall we call it a hypothesis for the present, until the fact of the decrease of hysteresis is firmly established? The swinging molecules, or clots of molecules, having a mass incomparably small in relation to the mass of the magnet, may be supposed to spread their own lines of force in their own neighbourhood; and these, under ordinary conditions of hysteresis, are considered to set up eddy currents, also in their own neighbourhood; that is, in the body of the iron. But, on the other hand, it may be argued that since the resultant lines of force are merely due to the combined effect of all the constituent molecules, we must look for a swinging of the whole resultant field. But this supposes a homogeneity of field; and the question then arises, is the field in the interior of a magnet practically homogeneous, or do the molecules or small aggregations of them, in behaving according to Prof. EWING'S hypothesis, redistribute the lines of force in their own neighbourhood, and can we consider their lines of force apart from the resultant lines of force of the magnet as a whole? It appears that the small local vibrations are held to account for ordinary hysteresis; but that when this alleged decrease is dealt with, the resultant external field is considered. We do not for a moment suppose that Prof. EWING is blowing hot and cold in this way; but as the difficulty referred to may occur to others, we hope he will give us further information on the subject.

A RATHER more complete proof is still wanting that this decrease actually exists, but it is not worth the while of engineers to spend time on the investigation. They could easily spare a little more power on well-loaded transformers; it is the extravagance of the idle ones that is offering so serious an obstacle to the progress of electric lighting by transformers. We hope to publish in an early issue a description of the very simple apparatus which Prof. EWING has employed in investigating this matter.

WE publish this week an article by M. PELLISSIER, in which he offers a simple explanation of the action of the Wimshurst machine. The theory of the influence machine has not kept pace with the development of the apparatus itself, for the explanations given in text books are much more applicable to the older than to the newer types of machine, and are especially unsatisfactory in accounting theoretically for the great practical improvement which has taken place. The parts of the machine forming the collectors figure prominently in the usual theory, as in the older class of machine, such as Thomson's replenisher, they were an important part of the whole. In recent machines, however, the collectors are a minor detail, just like the brushes of a dynamo, and M. PELLISSIER points out that, as the Wimshurst machine will fully charge itself without the aid of collecting combs, the theory of its action must be independent of them, and may be simplified by supposing them removed. The theory of M. PELLISSIER is very similar to that given by Prof. THOMPSON in his classical Paper on the "Influence Machine," read in 1888 before the Institution of Electrical Engineers. The matter is, however, put in a novel way, and the steady increase of charge is explained very satisfactorily. As the author points out, the explanation of the self-excitation of these machines is still obscure. It is generally put down to residual electric charge on the plates, just as dynamos are supposed to excite owing to residual magnetism in the field. It must, however, be borne in mind that the polarity of each sector in a Wimshurst machine in action is constantly reversing, so that residual effects can hardly be expected.

A SATISFACTORY method for determining alternate-current curves is much needed, and in many ways this want seems supplied in the apparatus referred to in another column, the details of which will be found described by M. BLONDEL in a recent number of *La Lumière Electrique*. The best research hitherto in connection with these curves is due to Prof. RYAN, an account of whose apparatus will be found in *The Electrician* for January 10th of last year. The success of this work was, however, largely dependent on the use of a new kind of electrometer. M. BLONDEL'S method requires no new instrument, and although the contact breaker is very elaborate, the curves can be very quickly obtained when the apparatus is once set up; and the method has the great advantage that the current and potential curves can be obtained simultaneously, and permanently recorded by means of photography. Nearly all the methods yet devised for finding these curves need some modification of the contact breaker originally used by JOUBERT, and their usefulness must greatly depend on the way in which this portion of the apparatus stands wear and tear. Apparently the new method is satisfactory in this respect, as it is asserted that the contact pieces have been used for an average of three hours a day for a month without serious deterioration.

WIDESPREAD sympathy has been shown for Sir JAMES ANDERSON in the bereavement which he has sustained by the death of Lady ANDERSON on September 25th, after a very short illness.

Esslingen.—We learn from the *Elektrotechnische Zeitschrift* that the Maschinenfabrik Esslingen proposes to erect a central station for the supply of light and power in that town.

The Old Students' Association.—The annual dinner of the O. S. A. has been postponed until Saturday, October 31st. It will then be held at the Holborn Restaurant at seven o'clock, and tickets may by obtained from the secretary or any member of the committee.

Digitized by Google

Odessa.—The lighting of the Harbour of Odessa for the Russian Government, which has been carried out by the Hamburg branch of the Thomson-Houston International Electric Company, is now in full work. The installation includes 64 arc lamps and 8 incandescents.

Spherical Harmonics.—Several correspondents have asked us where Prof. Perry's Table of Zonal Spherical Harmonics is published. We are informed by the author that it will probably be found, together with a few examples of its use, in the forthcoming October number of the "Philosophical Magazine."

Liverpool Electrical Engineer.—The Liverpool Corporation have received 93 applications for the position of electrical engineer. The Committee unanimously appointed Mr. J. C. Sherman to the vacant post. He has had a training under Prof. Lodge, and has for the last three months been engaged in working for the Corporation.

"The Times" and the Frankfort Exhibition.—The "leading journal" may generally be looked to for early, complete, and original news; but the whole of the account of the Frankfort Exhibition, which appeared in its columns "From a Correspondent at Frankfort" on Monday, the 28th, is to be found verbatim "By the Editor" in a contemporary of September 25th.

Proposed Lighting of the Sheerness Naval Barracks.—The Admiralty have under consideration proposals for lighting Sheerness Royal Naval Barracks with the electric light. An estimate has been forwarded of the cost, together with estimates of the expense of several other improvements in the establishment, which is about to be converted into a school of gunnery.

A Compressed Air Power Supply for Lucerne.—The electrical power plant in use at Lucerne having been found insufficient to meet the demands for small powers, amounting to about 1,440 H.P., it has been decided to erect a plant on the compressed air system, and the contract has been given to Messrs. Riedinger of Augsburg, which firm carried out the work in connection with the compressed air plant at Offenbach. It is expected that the Lucerne plant will be in working order within two years.

Train Lighting.—One of the express trains running between Berlin and Frankfort has been fitted with the electric light. Each coach has two distinct storage batteries, and the lamps are on two distinct circuits, so that in case of accident to one circuit, or on changing the batteries, the carriage shall not be left entirely without light. The storage cells are especially designed to stand rough handling, and have a capacity of 200 ampere-hours. Each battery supplies current to four 8 c.p. lamps for the compartments and to one 5 c.p. lamp in the lavatory. The batteries, which weigh 6 cwt. each, are placed in boxes underneath the carriage floor, and can be taken out and replaced very rapidly.

Heriot-Watt College.—The new session of this College commences on Tuesday, October 6th. Last session Mr. William G. Rennee, a student of the College, obtained one of the four Whitworth Scholarships annually offered for competition throughout the United Kingdom, and of the value of £125 per annum, tenable for three years. Also in the Technological Examinations of the City and Guilds of London Institute, 5 prizes, 8 medals, and 80 certificates were awarded to the students of the College, including the third prize and medal in Electric Lighting and Transformer of Power awarded to Mr. John Henderson. Particulars of the Engineering Classes will be found in our advertisement columns.

Berlin.—We learn from the *Volkszeitung* that a detailed project for the erection of a system of electric railways in Berlin has been laid before the municipal authorities by Messrs. Siemens and Halske. According to this firm elevated roads form the only feasible method of providing means of rapid transit. The first line which it is proposed to take in hand is the South or Canal line, extending from the Zoological Gardens along the Landwehr Kanal and the Skalitzerstrasse to the Oberbaumbrucke and the Warschauerstrasse terminus of the City Railway. Should this line, which would have a length of 8·9 km., prove successful, seven other lines in connection with it, having a total length of 40 kms., would be proceeded with.

St. John's Church, Newcastle.—This church has been supplied with electric light, which was used for the first time on the occasion of the harvest festival on the 24th ult. There are 22 lamps fixed, each of 100 candle-power. They are so arranged that sections of them can be shut off separately from the others, so that the light can be reduced at any time, as, for instance, during the sermon. The lamps hang from the apex of each arch. There are six lights in the chancel, which are arranged so that two, four, or the whole number can be used, as the case demands. The most pleasing feature was the great improvement obtained by the removal of the heavy gas pendants from the central aisle. The current is supplied by the Newcastle and District Electric Lighting Company.

The Phonopore.—This remarkable telegraphic system is coming into practical use on several lines in this country. One of the Great Northern Railway Company's lines from King's Cross to Retford is fitted with it, and on the Midland Railway a duplexed passenger line between St. Pancras Station and Derby is arranged with a phonopore connection for the goods service; between the goods stations some 250 messages a day have been sent over it for the last two months. On the Great Western Railway a phonopore set is provided on a line between Paddington and Exeter, there being five single-needle intermediate stations which work independently of the phonopore. The mechanical adjustments of the instrument have been modified, and it has now assumed a thoroughly practical form.

Obituary.—We regret to record the death at Greenwich, on September 26th, at the age of 46, of Mr. Thomas John Brown, the Chief Electrician of the Telegraph Construction and Maintenance Company, in succession to the late Mr. Joseph May. Mr. Brown entered the service of the Telegraph Construction Company in 1864, having previously been engaged with Messrs. Glass, Elliott and Co. He had been occupied on all the important Atlantic cable expeditions, and also in the laying of many of the Eastern, Eastern Extension, and Brazilian Company's cables, his last expedition having been on the triplicate Aden-Bombay section early in the present year. Mr. Brown was esteemed a faithful servant by the Telegraph Construction and Maintenance Company, and his loss will be sincerely regretted by a wide circle of friends. We regret to record the death at Vienna on September 26th, of Mr. John Douglas Lyle Gibbs, after a protracted illness. Mr. Gibbs was for many years the Eastern Telegraph Company's manager in Egypt, and has since represented that Company at Vienna.

The Junior Engineering Society.—The tenth annual general meeting of this flourishing society was held last Friday evening at the Westminster Palace Hotel, Victoria-street, Westminster. Mr. W. J. Tennant, Grad.Inst.P.A., occupying the chair as usual. A highly satisfactory report for the past session was read by the Secretary, Mr. Walter T. Dunn, showing an increase in membership of 34 per cent. In consideration of the long cherished project for publishing the proceedings of the Society, and possibly opening a reading-room and museum of its own, it was moved from the chair that the subscription of members over 21 years of age be increased; after a long animated discussion this motion was carried. Officers for the ensuing session

Digitized by Google

were elected. Mr. Tennant having held the post of chairman for so long, withdrew his name from the list of nominations for the position, in case he should be re-elected. Mr. S. Boulding was elected in Mr. Tennant's place. An attractive programme of excursions and other arrangements is in course of preparation for the eleventh session. It is interesting to note that this Society, founded ten years ago by half-a-dozen young engineers, has now over 260 members of all classes enrolled.

Production of Copper in the United States.—A special bulletin, issued from the Census Office, states that since the Census year 1880, the United States has risen to the rank of the largest copper producer in the world, outstripping by far any other country. During the decade Arizona and, later, Montana have become important producing States, the latter now acquiring and maintaining its rank as leader. While by far the greater part of the metal produced is obtained from ores in which lead, gold, and silver are the principal constituents of value, these quantities are difficult to trace to their source. The ores are purchased by lead and copper smelters in the open market, often in small parcels, indirectly through sampling works. Sometimes copper is not even present in the original ore in marketable quantity, and becomes a factor only when it appears in a concentrated form in the matters of lead smelters and refiners. The copper product of the United States was as follows, in pounds, in the calendar year 1889 :—

Arizona	31,586,185
Michigan	87,455,675
Montana	98,222,444
New Mexico	3,686,137
Colorado	1,170,053
Idaho, Nevada, Utah, California, Wyoming, and Vermont	571,882
Southern States	18,144
Lead smelters and refiners	3,345,442
Total	226,055,962

Statistics of Lightning in Germany.—Lightning casualty returns have been made in conformity with a German Ministerial Order, showing the extent to which the buildings belonging to or under subsidy from the State have, within the period from 1877 to 1886, been damaged by lightning. The number of buildings with regard to which returns were collected was 53,502, of which 22,682 were actual State property, and 30,820 were entitled to State subsidy for rebuilding or repair. Buildings were struck in 264 cases, or about five for every 1,000 buildings in ten years. Of the various classes of buildings the number struck per 1,000 for the period are as follows :—Elementary schools, 0·8 ; parochial houses, 1·4 ; revenue buildings, 1·7 ; prisons and penitentiaries, 3·4 ; forest-rangers' houses, 7·2 ; churches, 8·2 ; court-houses, 11·9 ; seminaries, 14·6 ; gymnasia, 15·4 ; university buildings, 24·1 ; domain buildings, 44·9 ; and horse-breeding establishments, 312·5. Those which are the property of the State are less subject to injury by lightning than those only under subsidy. Out of the 264 cases in which the lightning struck, eighty-one, or not even one-third, resulted in a fire. The amount of injury wrought by lightning on the 53,502 houses coming within the scope of these statistics was £56,834, or £215 for each casualty, or 21s. per building in ten years, about 2s. per building per annum. The amount of injury done to domain and horse-breeding establishments was considerable, amounting to £42,000, or more than two-thirds of the total injury caused by lightning. It has been calculated, from the returns of sixty fire insurance companies of Germany, Austria, and Switzerland, embracing the period from 1855 to 1877, that the danger from lightning has increased two and a-half fold in those countries, during the period named. The danger is said to have increased three-fold in Germany within the last thirty years. The average loss sustained annually by Germany from this cause is computed at from six to eight millions of marks. Casualties have thus increased in the period of lightning conductor extension.

Underground Telegraph Wires in China.—The *Electrical Engineer* of New York is responsible for the following :—"A superstitious reverence for the dead accomplished years ago in China something that regard for the comfort and safety of the living, even when aided by judicial mandates and radical municipal methods, has been only partially able to accomplish in this country," said a telegraph lineman who was in the employ of the company that established the first telegraph line in China. "The telegraph wires are placed underground there, and if the company had not so disposed of them there would have been no telegraph lines in China to this day. Dead ancestors are held in peculiar reverence in that curious country, and the casting of a shadow upon the grave of an ancestor is looked upon by the Chinese as an insult not to be borne, and it is always resented with impetuous rage. Now there are no cemeteries or general burying grounds in China, but every family's ancestors, particularly in the rural districts, are buried on the family premises. Consequently, every yard or garden is a receptacle of ancestral remains, and, as China is thickly populated, the revered bones of dead and gone Mongolian progenitors may be found resting beneath every few rods of earth. When the telegraph company went to work to put up the poles on which to hang its wires the workmen were embarrassed every little while by wrathful Chinamen, who would rush angrily upon certain poles and chop them to the ground, and warn the workmen with much furious chatter that they would put them up again at their peril. The cause of this interference was unknown to the workmen, who were at last forced to discontinue the work, and explanation was demanded by the authorities. Then it was learned that the poles that were cut down had cast a shadow some time during the day on the graves of revered ancestors of Chinamen, and the insult could be wiped out in no other way but by summarily removing the poles. It was found that this superstition was too sacred a one among the Chinese to be overcome by persuasion or bribery, and at last the telegraph company, as a matter of economy and self protection, laid their wires beneath the surface, where they have been ever since."

An Obstacle to our Foreign Trade.—It will be remembered that recent Consular reports from Italy and Japan have referred to the loss of trade owing to firms in England sending to those countries circulars and price lists based on the English weights and measures. The metric system is used in those countries, and our French, German, and other competitors use it in their quotations ; but the English firms are content to puzzle buyers with weights and measures which are very troublesome and not understood. A similar complaint now reaches us from Egypt, and the Consular report just issued (annual series of Foreign Office Reports, No. 944,) points out that our weights and measures are "utterly unintelligible" to a large proportion of the persons to whom export houses in this country forward their circulars and price lists in Alexandria and Cairo. The metric system of weights and measures is in force in Egypt, and exporters of English goods to that country should, of course, adopt it in their quotations and transactions. Not to do so is indeed suicidal shortsightedness, and it is to be hoped that the day is not far distant when the metric system of weights and measures will be generally adopted in England. If this needful reform is not soon undertaken there is little doubt that our foreign competitors will get a hold of our customers abroad which it will not be easy to shake off. In Australia it has been suggested that the adoption of the metric weights and measures should be carried out as one of the early labours of the coming Commonwealth Government of Federated Australia. In the *Sydney Morning Herald* of July 11th last there is the following forcible reference to the subject :—"The fact that such an absurdity as our present monetary system and that of our weights and measures should have survived so long shows how strongly they must have entrenched themselves in the stupidity of human nature. It is a shame to our intelligence that such a burden should have been tolerated so long, and the advance of Australia into the field of nations should be made the occasion of throwing off an incubus that we and our fathers have groaned under so long. It is the business of the colonies to lead old Mother England by her apron strings, as we have often done before ; and there is not much likelihood of her refusing to follow us in a reform like this, that sooner or later will be imperatively demanded by the advance of the intelligence of the age." The foregoing matter has been sent us by the Secretary of the Decimal Association, and we insert it at his request, without assuming any responsibility for opinions advanced.

MAGNETISM IN IRON AND OTHER METALS.*—LII.

BY PROF. J. A. EWING, F.R.S

(*Continued from page 586.*)

§ 178. **Retentiveness of Nickel.**—A reference to the curves which were given for nickel when the effects of stress were discussed in earlier articles of this series (§§121-122, Figs. 95, 96, 98, and 99,) will show that the presence of longitudinal *push* has a highly favourable effect on the retentiveness of that metal, and on the maximum of residual magnetisation. Pull, on the other hand, is extremely unfavourable to the retentiveness of nickel. A comparison of the results set forth in Figs. 98 and 99 shows that the value of $\frac{d\,\mathsf{I}_r}{d\,\mathsf{I}}$, which is at no stage great in unstressed nickel, rises to a maximum approaching unity when the metal is tested under the influence of strong longitudinal push. And it is, at least, highly probable that the same thing occurs in the steep stage of the magnetising process in the tests under torsion figured in Figs. 120 and 121, § 141.

§ 179. **Amount of Retentiveness possible under the Molecular Theory.**—The full bearing of these experimental results on the molecular theory is not easily traced, and it would be scarcely profitable to speculate at present on the forms in which the groups of molecular magnets may conceivably be arranged. It is, however, important to notice that the theory leaves ample room for even the high retentiveness which iron is found to possess. To show that this is so we may consider what would be the saturation value of the residual magnetism if the structure consisted of lines like those of Fig. 145, with the centres of the molecules grouped in cubical order. It would be unreasonable to postulate any particular directional relation between the lines of centres and the direction in which the piece is to be magnetised. We shall suppose that the structure is an aggregate of tribes of molecules, with a cubical formation for each tribe, but with all possible variety in the direction of the lines of centres.† In the piece as a whole the directions of the lines of centre may be taken as uniformly distributed; in other words, they might be represented by all possible radii of a sphere, drawn so that the points in which they meet the spherical surface are equally spaced.

Suppose that a very strong magnetising force H is applied, so that saturation is produced, and that the force is removed. We have to consider how much residual magnetism will be found when the molecules have returned into lines in which they are stable, and which are as favourably directed for giving residual magnetism as the assumed structure of the substance will permit.

Let α be the angle at which any line of molecules is inclined to the direction of H, before the process of magnetisation begins. Since the distribution of direction is by assumption uniform, the number of molecules whose inclinations are less than α will be to the whole number in the proportion which that part of a spherical surface cut off by a cone of semi-angle α (with its vertex at the centre), bears to the whole spherical surface. In the same way the number of molecules whose inclinations lie between α_1 and α_2 will be proportional to the area of the belt of the sphere's surface, which is cut off between cones with α_1 and α_2 for semi-angle. Let the whole number of molecular magnets per unit of volume be n. Then the number whose inclinations lie between α_1 and α_2 will be

$$\frac{n}{2}\int_{\alpha_1}^{\alpha_2} \sin\alpha\, d\alpha.$$

Let θ be the inclination of a molecule after it has been displaced by the application and removal of H. If m is the moment of a single molecule, it contributes $m\cos\theta$ to the residual magnetism. The whole amount of residual magnetism contributed by those molecules whose original direction ranged from α_2 to α_1, will therefore be

$$\frac{mn}{2}\int_{\alpha_1}^{\alpha_2} \sin\alpha\cos\theta\, d\alpha.$$

And to find the whole residual magnetism we have to extend the limits of this integration to include all the initial directions from $\alpha = 0$ to $\alpha = 180$ deg.

We have next to consider the relation of θ, the inclination after H has been applied and removed, to the original inclination α. Our assumption as to the structure makes the permanent deflection of the molecule necessarily either 0, or 90 deg., or 180 deg.

(1) Molecules for which α is less than 45 deg. will suffer no permanent deflection. This is because the original lines are more favourably directed than lines at right angles to them. For these molecules $\theta = \alpha$.

(2) Molecules for which α is greater than 45 deg. and less than 135 deg. will be permanently turned through one right angle. For these molecules $\theta = \alpha - 90$ deg., and $\cos\theta = \sin\alpha$.

(3) Molecules for which α is greater than 135 deg. will be permanently turned through two right angles. For these $\theta = \alpha - 180$ deg.

The whole residual magnetism, therefore, consists of the sum of three terms, namely

$$\frac{mn}{2}\int_0^{\frac{\pi}{4}} \sin\alpha\cos\alpha\, d\alpha + \frac{mn}{2}\int_{\frac{\pi}{4}}^{\frac{3\pi}{4}} \sin^2\alpha\, d\alpha + \int_{\frac{3\pi}{4}}^{\pi} \sin\alpha\cos(\alpha - 180°)\, d\alpha.$$

The first and third terms are of equal value. The integral of the first term is

$$\frac{mn}{2}\left[\frac{\cos 2\alpha}{4}\right]_0^{\frac{\pi}{4}} = \frac{mn}{2}\times\frac{1}{4}.$$

The integral of the second term is

$$\frac{mn}{2}\left[\frac{\alpha - \sin\alpha\cos\alpha}{2}\right]_{\frac{\pi}{4}}^{\frac{3\pi}{4}} = \frac{mn}{2}\left(\frac{\pi}{4} + \frac{1}{2}\right).$$

The whole residual magnetism is therefore

$$\frac{mn}{2}\left(2\times\frac{1}{4} + \frac{\pi}{4} + \frac{1}{2}\right) = \frac{mn}{2}\left(1 + \frac{\pi}{4}\right) = 0\,8927\; mn.$$

This is the residual magnetism of saturation, and is to be compared with the induced magnetism of saturation, which is mn.

Assigning to mn the value 1,700 this calculation shows that a continuous structure of the kind postulated, cubical in arrangement, is competent, on the molecular theory, to have nearly 1,500 units of residual magnetism, an amount considerably greater than experiments show even the most retentive iron to be capable of holding. It is clear, therefore, that intermolecular magnetic forces are abundantly sufficient to account for residual magnetism, and that the actual structure of soft iron, and still more that of hard iron, steel, nickel, and cobalt, is less favourable to retentiveness than is the simple structure we have been discussing here.

§ 180. **Hysteresis and the Dissipation of Energy.**—The molecular theory shows that hysteresis is to be expected whenever the magnetism of iron is caused to alter through anything more than a very narrow range. It occurs when the molecular movements are sufficiently great to involve the breaking up of old ties, and the formation of new ones, on the part of some, at least, of the molecules. In other words, the necessary and sufficient condition for hysteresis is that there must be an unstable phase in the movement of some of the molecules. The changes of magnetism will then lag behind the exciting cause of the change, whatever that may be.

When the change is restricted within very narrow limits there is no hysteresis, for the molecular movements are then of the quasi-elastic type, occurring without rupture of the molecular ties. A very weak magnetic force, applied and removed (whether acting alone or superposed on a steady force), or a very small change of mechanical strain, will, if it be many times repeated, cause small changes of magnetism which do not involve hysteresis, because the molecular magnets are then suffering deflections with respect to which they are stable. But when

* All rights are reserved.

† The structure may be continuous; in other words, the transition from one direction in the line of centres to another may occur through very slight distortion of the cubical formation.

Digitized by Google

the action is extended by using larger magnetic forces or larger variations of mechanical strain, so that the molecules are deflected far enough to become unstable, hysteresis comes into play. We find it, in fact, manifesting itself in all save the narrowest cycles of magnetising force, of longitudinal pull, of torsional strain, and so on.

The dissipation of energy which has been shown to accompany hysteresis in cyclic variations of magnetism is an obvious outcome of the mechanically irreversible character of these unstable molecular movements. When the molecule's equilibrium is upset it tumbles over, and acquires kinetic energy in falling towards a new position of equilibrium. It oscillates about that, and communicates oscillations to its neighbours, until the motion is damped out by setting up eddy currents in the surrounding conducting mass, and the energy of these currents is in turn converted into heat. The damping effect of eddy currents in the surrounding medium may even be so great that there is no continued oscillation; the molecule may be as it were let down gently like a body connected to a dash-pot. In any case, the ultimate effect is that a magnetic cycle generates heat in the substance of the metal. We have seen already that when the cycle is produced by reversing the magnetising force H, this heat is the equivalent of the quantity $\int I\,dH$, and numerical values of it have been given in earlier chapters.

But what will be the heating effect when a magnetic cycle is performed, not by varying the amount of H but by turning the iron round in a constant magnetic field? The question is of much practical interest, since that is the way that the magnetism is reversed in the core of a dynamo armature of the Gramme ring or the drum type. Experiments to answer it are as yet wanting. It appears to have been often taken for granted that the same amount of work is spent in the two cases, but there is no apparent basis for the assumption. In a series of experiments on dynamo armatures by Mr. Mordey*, when a successful attempt was made to separate the loss of power due to magnetic hysteresis for that due to Foucault currents, the loss due to hysteresis was found to be rather less than the amount of energy which would be used up in reversing the magnetism by varying the field without rotation.

The molecular theory makes it probable that the work spent in reversing magnetism will be less when the reversal is accomplished by rotation in a constant field, than when it is accomplished by reducing the magnetic force to zero, and restoring it with sign reversed. A difference of this kind is especially to be looked for when the field is strong. In fields of no more than moderate strength, the turning round of the iron will involve breaking of molecular ties, with those unstable movements to which the dissipation of energy is due. But when the field is very strong so that the iron is nearly saturated, every molecule points steadily in the direction of the magnetising force all the while, and there is no opportunity for irreversible movements. This deduction from the molecular theory seems to have been first pointed out by Mr. Swinburne. The matter is well worth experimental examination.

§ 181. Dissipation of Energy through Hysteresis in the Cores of Transformers.—This is another practical case of magnetic reversals on which the molecular theory seems to have an important bearing. In a transformer, the presence of the secondary coil has of course no influence on the amount of energy dissipated in reversals of the core's magnetism, so long as the secondary circuit is open. But when the secondary circuit is closed, especially through a low resistance, it assists in damping the unstable swings of the molecules, and a part of the energy goes into it which would otherwise be wasted in heating the iron. It appears probable that the damping action of the secondary coil will tend to establish a *régime* in which the molecular magnets swing with some approach to unison, crowds of them keeping step and so to a great extent giving up energy to the secondary circuit, instead of wasting it in local eddies within the iron. This consideration leads us to expect that the waste through hysteresis in a transformer will be less when the load is heavy than when it is light, possibly much less. Experiments on the efficiency of transformers under various amounts of load have in fact led Mr. Mordey and Prof. Ayrton to conclude that this is the case. This subject, like the one referred to in the last paragraph, calls for a fuller examination than it has yet received.

§ 182. Reduction of Hysteresis by Vibration, &c., and other Disturbances.—We have seen (§§ 84, 85, 129) that mechanical vibration lessens the differences of magnetic conditions that are brought about by hysteresis. It makes the metal readier to respond to any influence which tends to alter the magnetism. In a soft iron wire, where its effects are most conspicuous, it practically abolishes the distinction between what we have called the first and second stage of the magnetising process, it destroys the retentiveness almost entirely, and it makes the magnetic effects of strain nearly reversible, so that the "on" and "off" curves for a cycle of loading come to be not far from coincident.

The molecular theory makes all this intelligible. Vibration, producing small periodical displacements of the molecular centres, sets the molecular magnets oscillating. The displacement of the centres, and still more, perhaps, the oscillation to which that gives rise, allows the molecules intervals of comparative freedom, and probably even goes so far as to vary the combinations in which they are grouped. Then if there is an external field the molecules yield readily to it in their freer intervals, and even when there is no external field a kind of shuffling goes on, one effect of which is to reduce residual magnetism. It may be, that in the removal of residual magnetism vibration acts in the first place locally; a cluster of molecules shaken up so that the residual magnetism of the cluster is less than that of surrounding portions will act to some extent like a cavity in the metal, producing a demagnetising field round about it. In the same way the demagnetisation of a long iron rod under vibration no doubt begins at and about the ends, where there is a self-demagnetising field, and then extends itself towards the central portion.

Any kind of disturbance that will give the molecular magnets intervals of freedom, or of diminished constraint, will tend to do away with hysteresis. Interesting examples of this will be found in a Paper by G. G. Gerosa and G. Finzi* in which experiments are described showing how cycles of reversal of magnetism become modified when a continuous, or periodically interrupted, or alternating current is made to traverse the piece under test, while slow reversal of the field goes on. The experiments dealt with iron, steel, and nickel wire in their annealed and hard state. A continuous current, traversing the wire while its longitudinal magnetism was being changed by applying and varying a longitudinal magnetic force by means of a surrounding solenoid, was found, as might be expected, to reduce the susceptibility of iron: the circular magnetisation maintained by the current in the wire left the molecules less than their usual freedom to obey the longitudinal force. When the longitudinal current, instead of being continuous, was rapidly interrupted without changing its sign, a molecular oscillation was set up which made the iron more than usually susceptible to weak longitudinal force; but when the field was strengthened the iron was still found to be less susceptible than when no current was passing through it. The mere make and break of the longitudinal current would, in fact, cause no more than a small variation of circular magnetisation, and would consequently do little to agitate the molecules. But when a rapidly alternating current of moderate strength traversed the wire, its susceptibility was notably increased; the magnetisation curve in that case lies above the normal curve everywhere except in the region of strongest magnetisation. The violent agitation brought about by rapid reversals of circular magnetism destroyed nearly all trace of hysteresis, and obliterated the usual distinctions between sucessive stages in the magnetising process. An illustration is given in Table XXXII. and Fig. 152, which relate to an experiment in which a piece of soft iron wire, 0·84mm. in diameter, was magnetised, first under the usual conditions (without any longitudinal current), and then when traversed by a rapidly alternating current of three amperes.

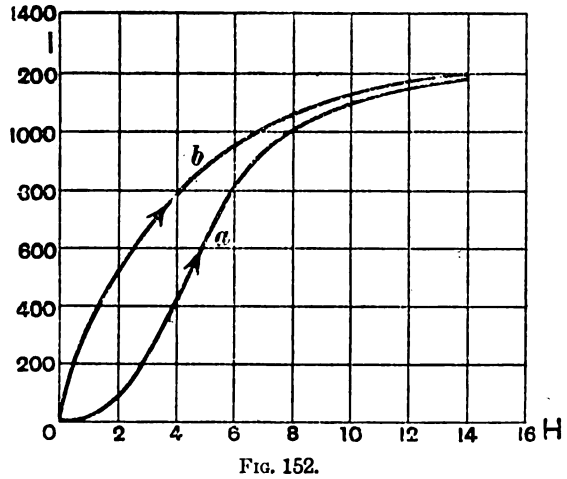

Fig. 152.

In Fig. 152 the curve *a* is the normal curve, and *b* is the curve obtained when the alternating current was in action. The table shows how little residual magnetism is left in the second case.

Fig. 153 exhibits in the same way the influence of the alternating longitudinal current on a cycle in which the longitudinal magnetism of another iron wire was reversed. The normal figure *a a* collapses, as an effect of the molecular shaking, into *b b*, which is very nearly a single curve.

Effects of the same kind were observed in steel and in hard iron, but the suppression of hysteresis was less complete.

The single curve by which the relation of I to H may be represented when hysteresis is done away with by sufficiently violent agitation of the molecules, may be expressed, with fair accuracy, by the formula

$$I = \frac{\alpha H}{1 + \beta H},$$

in which α and β are constants for a given specimen. This formula, which was proposed by Fröhlich as a general means of expressing the relation of magnetism to field, is, of course, of

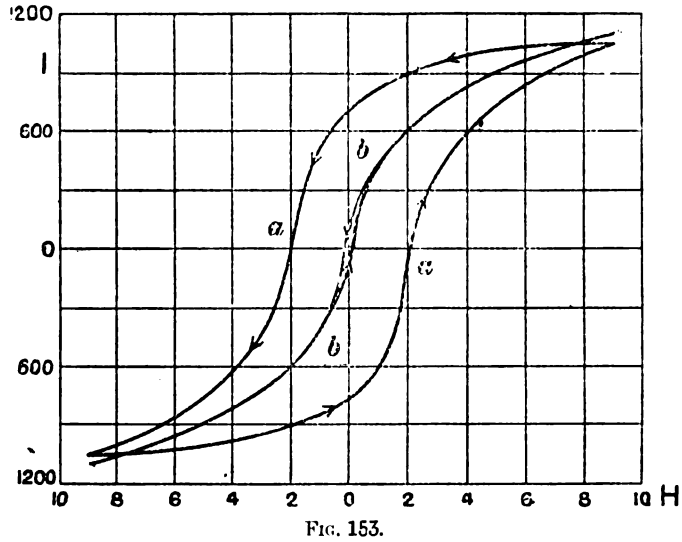

Fig. 153.

no service so long as hysteresis is operative, since I then depends not only on the existing value of H but on previous values: it will not even serve to express the curve of initial magnetisation in a virgin piece. But when hysteresis is eliminated, as in these experiments, it may be made to fit the curve reasonably well. Values of the constants α and β will be found in the Paper from which these results are quoted.

(To be continued.)

THE PHOTOGRAPHIC RECORD OF ALTERNATE-CURRENT CURVES.

In a recent number of *La Lumière Electrique* M. Blondel describes some apparatus designed for the determination of the periodic curves representing alternate currents. It consists of an extension of the apparatus originally devised by Joubert, who, it will be remembered, used a contact maker, revolving with the alternate-current dynamo, to make connection with a brush once during a revolution, and thus to charge an electrometer to the voltage generated in the dynamo at the corresponding part of the period. By adjusting the position of the brush the voltage could be measured at all

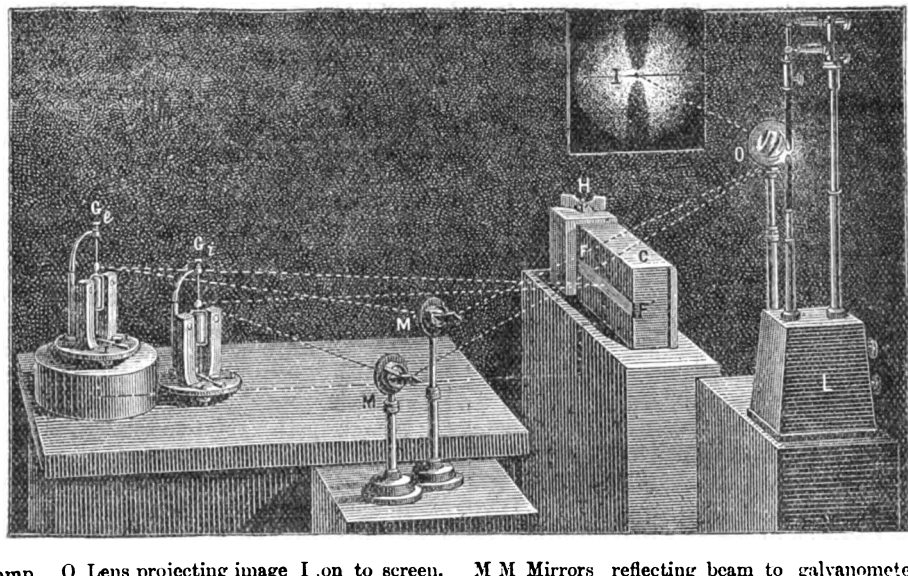

Fig. 1.—L Arc Lamp. O Lens projecting image I on to screen. F F′ Photographic registering slip. M M Mirrors reflecting beam to galvanometer mirrors G_e G_i. H Clockwork for moving the slip.

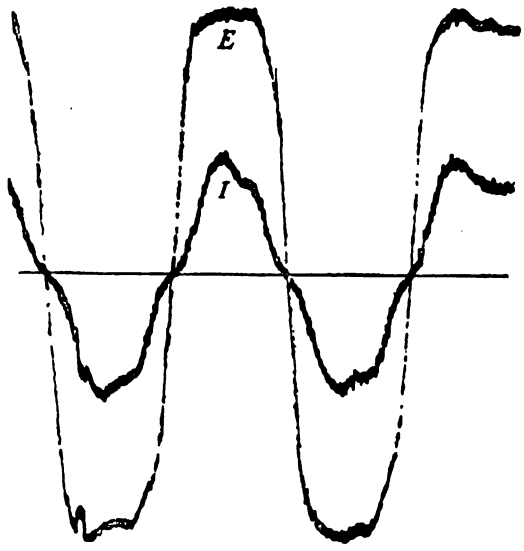
Digitized by Google

parts of the period and the complete curve obtained. After an exhaustive comparison of the effects obtained with galvanometers and electrometers, M. Blondel finds the former preferable, and uses a d'Arsonval galvanometer in series with a condenser instead of the static instrument. It is necessary in this case to use two brushes, one for charging the condenser and the second for discharge through the galvanometer. The two brushes are fixed to an arm moveable about the same axis as the revolving contact maker, and this arm is turned at a regular rate by clockwork. The scale on which the galvanometer spot is focussed consists of sensitised paper, and is moved vertically by clockwork. The photographic record obtained is, therefore, an accurate trace of the alternate-current curve. The curves obtained are potential curves, or current curves, according as the condenser is connected with two points of the circuit whose voltage is required, or to the terminals of a standard resistance in series with the main current. In all the cases described by M. Blondel the apparatus was duplicated. Two galvanometers were used, one for current and the other for potential. The spots of light were, however, focussed on the same scale with a common zero, the light being obtained from a powerful arc lamp, and reflected on to the instruments by mirrors suitably placed. The double curve thus obtained is such that corresponding ordinates represent the simultaneous values of the current and electromotive force. The figure



given shows the curves obtained with an arc lamp worked with the alternate currents produced by a Méritens magneto machine. The curve I is the current curve, while curve E represents the electromotive force.

When the apparatus is once set up it is possible in a comparatively short time to make a complete study of an alternator under all circumstances of use. A complete alternate current curve can be obtained in two or three minutes.

THEORY OF THE WIMSHURST MACHINE.*

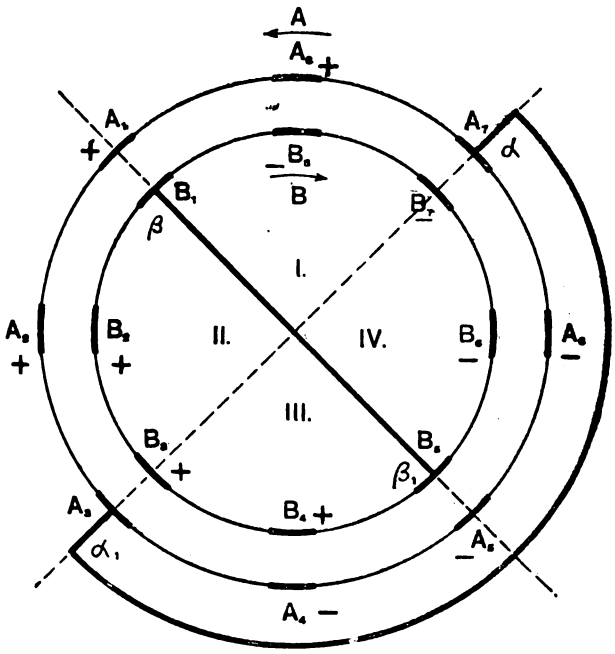
BY M. G. PELLISSIER.

The Wimshurst machine was invented about 1883, and its use has spread rapidly on account of its possessing the valuable properties of quick self-excitation, certainty of action in all weathers, and entire absence of reversal. Its theory is, however, very little understood, and M. Gariel, in his "Traité d'Électricité" has gone so far as to say that it is not possible to give it in a satisfactory manner.

It can be ascertained by experiment that a Wimshurst machine works perfectly when the combs and discharging rod are drawn back, and the action of the combs can, therefore, be neglected in the theory of the electrical action. If the distribution on the plates of the machine when it is in motion be investigated, it will be found to be as indicated by the signs in the diagram. In order to prove this Mr. Wimshurst has constructed special apparatus.

One of these instruments, the "sparking machine," is an ordinary one simplified, and consists of two glass plates carrying a large number of tin sectors very close together; these are put in motion with the fingers on a common axle held in the hand; each plate is furnished with a conductor placed along a diameter. As soon as the discs revolve, the sectors become surrounded with halos, sparks fly from point to point, and, when viewed in the dark, a very fine effect is presented. The other instrument only differs from an ordinary machine in having its plates made of an elastic material; when in motion they are seen to attract one another in quadrants I. and III., and to repel in II. and IV.

In the following Paper we have sought first to explain how the distribution shown in the diagram can be set up, and then how it is that the charges rapidly increase. In Fig. 1 the front plate is represented by the inner circle; B_1 B_2 are the sectors, of which we will assume there are eight; $\beta\beta$, the diametric conductor. The outer circle represents the back plate, A_1 A_2 its



sectors, and $\alpha\alpha$ its diametric conductor. The two wheels turn in opposite directions with the same velocity.

Let us consider one of the sectors, A_1, of the back disc at the instant that it is opposite the diametric conductor, $\beta\beta$, of the other plate; and we will assume that a sector, B_1, of the disc in front is at the same instant in contact with the brush β.

Let us suppose, without inquiring the reason, that the sector A_1 has a weak positive charge, it will induce on B_1 a negative charge, and then proceed itself towards α_1. When it arrives at this point, that is to say, after revolving through 90 deg., B_1 will, on account of the opposite directions of rotation of the two plates, have arrived opposite the brush α, which will be in contact with the sector A_5, while B_5 will be opposite A_1 at α. The charge carried by B_1 will induce on A_5 a positive charge, while A_1, which is positive, will be discharged to earth, since $\alpha\,\alpha_1$ is not insulated.

After a further rotation through 90deg. A_5 carrying a positive charge, will take the place of A_1, while B_1 and B_5 will change places. The series of actions just explained will be gone through again, and, since the induced charges are less than the original, the machine would soon cease to work.*

* From *Journal de Physique.*

* This, in fact, is what happens when combs are placed opposite A_2 B_2, and A_6 B_6 and are put to earth. If the theory of the machine under these conditions be examined, it will be seen that the second series of phenomena about to be described do not take place; the charges then diminish in geometrical progression, while the operations increase in arithmetical. It is this which points to the office of the combs in the electrical reactions.

Digitized by Google

But A_1 does not act only on the sectors of the second plate, but also on the neighbouring sectors A_2 A_3; when they come in contact with the brush α_1 the positive charge flows to earth and they leave the diametric conductor with a negative charge which they carry towards the brush β_1. This brush acts by induction on the sectors of the second plate, which acquire a positive charge and turn from the brush β_1 in a clockwise direction.

Thus it is sufficient for the sector A_1 to have at the start a slight positive charge in order to bring about the distribution shown in the diagram. All the sectors of the back plate situated on the left between the brushes α and α_1 are positively electrified; the opposite sectors on the same plate are negative, while on the front plate all the sectors at the top between β and β_1 are negatively electrified and the opposite sectors at the bottom are positive. In the top quadrant I. the charges are of opposite sign and attract one another; the same holds good for III., while in II. and IV. the charges are of the same sign and repel one another; and if combs be placed at these points, the one on the right will collect negative electricity, and that on the left, positive.

It remains to examine how these charges go on increasing. To do this, let us take the machine in any position whatever, and consider the electrical actions that are taking place on any sector, say B_1, in contact with a brush. This sector is under the influence of (i.) the negative sectors, B_8 B_7 B_6; (ii.) the positive sectors, B_2 B_3 B_4; (iii.), the positive sectors A_8 A_1 A_2 of the back disc. Since the two first sets are symmetrically disposed, they neutralise one another, and the action of the three sectors A_8 A_1 A_2 alone remains, each of these tends to give it a charge nearly equal to its own in quantity, but opposite in sign. The sum of these actions will give to B_1 a charge that is approximately three times its original charge.

The same thing holds good for the other sectors A_8 B_5 B_7 and is renewed for each of the sectors successively. The charges will thus go on increasing in consequence of the mutual reactions up to a point that is determined by the leakage. The action of the machine being independent of the combs, it will continue to work when the knobs of the discharger are separated beyond the sparking distance. This is the explanation of the valuable property that the Wimshurst machine possesses of never failing nor reversing, as is often the case with Holtz and Voss machines.

It is necessary to add to the actions just considered the effects produced on the glass, which are far from being negligible; indeed, the Wimshurst machine can be made of two plates of polished glass, and with combs instead of brushes at the extremities of the diametric conductor. The initial charge has to be given by means of an external source, placed, for example, opposite A_1.*

This form of Wimshurst machine recalls a Holtz of the second kind; the German *savant* had, in fact, made, in 1869, a model of this apparatus, with two diametric conductors in the form of a cross, one before each plate;† he even added‡ that this machine could be made self-exciting by placing metallic sectors on the plates and substituting brushes for combs on the diametric conductors. It appears that Mr. Wimshurst was unaware of Holtz's work when he invented his machine.

The chief part played by the sectors seems to be to facilitate the self-excitation and to diminish the effect of atmospheric moisture. The greater the number of sectors, the more rapid is the excitation; thus with eight sectors, or any less number, the machine has to be excited from an external source; with 16 or 18, it rapidly excites itself under almost all atmospheric conditions; while with 40 the action is so energetic that it is very difficult to prevent the machine exciting itself even under very unfavourable conditions as to moisture. At the end of a half turn of the handle, Wimshurst machines are completely excited.

The one point that remains obscure in the theory of influence machines is the origin of the original charge. It has been ascribed to (i.) a residual charge on the plates; (ii.) electrification of the plates by friction with the air; (iii.) electrification of the metallic sectors by the natural electricity of the different layers of air, which are at unequal potentials; (iv.) electrification by contact.

Without denying the existence of these various causes the last appears the most probable, more especially since the self-excitation is only present in machines furnished with metallic sectors and contact brushes, *e.g.*, Bennet doublers, Töpler, Voss, Thomson and Wimshurst machines. It would be interesting to have exact experiments on this subject.

* In the ordinary machine, when the brushes do not touch the sectors, the machine can be made to work by starting it with a charge from an electrified body.

"Permanent Fortifications for English Engineers." By Major J. F. Lewis, R.E. (Chatham: W. and J. Mackay and Co,)

The C.-G.-S. System.—In a contribution to *Nature*, Prof. Perry writes:—In new applications of physics, in electrical engineering, for example, the use of the C.-G.-S. system is not only easy; it requires a large amount of ingenuity in any engineer to calculate in any other than in C.-G.-S. units, unless, indeed, he ignores all the experimental determinations already made for him and tabulated in the C.-G.-S. system. And yet such ingenuity has already been exercised, and laborious investigations have been carried out by some electrical engineers, with the result that certain parts of electrical engineering are getting to be even more unscientific in the units employed than any part of mechanical engineering. In the subject of heat, we can now ignore the steam-engine constructor; we can say to him, "Go on using your wretched pounds per square inch and your foot-pounds per minute, and we will go on using our dynes per square centimetre and our ergs per second because we are nearly independent of one another;" but we can make no such speech to the electrical engineer. We physicists have to say to him that we rely upon him to make new discoveries, to state to us new problems; and if he gives us information in vague units of his own, we cannot tabulate it for general use, and if he does not state to us his problem in the usual language, we are unable to understand him, and we can be of no mutual use to each other. But when he says to us that our language is cumbrous, that he has ideas to express for which we have no words, when he uses towards us, properly for once, that adjective "academic" which has been more misused than Shakespeare's word "occupy," the culprit and the judge change places. We can blame him if he invents unsystematic units, but not until we have given him the language and units that are correct. And in some particulars the electric engineer has the right to blame us. For example, any definition of unit electric current is so stupid that a multiplier or divisor of π or 4π enters quite unnecessarily into all electro-magnetic calculation. The engineer and experimenter care less than nothing for "magnetic susceptibility" or for "intensity of magnetisation," or for "free magnetism"; these are, to him, mementos of the time of twelve years ago, when the inventor made bricks in Egypt, and the very cleverest mathematical electricians were only distinguished from other inventors by the greater magnitude of their blunders. Dr. Hopkinson and Mr. Kapp and Mr. Bosanquet have given us simple ways of dealing with practical problems, and some of these are now known to every apprentice of an electric engineering factory; but we know of no mathematical treatise in which they are recognized.

Advertisement Rates, &c., forwarded on application as above.

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday. Renewals of expiring advertisement orders and alterations to standing advertisements should be in Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday.*

SMALL PREPAID ADVERTISEMENTS *accepted up to 4 p.m. Thursday.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, 1891, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with well-written Biographical Notices of leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1891 should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Prospectuses free.

ELECTRICAL BOOKS AND PUBLICATIONS.

All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

"THE ELECTRICIAN" *Series at present consists of—*

RAILWAY TELEGRAPHY.

Within a few hours of the recent railway collision near Burgos the Spanish Government proceeded to consider what steps should be taken to prevent the recurrence of such a catastrophe; and, after ordering an enquiry and resolving on "several drastic amendments in the railway regulations, they at once came to the conclusion," says a REUTER'S telegram, "that certain modifications were absolutely necessary. For example, the telegraphic instruments generally employed on the Spanish railways are those of the Breguet system, which admits of all sorts of misunderstandings arising, there being no printed tape or other record of the message transmitted." A meeting of the Cabinet of the Spanish Government irresistably calls to mind a picture of a council of grave VELASQUEZ grandees, with ruffs and swords and buckled shoes, and the idea of their consideration of the relative merits of the Breguet A, B, C, instrument and the Morse recorder for use in a railway signal cabin strikes one as rather incongruous. A later telegram announces that a Royal Decree was published on the 26th ult., in the *Official Gazette*, directing all railway companies to substitute the Morse apparatus for the instrument now in use on the railway telegraphs.

It is easy to imagine that the Spanish Government, having heard of the ingenious improvements which have been introduced in telegraphy, whereby tapes may be printed and records of the messages may be made, should immediately conclude that some such recording system would be highly desirable; and no doubt these views would be shared to-day by many of the English public who live among, and who hear a good deal about mechanical and electrical doings. As a matter of fact, a Morse recorder is not only practically unknown in our signal cabins, but where it has been employed in our post-offices, it is rapidly giving place to the ordinary sounder. It must be remembered, moreover, that telegraphy owes its introduction to the patronage of railways; and while railway telegraphy has become practically a separate and highly important branch of this industry, it is by no means conservatively inclined as regards introduction of new improvements.

Digitized by Google

Telephones are extensively used to supplement the signalling instruments; and the ingenious phonopore, which has for so long struggled to gain a footing, is now at work, not on the Post-Office or on private telegraph lines, but upon the Midland and other railways, where this latest development is highly appreciated. In the early days of railways trains were signalled by means of needle instruments; but these have given place, as far as the routine work is concerned, to bell, annunciator, and other signals, including the automatic locking devices which in so many cases make it almost impossible for a careless signalman to make a serious mistake. It has long been known that recording apparatus will not prevent misreadings, and the possibility of referring to a tape, after an accident, offers but little consolation to sufferers, and no great satisfaction to the officials. A recording instrument, if not an encouragement to inattention, is, at all events, not conducive to alertness. The signals used in railway work are quite unmistakable, while the recording system, when fully developed into the type-printing instrument, occasionally relapses into a language which appears to be a dialect of Welsh.

It has been suggested more than once, that every signal, whether transmitted or received, and every lever that is pulled over or released, should mechanically record itself on a moving band of paper, on which a clock would print the hours and minutes. Such an apparatus could be easily designed by any mechanician; but experienced railway men ask, is this to supersede or to supplement the entry of such events in the usual manner? They admit that an automatic record of this kind would assist in tracing negligence to its source, but they place a high value on the definite attention to the signals which is demanded by the very fact that they must be entered up by hand, while an entirely new danger is introduced by the well-known liability of the inking arrangement to fail. We hope therefore that no false trust will be placed in the use of Morse recorders, and that an enquiry be made into the action of the Spanish officials who permitted the signals to be placed under the charge of a young man of 18, an apprentice telegraphist, who received no salary, and who was employed in miscellaneous services at the Burgos railway station.

ALTERNATING CURRENT ELECTRIC SUPPLY STATIONS.*

BY DR. J. A. FLEMING, M.A.

(*Continued from page 584.*)

§ 2. **Condensation.**—It has been shown that the application of condensers to central station engines enables much higher generating efficiency to be obtained at low loads, that is to say, that condensing plant, although it increases the economy when the steam dynamos are running fully loaded, has greater effect in reducing the loss of efficiency when they are only partly loaded. Mr. Crompton found this to be very noticeable at the Gothenburg Central Station, where there are dynamos rope driven by 200 H.P. vertical triple-expansion condenser engines. During the first year water for condensing purposes was not available, and the engines had to be run at high pressure, exhausting into the atmosphere. Although the consumption of coal was not found to be excessive at the time of highest load, yet such a saving was effected at the time of low loads, when the condensing plant was put into action, that the total fuel consumption for the year was reduced by 60 per cent. This fact has also been brought out by some important experiments made by Mr. Willans, in which he illustrates very forcibly the truth of the above statements.

Mr. Willans has made special experiments with one of his own engines, to test the effect of condensation on the steam consumption of the engine at various loads. These experiments are charted in the annexed diagram, being reduced for simplicity to the equivalents for a 100 H.P. engine. The water per hour used by the engine is represented by the vertical ordinates in Fig. 3, and the horizontal distances are the indicated horse-powers of the engine. The diagram of the water used per indicated horse-power is a straight line. The line showing the water used when the engine works condensing lies below, and parallel with the line representing the same when the engine is used non-condensing. This diagram shows that the total water used by the engine is proportional to the indicated horse-power *plus* a constant quantity, and that this constant quantity, which is the water used per hour when the engine is running unloaded, is greater for non-condensing than for condensing working. Hence it is clear that condensing increases the efficiency of the engine—that is, decreases the water used per hour relatively more at low loads than at full load. Broadly speaking, if an economy of 18 to 20 per cent. of the feed water could be effected at full load, 40 per cent., or more, might be saved at low loads. These experiments indicate the great value of condensation at low loads, as well as the immense waste incurred in water, and, therefore, in coal by working engines only partly loaded.

In the design of large stations this question of condensing ought, therefore, always to be held in view; and for that reason it is important to locate the station, if possible, in a position in which water for condensation can be procured without pumping the water a considerable distance. For surface condensers the

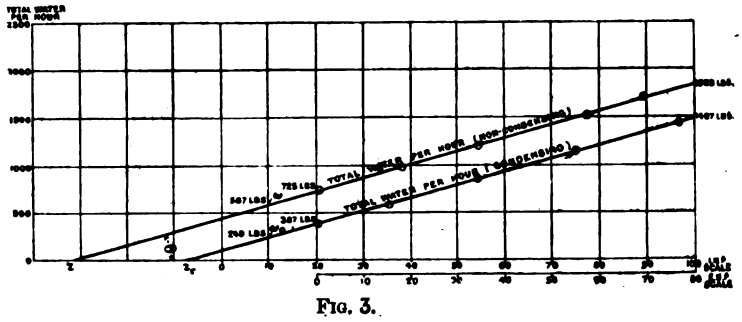

FIG. 3.

circulating water required will be about twenty times the weight of steam to be condensed, or about at the rate of forty to fifty gallons per hour per indicated horse-power, and hence, for large powers the amount of circulating water required is very considerable. In laying down pipes for the circulating water, or better still, in excavating conduits, allowance must always be made for the full extension ultimately required. In some town stations artesian wells have with advantage been sunk for this purpose; but in any case it is necessary to bear in mind the condensers must be placed in close contiguity to the engines from which they take steam, or else a considerable reduction in the vacuum in the cylinders of the engines will be found. Even if water sufficient for surface or jet condensation cannot be obtained, it is yet worth while, as Mr. Crompton has pointed out, in many cases, to put down air-condensing plant, even if such plant can only be put in of sufficient size to condense the steam at light loads, allowing the exhaust steam at the heavy loads to escape into the atmosphere. Such partial condensation would, in the opinion of many engineers, result in a considerable reduction of the whole coal bill for the year.*

§ 3. **Utilisation of Water Power.**—In many cases water power is available for the purposes of electrical generation, and in these cases the alternating current system presents great advantages in permitting the transmission of considerable quantities of electric energy at high pressures over great distances through comparatively small conductors. Considerable improvements have of late years been effected in the means by which such water power can be utilised. Amongst these may be mentioned the Pelton water-wheel, largely used in California and in other places to utilise high falls of water.

In this water motor a wheel is provided on its periphery with a series of peculiarly curved buckets (*see* Fig. 4), and jets of water are thrown into these buckets, setting the wheel in motion. The form of bucket is designed to cause the impinging water to leave the wheel with as little velocity as possible, and hence to give up nearly all its kinetic energy to the wheel. In the practical use of these wheels, water from some source is led to the wheel by hydraulic piping, often from great heights and distances. The best useful effect is found to be obtained when the bucket speed is half the velocity of the water issuing from the jet. Tests have shown that the Pelton wheel has a mechanical efficiency of 87 to 90 per cent. Hence, whenever a natural fall can be obtained, by means of which water can be delivered from one level to a much lower one, this motor enables such energy to be rendered available for conversion into electric energy. A large number of hydraulic electric stations are at work in California, using in some cases falls of water of upwards of 1,600ft. in height, the energy of which is utilised by Pelton wheels. At Aspen, in Colorado, a large electric light and power station is at work, in which some 1,400 H.P. is so utilised by Pelton wheels; amongst the other plant, Westinghouse alternators being employed for incandescent lighting. When hydraulic governors are added to control the wheel-speed, the greatest possible uniformity of driving can be attained, and the Pelton wheel shows itself to be a motor peculiarly adapted for electric lighting purposes.

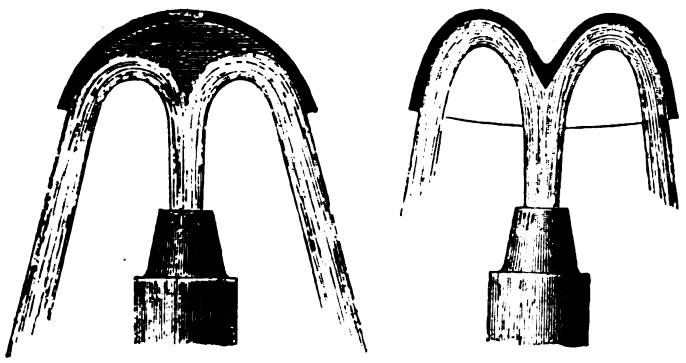

FIG. 4.

§ 4. Water Motor Installation at Tivoli, near Rome.—One of the finest examples in Europe of water-power utilisation in connection with alternating currents is the new electric station which is being established at Tivoli, near Rome. As is well known, there is at the town of Tivoli a large and valuable supply of water power, and recently a portion of this has been utilised in the establishment of a large alternating current station for 2,000 H.P., intended to supply a portion of the city of Rome with electric light. A part of the Falls of Tivoli is conducted along an aqueduct, at the extremity of which the water falls into a large iron fall-tube, 1·6 of a metre in diameter. This fall-tube is 48 metres in vertical height, and has a capacity for delivering three cubic metres of water per second. At the lower level of the fall-tube the electric station has been erected on the side of the hill, and the fall-tube, terminating near it, branches into three secondary supply tubes, which convey the water into the building. Each of these branches feeds three Pelton water-wheels, two of which are about 300 or 400 H.P. and one smaller. The six larger Pelton wheels are coupled direct to 350 H.P. Ganz alternators of the form described in Chapter II., § 1. The supply of water to each wheel is governed by hydraulic inlet valves which are worked by a sensitive hydraulic relay, the relay being set in operation by a centrifugal governor. By this means the speed is automatically kept constant, independent of the working of the machine. In addition to the six 350 H.P. alternators, there are three other direct current machines used as exciters, which are also driven direct from the smaller Pelton wheels. Each alternator is designed to furnish current at 5,000 volts pressure and 45 amperes. The machines will be driven at a speed of 170 revolutions per minute. Other arrangements for regulating the pressure are arranged as described in Chapter I. The alternating current so generated is to be transmitted to Rome, a distance of 25 kilometres, by means of four stranded copper cables, each being 100 square millimetres in cross section, and capable of carrying 120 amperes. These are to be carried overhead on iron poles placed 35 metres apart, and about 30 feet high, insulated by means of double-shed oil insulators, specially designed for this work by Prof. Mengarini. The lower part of the insulator (*see* Fig. 5) can be lowered to remove or renew the oil, and when raised into place it keeps the flanges of the upper part wet with oil, and yet renders it impossible or difficult for insects to get round into the interior. A drop of

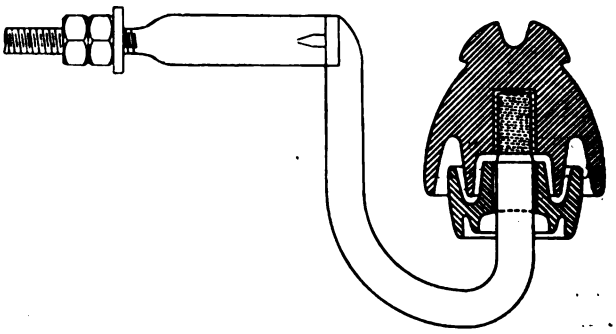

FIG. 5.

1,000 volts, or 20 per cent., is to be allowed in these lines. At the far end of these trunk mains the pressure will be reduced by step-down transformers to 2,000 volts, and distributed underground by Siemens cables to secondary centres, at which it will be again reduced to 100 volts. The six machines are all capable of being worked together in parallel, the maximum number of five being used together, and one machine being always in reserve. Two of the exciters are sufficient to supply exciting current to the whole of the dynamos, the third being a reserve.

(To be continued.)

SAYERS' PATENT PLATING DYNAMO.

We illustrate below a new dynamo, which is being manufactured and introduced under sole licence from the patentee by Messrs. T. L. Hemming and Co., of Birmingham, which has very substantial advantages for electro-plating, or any purpose requiring low pressures. Hitherto, dynamo builders have had to

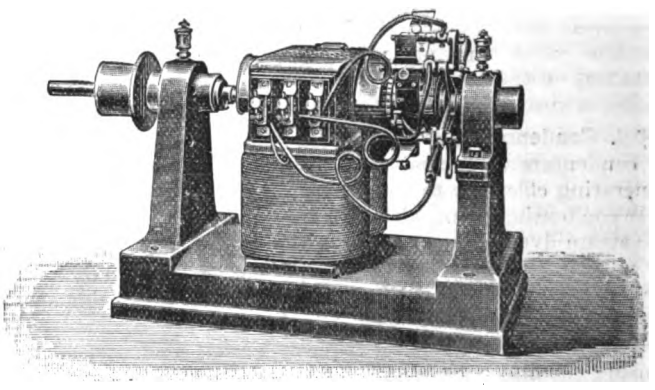

FIG. 1.—Sayers Patent Plating Dynamo.

reduce the number of convolutions on the armature, and consequently the sections of the commutator to the lowest practicable number; to reduce the strength of the exciting field, and finally to reduce the speed of the machine, until something approaching the correct voltage is reached. Generally (unless the machine is a very small one) a considerable amount of resistance must be included in the circuit in order to bring the pressure on the vat terminals down to the required value. Now, reducing the number of sections on the armature and

Digitized by Google

working with a weak field are both prejudicial to the working of a machine as regards sparking, and the low-speed means a small output and increased first cost. The result is that up to the present machines for electro-plating have been far behind those for lighting purposes as regards sparking, and much larger than would have been required had their full capacity for generating electrical energy been available for useful work.

The novel features about the "Universal" Dynamo consist in making a number of deep channels or slots in the polar surfaces parallel to the axis of the armature and applying light subsidiary or intermediate brushes to corresponding points on the commutator of the machine; between any two of which half the total current which the armature is constructed to carry can be drawn off, at a voltage determined by the winding of the armature and the friction of the total field which is cut by the coils between the two brushes. The effect of the channels in the polar surfaces is, of course, to produce corresponding weak places in the magnetic field, with the result that the coils may be short-circuited when passing through these positions by the subsidiary brushes without any harmful effect; in fact, under certain conditions, i.e., when the current generated in the short-circuited coil by the weakened field is equal to the current flowing in the next section to which the coil is passing the sparking will be *absolutely nil*. The invention can be applied to either ring or drum armature machines, but the drum armature is the most suitable.

With a drum armature machine, no matter whether current is drawn from one side only of the commutator or from both sides at irregular positions, the distortion of the field is the same on both sides of the armature as the wires of any coil are on both sides; but with a ring armature the effect of current in one part of the armature different in value to the remainder will, of course, cause local distortion and possible sparking.

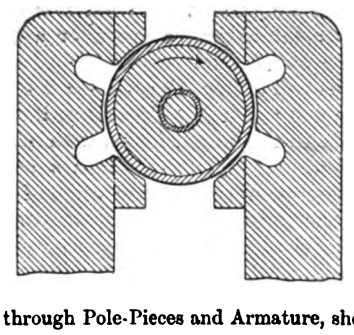

Fig. 2.—Section through Pole-Pieces and Armature, showing Air Gaps.

With a drum armature the channels on either pole-piece must be diametrically opposite, but with a ring armature the two polar surfaces may be divided into different numbers of portions so as to get different voltages on one side to those obtained on the other.

The additional brushes are not found objectionable in practice; they never have to carry more than half the current which the main brushes carry, and generally carry much less than half, so they can be made very light. With a drum armature or with a ring armature when the channels and brushes are alike on both sides, the subsidiary brushes may be connected together in pairs (the brushes, which are the same distance from one or other main brush, of course being connected together) not those diametrically opposite, except in the case of the central ones.

Under this patent Messrs. T. L. Hemming and Co. construct machines to give 10 volts at main brushes for plating with brass, say, 7·5 volts for nickel plating, and 5 and 2·5 volts for silver and copper depositing. Obviously 4 vats of 2·5 volts each can be employed if desired, the E.M.F. in either being practically unaffected by the current in the others, although the vats are connected in series. If the user desires he can connect up his vats upon the three-wire (or rather multiple) wire system; but this is not essential, as the distances are not usually great, so that separate leads can be brought to each brush from the vats. Thus in the "Universal" dynamo, while a good output can be obtained from the machine, a sufficient number of sections can be employed to secure absence of sparking.

NATIONAL ELECTRIC LIGHT ASSOCIATION.

A considerable part of the proceedings of the Convention of the National Electric Light Association of the United States is made up of speeches rather than Papers or other contributions. These speeches are not generally of a scientific, but rather of a congratulatory character, rhetoric being sought for rather than scientific accuracy. Mr. Erastus Wiman in the course of a speech said that he wished to impress on his friends in Canada the advantage that the electric system has in the transmission of power. He was in Boston on Friday, and stood in one station which had a potential of 20,000 H.P.—a power so vast as almost to be beyond human conception. Fancy, if they could, 20,000 horses under one cover, saddled and bridled and ready for a start. Fancy the forces that were latent in that potential under that roof; and yet away off in some distant avenue, by some delicate wire, it was necessary only to touch the button and the power did the rest. So it would be in Montreal.

The President, Mr. C. R. Huntley, followed the introductory orations with a practical address, in which he described a "zone system" of electrical distribution.

The idea embodied in this zone system could best be explained, perhaps, by taking a concrete, practical example, and for this purpose the present occasion made the City of Montreal an interesting one. Setting aside for the moment the possibility and even the probability of the transmission of electrical energy to the city from the power obtained at the Lachine Rapids, the President assumed a station erected at the water front of the harbour. It would, he believed, be granted that up to within a distance of one-third mile radius the three-wire low-tension direct-current system of distribution answers fully every requirement of simplicity and economy; and hence if, with the station as a centre, he drew a circle having a radius of one-third mile, he would have a zone supplied in the most economical manner for every class of light and power apparatus now familiar to them. Coming to the districts beyond the first zone, he was necessarily obliged to have recourse to higher potentials for the feeders, and the selection of the proper potential was a matter of simple calculation. He might, for the sake of this argument, call it 500 volts. Continuing on in this way, in steps of 500 volts, successive zones, half a mile across, might extend in the aggregate to several miles without reaching the limit of potentials which have been found to be perfectly feasible in practice. In the example no reference was made to the nature of the current employed or to the method of local distribution. Evidently they might readily resort to the alternating system, employing converters to reduce or raise the potential, or to the direct current reduced from high to low by motor dynamos. Either one is perfectly practicable. Perhaps some of their new school of electrical engineers would show them how to use the same circuits for both alternating and direct currents. He was convinced that the most economical way to distribute the current to the consumers at the point of delivery was by low-pressure conductors, in contradistinction to the plan now generally in vogue of giving each customer a converter of his own, or, in the direct system, a separate motor dynamo. In Buffalo they are now introducing gradually 200-light converters and replacing the smaller ones heretofore employed. Nor do they propose to stop there, but expect to instal converters of still higher capacity, distributing the current to a number of customers by low-pressure mains centreing at the large converters. As addressing himself to practical men, he need not refer to the fact that it costs practically no more labour, &c., to put up a 200-light converter than it does a 10-lighter, while the initial cost per light is less in the case of the larger converter.

With regard to the underground question, the President said that they had gratuitous advice, assistance and abuse to such an extent that less progress was made than in any other part of the work. They all want to put their wires under ground, where the number is so great as to make them unsightly or unwieldy, and not a few of them have been parties to experiments now written off to profit and loss. As soon as the time arrived when every house had its wiring as a matter of course, just as now it has piping for water and gas, it would be a comparatively easy matter to lay down comprehensive underground systems. But at the present time the customers for current

Digitized by Google

are scattered and not continuous. The man with enterprise enough to take electric light and power soon moves into a larger store. His successor does not want the service, but gropes along with kerosine or spoils his goods with gas. Cutting out disused underground services is an added risk and expense, and 10 lights could be installed on overhead circuits for $10 where with underground the cost would be $50. It follows that in any city—Buffalo for example—they would not make one underground connection where with overhead wires they would have made twenty. Now, are the public or are we the greatest losers? The public, he thought. It was as unreasonable in most instances to demand underground wires as it was to expect every railroad to make every crossing above or below grade. But for their overhead wires, America would not be to-day the great land that it is of electrical triumphs: and, while he hailed with delight every advance in the solution of the underground problem, he hoped long to gladden his eyes with the sight of a pole well set and a wire well strung.

Another stirring question of the hour was that of municipal ownership. He believed that the most conclusive answer they could make to the sophisticated arguments of an ill-disguised socialism presenting itself in this municipal ownership scheme, was to give the very best service possible at the lowest rates compatible with fair profit.

Second Day.

The first business on the second day (September 8th) was the reading of the Report of the Committee on "The Relation between Manufacturing Companies and Central Stations." This report emanated from the Committee on Relations between Parent and Sub-Companies, and merely stated that no matter had been brought to its attention. The matter led, however, to a discussion of considerable length. Mr. Weeks recapitulated the early history of the electric industry in America, and reminded the meeting of the extravagant statements of parent companies as to the performances of their patented machinery. "These companies (said Mr. Weeks) guaranteed to purchasers: First, high efficiency; second, patent protection; and, third, exclusive rights in their respective territories. They assured investors that the new light could be produced cheaper than gas, and, in order to compete with gas and increase the demand for the apparatus, they advised continual reductions in rates of service. Companies speedily organised in the larger cities, and capital smiled on electric light investments. It was soon found, however, that various so-called systems of electric lighting were extremely crowded, and the apparatus was so short-lived that investments must be increased to meet the demand for improvement and for renewals, for which the parent companies made little if any discounts. Still, so confident were the local companies in success during future years, and so blindly credulous in the good faith of manufacturers, that the additional capital flowed in, and the parent companies were enabled to enlarge their producing powers and to increase their dividends. In the course of time it began to appear that the second claim of the parent companies, in consideration of which local companies had paid such high prices, could not be maintained. Patent protection was not given. The pioneer enterprises saw their field invaded by apparatus employing the very devices for which they had paid so liberally upon the assurance that those devices were controlled by the grantors. As the parent companies found themselves with immense producing powers, and without sufficient demand to employ them, the very powerful ones began to purchase the business and factories of the weaker, presumably to clear the field of competitors, and the temptation to violate their contracts with pioneer local companies proved to be strong. But worse treachery followed. The most outspoken of the electric light has always been gas. The parent electric companies were bitter in their denunciation of the methods employed by the gas interests in their efforts to prevent the establishment of the new industry, and until their revenues from local companies began to fail, assisted the latter in the struggle in every way which did not seriously affect their pockets. At the present time the condition of affairs is changed. The gas interests are still opposed to the electric light. But as this has shown that it has come to stay, gas companies all over the world are preparing for a new effort. They will wage war with our weapons—with cheap apparatus furnished them by our parent companies. They will endeavour to demoralise the field of electric lighting so that legitimate business cannot stand the strain. Parent companies are selling to the gas interests—and they have the effrontery in their advertisements to boast of their success—apparatus that employs the very devices whose exclusive control had been guaranteed to the interests that the new purchasers are straining every nerve to kill. And this is being done at a most critical period, when depreciation is becoming known at its full value; when, owing to the general depression, market values of service are at their lowest, and when there is a strong tendency on the part of municipalities to demand of the electric industries expensive, doubtful changes, and to curtail their privileges and reduce their rights. The manufacturing companies are indirectly and directly promoting this tendency, and are inciting municipalities to purchase plants, thus depriving local companies of that profitable service which they themselves have created. To the one hundred thousand stockholders in the local companies of America is chiefly due the establishment of the new industry. They have produced the sinews of war, and by them the battle has been fought and won. From them parent companies have derived support which has made them what they are. For this veteran service and this timely support what return do parent companies make? Having possessed themselves of many millions of our hard-earned money, they are now violating their most sacred obligation and betraying us to the enemy."

Mr. Weeks then worked himself up to a very ardent denunciation of this policy, and introduced the various analogies, Agricola and the viper, Frankenstein, Achilles, Virgil, and other classical allusions. "Let us enter into a compact," he continued, "whereby we will pledge ourselves to purchase apparatus only of those companies who will treat us fairly, and in case we cannot get such fair treatment, in case we are met by a combination, a trust or a pool on the other side, let us pledge our united support to a new manufacturing enterprise, which will enter the field with this guaranteed business to rest upon; and, Mr. President, if as a last resource, if the worst comes to the worst, let us with our upward of one hundred millions of investment call into a common fund from one to five, ten, or even twenty per cent. of our investments, and standardise our apparatus, and do our own manufacturing."

After some remarks from Judge Armstrong and Mr. Wilmerding, Mr. Francisco, who holds very strong views about the principle of municipal lighting, said that he was strongly in favour of this movement, and hoped that the central-station men of America would take hold of this as a body and carry it through as a body, united and strong; and there was no question in his mind, if they would do that, but that they will succeed and that they will support themselves without any difficulty. "It is not a warfare. That is not the idea. It is simply self-protection. That is what they are after and nothing more. They do not want to inaugurate a warfare against the manufacturing companies or the parent companies. That is not the idea. But they want to simply say to them when we have purchased a thing they have the right to use it. What they want is protection."

Mr. T. Carpenter Smith said that he was very much interested in one proposition put forward by Mr. Weeks where he spoke of forming a company for the manufacture of apparatus. He thought that in that suggestion there was a weapon that lay ready to the hand of every central-station man. They knew that there was enough machinery on which the patents have entirely run out which could be used for nine-tenths of the lighting in an electric-light station, referring more particularly to arc apparatus. The one feature in an arc machine which has been used to sell apparatus more than another and which has been used by parent companies, one against the other, was that of a good regulator. He had had some little experience—not very much—in arc lighting, and he had found that the best regulator of an arc machine was a good big load. He thought that there was not a central station in the country but that has bought and paid for enough patent regulators to take care of all their small circuits—all their cut circuits—and he thought if this committee put in

Digitized by Google

the hands of every central station information that would enable them to buy machines which would run their full circuits and let them keep those for which they have already paid heavy prices to run their cut circuits, that they had got a weapon to bring the parent companies to a sense of what it meant to lose nine-tenths of their business at once. He felt that this committee, if it were continued, should look at the matter in that light. It was information of that kind which they want circulated among the central stations.

A motion was carried by the meeting that the Committee on Relations between Parent and Sub-Companies be instructed to formulate a definite plan of procedure for the protection of the central-station companies and prepare the necessary articles of agreement, and report the same to the Association in executive session at its next Convention.

Mr. Hornsby then read a Paper on the Chicago Exhibition, and Mr. Peck presented, as the report of the electrical section of the Committee on Data, a form by which to record data concerning street lights.

In the discussion which followed, Mr. Weeks alluded to the very inaccurate and misleading statistics which had been published by the Census Department. For instance, the statement was made that in San Francisco the price is $440·67 for one arc lamp for one year, and in Denver $58·46. Those statements were made simply without any qualification whatever. The facts were that in San Francisco, where it should be remembered coal is $7 per ton, the highest price paid for any one lamp per year is $361·90, and that was a 4,000 c.p. lamp maintained at a point remote from the central station with a considerable mileage of circuit in order to reach that point, of course. The rate that he got there was $150 within a certain radius and $216 outside and for tower lighting, two very different propositions. He had occasion to look into the matter of distribution extensively of late, and he found that the distribution of municipal lights ranges all the way from eight and six-tenths lamps per mile of line down to one lamp per mile of line. Any electrical engineer will at once appreciate the importance of this, and that element should always be included if a comparison of prices is made. Of course there were other elements that occur to almost every one—the system used, the watts consumed, the period of contract, the price of coal, whether it be water power or natural gas—but the mileage of circuit per lamp seems to have been generally overlooked. It is important in two ways—first, it determines the amount of investment. He found in the cities that he had looked up that the investment per lamp in street systems ranges from $35·87 to $190·40. They could readily see that when it comes into operation it would be still more important, as not only has the resistance of the line to be overcome, but it has to be controlled and maintained, and the trimmers have to traverse all of this distance.

The Committee on Legislation had no report to make. The design of that committee was that the members from each State would give the matters of legislation occurring within his jurisdiction to the chairman of the committee, so that it could be formulated and submitted here—a splendid scheme, said Judge Armstrong, but unfortunately it has not worked at all. He believed that the usual number of underground bills were introduced, one bill, about getting away up in the air some two or three hundred feet, was also introduced, but nothing came of any of those measures. There was another bill introduced to the effect that no wire should be operated in the State carrying a voltage of more than one thousand volts. That also died in the committee.

Dr. Louis Bell called attention to the existence of the fake electric light companies—companies existing on paper, with a board of stockholders, usually composed of the stockholders of the gas company, holding meetings once a year if it is absolutely required by law, and existing simply for the purpose of stopping legitimate electrical enterprises. They obtained charters, and they simply hung on to them, stayed there like dogs in the manger, refusing to let any electric light company get a foothold, and stopping the organisation of new companies. In the first place it is an outrage upon electrical people in general, who want to see the electric light extended, and in the next place it is particularly tough on companies which might if permitted in towns do a good deal of electric lighting. He did not know whether there could be a a reasonable possibility of legislative prevention of this, but it would be a mighty good work for this association to take up.

On the report of the Committee on Underground Conduits Mr. Francisco said that they had found that the subject of underground conduits was one that was liable to involve quite a study in relation to a great many statistics and a great many points. They went to work to get at the bottom—to get at the facts. They collected a good deal of information in regard to that matter, but the time has been so short that it had been impossible to get the report ready at this meeting. He had been in correspondence with parties in London with regard to the entire underground conduit business of London. The position that he had taken, and that the Committee took was, that if there was a system of underground wiring that was practicable and proper, they wanted to find out what was the best system, and then leave those that want to adopt it, upon the information which we may obtain, to decide as to that which was the best, the most practicable, and the most serviceable.

The report of the Committee on Safe Wiring, of which the full text is given elsewhere, was then read. Mr. Law, who had been actively engaged in preparing these rules, wished to call the attention of the Convention to the fact that they were divided into three sections. "One section says what you shall do, another section says what you shall not do, and another section says what you should do. Perhaps some of these sections that may look a little bit obnoxious to you may be those that would recommend you to do so and so, instead of saying that you shall or shall not do it. I call your attention to that," said Mr. Law, "so that you may notice these points when you come to read the rules."

Third Day.

On the third day a discussion was opened on a Paper on "Distribution and Care of Alternating Currents," which had been read by Mr. T. Carpenter Smith at the meeting of the Association at Providence, six months ago. The speakers directed their remarks to the best arrangement of fuses or transformers and the circuits in connection with them. A Paper was read by Mr. G. A. Redman on "Central Stations operated by Water Power." Various kinds of turbines were briefly described, and a number of practical suggestions as to arranging the race-ways, sluices, and other details were given.

The next Paper was that of Mr. H. Ward Leonard, "A Central Station combining the Advantages of both the Continuous and Alternating-Current Systems." The author proposes to supply a continuous current for the central portion of a town during the day time, when power is required, but to supply the outlying districts with an alternating current at night for lighting. He would thus supply current for lighting continuously throughout the twenty-four hours, but would avoid using the alternate current on a light load. But only one set of conductors is to be provided for the consumers, who are to be connected to a three-wire system. The central and the outlying portions are to be connected by switches. These are kept open during full load. The three-wire system supplies the town, and high-pressure feeders supply the transformers for the outskirts, the secondary circuit giving 220 volts, and the third wire being connected to the middle of the secondary. When the load drops at midnight, an operator is sent out who goes to each section supplied by a transformer, and by throwing a switch transfers the secondary wiring from the alternating system to the three-wire mains. In this way the small remaining load is gradually transferred to the three-wire plant, and then the alternating plant is shut down. The continuous current continues in operation all night and all the next day. In the discussion, Mr. Carpenter Smith advocated the use of alternate currents, and thought it better to have separate circuits for power and light. "Say what you will," he concluded, "it comes down to this: that it is the consumer who will regulate the running of your station. If he does not regulate it by legislation he will do it by hurting your business, by refusing to take what you supply under arbitrary conditions. And so we come back to the proposition with which we started—that no corporation, individual, or Government can say 'the public be damned' and not suffer for it."

Digitized by Google

Mr. Burleigh followed with a Paper on "Uniformity in the Method of Keeping Central Station Accounts," which elicited a long discussion, wherein it appeared that at some stations the managers did not know at any given time how much load was being carried by the engines. Mr. Nicholls explained that this might be done with the assistance of ampere meters, and instructed the meeting how to plot the readings against time.

FOURTH DAY.

The fourth day was begun by a Paper on "Three Years' Development of Electric Railways," by Mr. Eugene Griffin, who began as follows: "The first recorded description of the electric car is found in the 4th verse of the 2nd chapter of Nahum: 'The chariots shall rage in the streets; they shall jostle one against another in the broad ways; they shall seem like torches; they shall run like the lightnings.' Notwithstanding this early mention it was not until 1888 that the electric railway became a practical commercial success. I fix the date at 1888, as it was in that year that Bentley and Knight opened the Alleghany City road to regular traffic; &c." The greater part of the Paper was historical. The author observed that Van Depoele used carbon brushes as early as 1883-4.

Considerable disappointment was expressed on the announcement that the Government had dropped the census of the electrical industry, at all events for the present; and after the usual amount of "whereas"-ing it was resolved in a very formal manner that the collection of statistics had better be begun again as soon as possible. The Report of the Committee on Safe Wiring was then read. A Paper was read by Mr. C. F. Field on "Electric Railroad Construction and Operation, and a Consideration of their Connection with Central-Station Interests." The first part of the Paper dealt with steam engines. The author thought that each unit should be entirely independent, and "this cannot be obtained in a safe and economical way by the use of our old friend the countershaft." He advocated a Corliss engine "of 500 H.P., operating at 80 or 90 turns, with a fly-wheel 18 to 20 feet in diameter, with belt centres of say 40 feet 2 inches." "On engines of this size and speed a fly-wheel capacity of approximately 600,000 pounds is about right." He alluded to direct driving, but said that "the trouble in this line has been to get electric manufacturing companies to take up the building of large multipolar generators adapted for direct coupling at a speed of from 100 to 200 revolutions."

FIFTH DAY.

On Friday, September 11th, the first Paper was that of Mr. J. L. Ayer, on "Some Details of the Care and Management of an Arc-Light System, as practised in the 'Municipal' of St. Louis." The Paper was of considerable length, and full of the practical details of running arc lamps on a large scale. Some rather astonishing revelations were made as to the inaccuracy of the ordinary measuring instruments in use in American stations. "It is rarely the practice in the smaller stations to have anything in the way of instruments except those furnished by the parent company, and possibly sometimes one outside instrument. We all know the utter unreliability of the ordinary commercial device furnished to us as an ammeter by these parent companies, and unless you do accurately know the amount of current, leaks will creep into the plant which I am sure would astonish anyone if they were to go at the matter carefully and measure them. I will give you a statement of a little test. Until I had made the test and made the comparison I could not realise that the difference or the opportunity for difference was so great. With 10 lamps adjusted to burn an average of 46 volts with 9·5 amperes of current, the average number of watts of the 10 lamps was 436 per lamp. Now, without changing the adjustment of the lamps in any manner, but simply increasing the current so that the ammeter needle read 9·8 amperes (an increase of 0·3 ampere, and you will find that the indicator furnished by our parent companies will not agree within half an ampere), with an increase of current of only 0·3 of an ampere the average consumption or increase of watts was 524, or an increase of 20 per cent. in the watts consumed. That was the result of changing only 0·3 of an ampere. When the current was increased so as to give the lamps 10 amperes we had an average voltage of 58 volts per lamp instead of 46, an average of 550 watts per lamp, or an increase of 33 per cent. in the energy consumed. There is a saving equivalent to a very handsome profit on your lamps." At another station they standardise the voltmeter and the ampere meter *every hour*.

Dr. Louis Bell remarked: "Take the best laboratory instruments and they will get out of adjustment with the most skilful use, and when they are subjected to a degree of care which could not be even approximated in the most refined commercial work. I think the cause of the error that is so frequently made in ascribing exceedingly fine regulation to commercial apparatus is due to the fact that it is not sensitive enough to show more variation. I have tested first and last in the laboratory a good many commercial instruments. I find that a good many are excellent for rough work. But the needle of a sensitive ammeter will sway through several divisions, while the indicator on the commercial instrument will not move at all. I have seen a delicate ammeter put on an arc light circuit; and then the regulator of the machine was fiddled with and see-sawed with until it ought to have changed the current by a number of per cent. As a matter of fact the commercial meter showed small changes, the accurate instrument big changes. And even those accurate instruments have to be standardised very frequently to get good results from them. There are to-day no ammeters and voltmeters suitable for portable use that can go without watching."

Mr. Orford thought that a voltmeter is quite unnecessary for incandescent work, but he was evidently an authority on arc lamps. "The arc lamp," he said, "is not such a sensitive instrument that it is going to go out because there is a variation of 10 per cent. even in your current. I think you can vary the current 10 per cent., and there is not a man in the room can tell the difference. I can give you an instance. I happen to be running a machine which is really a 65-light machine. I was competing with the Thomson-Houston. I gave them pretty good competition, and I dropped the current. I had 75 lights on the machine. I dropped my current down, and there was not a person who knew anything about it. In fact, a couple of years afterwards, one of the lamps which I had had in use happened to get into the hands of one of my former competitors, and he got it on his regular 10-ampere circuit, and he was surprised at the action of the lamp, and wondered why the lamp had changed so much since I had it. He was not aware that I was running eight amperes. My competitor was running 10. Consequently, you see that the difference of a quarter of an ampere even in a lamp is of no moment."

The last Paper by Mr. E. P. Warner, on "Different Forms of Carbons used in Arc Lighting" was not read, for want of time. He advocated single lamps with carbons 14in. long and five-eighths of an inch in diameter, and described the following experiments:—"Two single lamps were connected in series in an arc circuit, one being supplied with five-eighth inch carbons 14in. in length, the other with one-half inch carbons 12in. in length; around each lamp was branched a voltmeter indicating the voltage. The lamps were then adjusted until they had the same voltage, and as current was of necessity the same in each it was a safe conclusion that equal amounts of energy were being supplied. Photometric comparison of the two lights was then made at the horizontal and at many different angles above and below, with the result that no perceptible difference could be found in the power of the lights; during the tests the current was maintained as constant as practicable, and care was taken to base the comparison on an average deduced from a large number of readings."

A Non-electric Incandescent Platinum Light.—In a note in the *Comptes Rendus* of September 14th M. Paquelin describes an incandescent platinum light devised by him. The apparatus consists of a strip of platinum coiled on itself and placed in a platinum bowl with a hollow stem. A gaseous mixture of air and some hydro-carbon vapour is then introduced under pressure in suitable proportions. The mixture is set alight, the flame disappears, and the platinum strip incandesces, the incandescence being the more intense the greater the pressure. With moderate pressures the light is comparable with that emitted by an electric amp. The whole apparatus can be plunged into water without the light being extinguished.

WIRING AND INSURANCE RULES OF THE NATIONAL ELECTRIC LIGHT ASSOCIATION.

A Committee of the National Electric Light Association of the United States have presented the following rules, which were adopted by the Association at Montreal, on September 10, 1891 :—

CLASS A.—CENTRAL STATIONS.

For Light or Power.

These Rules also apply to dynamo-rooms in isolated plants, connected with or detached from buildings used for other purposes. Also to all varieties of apparatus, of both high and low potential.

Generators or Motors must be—(1) Located in a dry place. (2) Insulated on floors or base frames, which must be kept filled to prevent absorption of moisture, and also kept clean and dry. (3) Not exposed to flying or combustible materials. (4) Each covered with a waterproof cover when not operating. In no case must a generator be placed in a room where any hazardous process is carried on, such as the working-room of a cotton, jute, flax, woollen, or flour mill.

Care and Attendance.—A competent man must be kept on duty in the room where generators are operating. Oily waste must be kept in metal cans, and removed daily.

Conductors.—From generators, switchboards, rheostats or other instruments, and thence to outside lines, conductors must be—(1) In plain sight. (2) Wholly on non-combustible insulators, such as glass or porcelain. (3) Separated from contact with floors, partitions or walls through which they may pass by non-combustible insulating tubes. (4) Kept rigidly so far apart that they cannot come in contact. (5) Covered with non-inflammable insulation material sufficient to prevent accidental contact. (6) Ample in carrying capacity to prevent heating. (*See* Capacity of Wires Table.) (7) Connected by splices or joints equal in carrying capacity to the conductors themselves, soldered if necessary to make them efficient and permanent. (8) When under floors or in distributing towers, placed in spaces ample for inspection and ventilation, and provided with special insulating covering.

Switchboards must be—(1) So placed as to make it impossible to communicate fire to surrounding combustible material; accessible from all sides when the connections are on the back; or may be placed against a brick or stone wall when the connections are entirely on the face. (2) Kept free from moisture. (3) Made of non-combustible material, or of hard wood, filled to prevent absorption of moisture. (4) Equipped with bars and wires in accordance with Rules 1, 2, 4, 5, 6, and 7 for placing inferior conductors.

Resistance Boxes and Equalizers must be—(1) Equipped with metal or non-combustible frames. (2) Treated as sources of heat. (3) Placed on the switch or a distance of a foot from combustible material, or separated therefrom by asbestos or cement.

Lightning Arresters must be—(1) Attached to each side of every overhead circuit connected with the station. (2) In plain sight. (3) On the switchboard or in an equally accessible place, away from combustible material. (4) Connected with at least two earths by separate wires of large size. (5) So constructed as not to maintain an arc after the discharge has passed.

Testing.—All series and alternating circuits must be tested every two hours while in operation to discover any leakage to earth, abnormal in view of the potential and method of operation. All multiple arc low potential systems (300 volts or less) must be provided with an indicating or detecting device, readily attachable, to afford easy means of testing where the station operates perpetually. Data obtained from all tests must be preserved for examination by insurance inspectors.

CLASS B.—ARC (SERIES) SYSTEMS.

Overhead Conductors.—All outside overhead conductors (including services) must be—(1) Covered with some insulating material not easily abraded. (2) Firmly secured to properly insulated and substantially built supports, all the wires having an insulation equal to that of the conductors they confine. (3) So placed that moisture cannot form a cross connection between them, not less than a foot apart, and not in contact with any substance other than proper insulating supports. (4) At least seven feet above the highest point of flat roofs, and at least one foot above the ridge of pitched roofs, over which they pass or to which they are attached. (5) Protected whenever necessary, in view of possible accidents, to conductors or supports, from possibility of contact with other conducting wires or substances to which current may leak, by *dead insulated guard irons or wires*. Special precautions of this kind must be taken where sharp angles occur, or where any wires might possibly come in contact with electric light or power wires. (6) Provided with petticoat insulators of glass or porcelain. Porcelain knobs and rubber hooks are prohibited. (7) So spliced or joined as to be both mechanically and electrically secure without solder. They must then be soldered to ensure preservation, and covered with an insulation equal to that on the conductors. The following formula for soldering fluid is approved :—Saturated solution of zinc, 5 parts; alcohol, 4 parts; glycerine, 1 part. Conductors should not be run over or attached to buildings other than those in which light or power is being, or is to be, used, but on separate poles or structures always easily inspected.

Service Blocks must be covered over their entire surface with at least two coats of waterproof paint, and so maintained. Telegraph, telephone, and similar wires must not be placed on the same arm with electric or power wires, and *should not* be placed on the same structure or pole.

Interior Conductors.

All Interior Conductors must be—(1) Where they enter buildings from outside terminal insulators to and through the walls covered with waterproof insulation, and must have drip loops outside, preferably slanting upward toward the inside and bushed with waterproof and non-combustible insulating tube. (2) Arranged to enter and leave the building through a double contact service switch, which will effectually close the main circuit, and disconnect the interior wires when it is turned "off." The switch must be so constructed that it shall be automatic in its action, not stopping between points when started, and prevent an arc between the points under all circumstances; it must indicate on inspection whether the current be "on" or "off," and be mounted on a non-combustible base in a position where it can be kept free from moisture, and easy of access to police or firemen. (3) Always in plain sight, never covered, except in special cases, where an armoured tube may be necessary. (4) Covered in all cases with a waterproof non-combustible material that will adhere to the wire, not fray by friction, and bear a temperature of 150°F. without softening. (5) In dry places, kept rigidly apart at least 10in., except when covered (in addition to insulation) by a waterproof, non-conducting and non-inflammable tubing, which must be strong enough to protect the insulating covering from injury. Conductors thus placed may be run not less than three inches apart, and be fastened with staples, under which are placed mechanically rigid insulating strips or saddles of greater width than the metal of the staple, by which possibility of injury to the tube may be prevented. (6) In damp places, attached to glass or porcelain insulators, and separated 10in. or more. (7) When passing through walls, floors, timbers, or partitions, treated as in central stations under like conditions.

Lamps and Other Devices.

Arc Lamps must be in every case—(1) Carefully isolated from inflammable material. (2) Provided at all times with a glass globe surrounding the arc, securely fastened upon a closed base. No broken or cracked globes may be used. (3) Provided with a hand switch, also an automatic switch, that will shunt the current around the carbons should they fail to feed properly. (4) Provided with reliable stops to prevent carbons from falling out in case the clamps become loose. (5) Carefully insulated from the circuit in all their exposed parts. (6) Where inflammable material is near or under the lamps, provided with a wire netting around the globe and a spark-arrester above, to prevent escape of sparks, melted copper or carbon. Incandescent lamps in series circuits, having a maximum potential of 350 volts or over, must be governed by the same rules as for arc lights, and each series lamp provided with a hand switch and automatic cut-out switch; when lights are in multiple series, such switches and cut-outs must not control less than a single group of lights. Electro-magnetic devices for switches are not approved. Under no circumstances will incandescent lamps on series circuits be allowed to be attached to gas fixtures.

CLASS C.—INCANDESCENT (LOW-PRESSURE) SYSTEMS.

300 volts or less.

Overhead Conductors.

Outside Overhead Conductors must be—(1) Erected in accordance with general rules for arc (Series) circuit conductors. (2) Separated not less than six inches, where they enter buildings as service conductors, and be provided with a double pole fusible cut-out, as near as possible to the point of entrance to the building, and outside the walls when practicable.

Underground Conductors.

Underground Conductors must be—(1) Provided with suitable protecting devices at the ends of tube or conduit services inside the walls of buildings as a guard against moisture and injury. (2) Terminated at a properly placed double pole house cut-out. (3) Of specially insulated conductors after leaving the tube or conduit, and separated by at least 10 inches, until the double pole cut-out is reached.

Inside Wiring.

Wire should be so placed that in the event of the failure or deterioration of their insulating covering the conductors will still remain insulated.

At the entrance of every building there shall be a double pole switch placed in the service conductors, whereby the current may be entirely cut off.

Conductors must not be—(1) Of sizes smaller than No. 16 B. and S., No. 18 B. W. G., or No. 3 E. S. G. (2) Lead or paraffin covered. (3) Covered with soft rubber tube. (4) Laid in mouldings of any kind in damp places. (5) Laid in mouldings with open grooves against the wall or ceiling. (6) Laid in mouldings where less than half an inch of solid insulation is between paralleled wire, and between wires and walls or ceiling.

Cleatwork is not desirable, and cleats must *not* be used unless—(1) In a very dry place. (2) In a place perfectly open for inspection at any time. (3) They are of porcelain, or well-seasoned wood, filled, to prevent absorption of moisture. (4) They are so arranged that wires of opposite polarity, with a difference of potential of 150 volts or less, will be kept at least two and one half inches apart, and that where a higher voltage is used this distance be increased proportionately. (5) There is a backing provided, of wood at least half an inch thick, well seasoned and filled, to prevent absorption of moisture.

Metal Staples must never be used to fasten conductors unless—(1) Provided with an insulating sleeve or saddle rigidly attached to the metal of the staple, and having such strength and surface as to prevent mechanical

Digitized by Google

injury to the insulation of the conductor. (2) Under conditions in which cleatwork would be acceptable or where driven into a moulding specially adapted for open work.

SPECIAL WIRING.

Wherever conductors cross gas, water, or other metallic pipes, or any other conductors or conducting material (except arc light wires), they should be separated therefrom by some continuous non-conductor at least one inch. In crossing arc light wires the low-tension conductors must be placed at a distance of at least six inches. In wet places an air space must be left between conductors and pipes in crossing, and the former must be run in such a way that they cannot come in contact with the pipe accidentally. Wires should be run *over* all pipes upon which condensed moisture is likely to gather, or which by leakage might cause trouble on a circuit. In breweries, stables, dye-houses, paper and pulp mills, or other buildings specially liable to moisture, all conductors, except where used for pendants, must be—(1) Separated at least six inches. (2) Carefully put up. (3) Supported by porcelain or glass insulators. Moisture-proof and non-inflammable tubing may be accepted in lieu of such construction. No switch or fusible cut-outs will be allowed in such places.

Interior Conduits must not be—(1) Combustible. (2) Of such material as will be injured or destroyed by plaster or cement, or of such material as will injure the insulation of the conductor, or construction that the insulation of the conductor will ultimately be injured or destroyed by the elements of the composition. (3) So constructed or placed that difficulty will be experienced in removing or replacing the conductors. (4) Subject to mechanical injury by saws, chisels or nails. (5) Supplied with a twin conductor in a single tube where a current of more than 10 amperes is expected. (6) Depended upon for insulation. The conductors must be covered with moisture-proof material. The object of a tube or conduit is to facilitate the insertion or extraction of the conductors, to protect them from mechanical injury and as far as possible from moisture. Twin tube conductors must not be separated from each other by rubber or similar material, but by cotton or other readily carbonizable substance. Conductors passing through walls or ceilings must be encased in a suitable tubing, which must extend at least one inch beyond the finished surface until the mortar or other similar material be entirely dry, when the projection may be reduced to half an inch.

Double Pole Safety Cut-outs must be—(1) Placed where the overhead or underground conductors enter a building and join the inside wires. (2) Placed at every point where a change is made in the size of the wire (unless the cut-out in the larger wire will protect the smaller). This includes all flexible conductors. All such junctions must be in plain sight. (3) Constructed with bases of non-combustible and moisture-proof material. (4) So constructed and placed that an arc cannot be maintained between the terminals by the fusing of the metal. (5) So placed that on any combination fixture no group of lamps requiring a current of six amperes or more shall be ultimately dependent upon one cut-out. (6) Wherever used for more than six amperes (or where the plug or equivalent device is not used) equipped with fusible strips or wires provided with contact surfaces or tips of harder metal soldered or otherwise having perfect electrical connection with the fusible part of the strip.

Safety Fuses must be so proportioned to the conductors they are intended to protect that they will melt before the maximum safe carrying capacity of the wire is exceeded. All fuses, where possible, must be stamped or otherwise marked with the number of amperes equal to the safe carrying capacity of the wire they protect. All cut-out blocks, when installed, must be similarly marked. The safe carrying capacity of a wire changes under different circumstances, being about 40 per cent. less when the wire is closed in a tube or piece of moulding than when bare and exposed to the air, when the heat is rapidly radiated. It must be clearly understood that the size of the fuse depends upon the size of the smallest conductor it protects, and not upon the amount of current to be used on the circuit. Below is a table showing the safe carrying capacity of conductors of different sizes in Birmingham, Brown and Sharpe, and Edison gauges, which must be followed in the placing of interior conductors.

Brown and Sharpe.		Birmingham.		Edison Standard.	
Gauge No.	Amperes.	Gauge No.	Amperes.	Gauge No.	Amperes.
0000	175	0000	175	200	175
000	145	000	150	180	160
00	120	00	130	140	135
0	100	0	110	110	110
1	95	1	95	90	95
2	70	2	85	80	85
3	60	3	75	65	75
4	50	4	65	55	65
5	45	5	60	50	60
6	35	6	50	40	50
7	30	7	45	30	40
8	24	8	35	25	35
10	20	10	30	20	30
12	15	12	20	12	20
14	10	14	15	8	15
16	5	16	10	5	10
		18	5	3	5

Switches must—(1) Be mounted on moisture proof and incombustible bases, such as slate or porcelain. (2) Be double pole when the circuits which they control are connected to fixtures attached to gas pipes, and when six amperes or more are to pass through them. (3) Have a firm and secure contact, must make and break readily, and not stick when motion has once been imparted to the handle. (4) Have carrying capacity sufficient to prevent heating above the surrounding atmosphere. (5) Be placed in dry accessible places, and be grouped as far as possible, being mounted, when practicable, upon slate or equally indestructible back boards.

Motors.—In wiring for motive power, the same precautions must be taken as with the current of the same volume and potential for lighting. The motor and resistance box must be protected by a double pole cut-out and controlled by a double pole switch.

Arc Lights on Low Potential Circuits must be—(1) Supplied by branch conductors not smaller than No. 12 B. and S. gauge. (2) Connected with main conductors only through double pole cut-outs. (3) Only furnished with such resistances or regulators as are enclosed in non-combustible material, such resistances being treated as sources of heat. (4) Supplied with globes protected as in the case of arc lights on high potential circuits.

FIXTURE WORK.

(1) In all cases where conductors are concealed within or attached to fixtures, the latter must be insulated from the gas pipe system of the building. (2) When wired outside, the conductors must be so secured as not to be cut or abraded by the pressure of the fastenings, or motion of the fixtures. (3) All conductors for fixture work must have a water-proof insulation that is durable and not easily abraded, and must not in any case be smaller than No. 16 B. & S., No. 18 B. W.G., or No. 3 E. S. G. (4) All burrs or fins must be removed before the conductors are drawn into a fixture. (5) The tendency to condensation within the pipes must be guarded against by sealing the upper end of the fixture. (6) No combination fixture in which the conductors are concealed in a space less than one-fourth inch between the inside pipe and the outside casing will be approved. (7) Each fixture must be tested for possible "contacts" between conductors and fixture, and for "short circuits," before the fixture is connected to its supply conductors. (8) The ceiling blocks of fixtures should be made of insulating material.

ELECTRIC GASLIGHTING.

Where electric gaslighting is to be used on the same fixture with the electric light—(1) No part of the gas piping or fixture shall be in electrical connection with the gaslighting circuit. (2) The wires used with the fixture must have a non-inflammable insulation, or where concealed between the pipe and shell of the fixture the insulation must be such as is required for fixture wiring for the electric light. (3) The whole installation must test free from "grounds." (4) The two installations must test perfectly free of connection with each other.

PENDANTS AND SOCKETS.

No portion of the lamp socket exposed to contact with outside objects must be allowed to come into electrical contact with either of the conductors.

Cord Pendants must be—(1) Made of conductors, each of which is composed of several strands insulated from the other conductor by a mechanical separator of carbonisable material, and both surrounded in damp places with a moisture-proof and a non-inflammable layer. (2) Protected by insulating bushings where the cord enters the socket. (3) So suspended that the entire weight of the socket and lamp will be borne by knots, above the point where the cord comes through the ceiling block or rosette, in order that the strain may be taken from the joints and binding screws. All sockets used for wire or cord pendants should have openings at least equal to ⅛in. gas-pipe size. (4) Allowed to sustain nothing heavier than a four-light cluster, and in such a case special provision should be made by an extra heavy cord or wire, as a mechanical reinforcement. (5) Equipped with keyless sockets as far as practicable, controlled by wall switches. In no case may a lamp giving more than 50 c.p. be placed in a key socket on a flexible pendant.

CLASS D.—ALTERNATING SYSTEMS.

CONVERTERS OR TRANSFORMERS.

Converters must not—(1) Be placed inside of any building except the central station, unless as hereinafter provided. (2) Be placed in any but metallic or non-combustible cases. (3) Be attached to the outside walls of buildings, unless separated therefrom by substantial insulating supports. (4) Be placed in any other than a dry and convenient location (which can be secured from opening into the interior of the building, such as a vault) when an underground service is used. (5) Be placed without safety fuses at the junction between main and service conductors, and safety fuses in the secondary circuits where they will not be affected by the heat of the converter.

PRIMARY CONDUCTORS.

In those cases where it may not be possible to exclude the transformers and primary wires entirely from the building, the following precautions must be strictly observed :—(1) The transformer must be located at a point as near as possible to that at which the primary wires enter the building. (2) Between these points the conductors must be heavily insulated with a coating of moisture-proof material, and, in addition, must be so covered and protected that mechanical injury to them or contact with them shall be practically impossible. (3) The primary conductors, if within a building, must be furnished with a double-pole switch, and also with an automatic double-pole cut-out where the wires enter the building, or where they leave the main line, on the pole or in the conduit. These switches should, if possible, be enclosed in secure and fireproof boxes outside the building. (4) The primary conductors, when inside a building, must be kept apart at least 10in., and at the same distance from all other conducting bodies.

Digitized by Google

SECONDARY CONDUCTORS.

The conductors, from the secondary coil of the transformer to the lamps or other translating devices, must be installed according to the rules for "inside wiring" for "low potential systems."

CLASS E.—ELECTRIC RAILWAYS.

POWER STATIONS.

All rules pertaining to arc light wires and stations shall apply (so far as practicable) to street railway power stations and their conductors.

RAILWAY SYSTEMS WITH GROUND RETURN.

Electric railway systems in which the motor cars are driven by a current from a single wire, with ground or floor return circuit, are prohibited *except* as hereinafter provided.—(1) When there is no liability of other conductors coming in contact with the trolley wire. (2) When the location of the generator is such that the ground circuit will not create a fire hazard to the property. (3) When an approved automatic circuit breaker or other device that will immediately cut off the current in case the trolley wires become grounded is introduced in each circuit as it leaves the power station. This device must be mounted on a fireproof base and be in full view of the attendant.

TROLLEY WIRES.

Trolley Wires must be—(1) No smaller than No. 0 B. and S. copper, or No. 4 B. and S. silicon bronze, and must readily stand the strain put upon them when in use. (2) Well insulated from their supports, and in case of the side or double pole construction, the supports shall also be insulated from the poles immediately outside the trolley wire. (3) Capable of being disconnected at the power house, or of being divided into sections, so that in case of fire on the railway route the current may be shut off from the particular section and not interfere with the work of the firemen in extinguishing the flames. This rule also applies to feeders. (4) Safely protected against contact with all other conductors.

CAR WIRING.

All wires in cars must be run out of reach of the passengers, and shall be insulated with a waterproof insulation.

LIGHTING AND RAILWAY POWER WIRES.

Lighting and power wires must not be permitted in the same circuit with trolley wires with a ground return, except in street railway cars, carhouses and power stations. The same dynamo may be used for both purposes, provided the connection from the dynamo for each circuit shall be a double pole switch so arranged that only one of the circuits can be in use at the same time.

CLASS F.—BATTERIES.

When current for light and power is taken from primary or secondary batteries, the same general regulations must be observed as apply to such wires fed from dynamo generators developing the same difference of potential.

CLASS G.—MISCELLANEOUS.

(1) The wiring in any building must test free from "grounds" before the current is turned on. This test may be made with a magnet bell that will ring through a resistance of 20,000 ohms, where currents of less than 250 volts are used. (2) No ground wires for lightning arresters may be attached to gas pipes within the building. (3) All conductors connecting with telephone, district messenger, burglar alarm, watch clock, electric time and other similar instruments must, if in any portion of their length they are liable to become crossed with circuits carrying currents for light or power, be provided near the point of entrance to the building with some protective device which will operate to shunt the instruments in case of a dangerous rise of potential, and will open the circuit and arrest an abnormal current flow. Any conductor normally forming an innocuous circuit may become a source of fire hazard if crossed with another conductor through which it may become charged with a relatively high pressure.

A. J. DECAMP, Chairman, STEPHEN E. BARTON, WM. BROPHY, M. D. LAW, T. CARPENTER SMITH.

Certain questions have come before the committee which they considered of too great importance to be decided at this stage. Among these are the subjects of the grounding of the neutral wire in compensating or three-wire systems; the grounding either permanently or by automatic cut-outs of the secondary wires in transformer systems; the adoption of a uniform alloy for fusible cut-outs, and the adoption of better methods for testing circuits.

From the nature of the electrical business and the rapid advance it is making, there must, of necessity, questions continually arise which can only be decided by a later and larger experience; therefore the object of the Association would be best served by the appointment of a permanent committee to whom should be referred all such questions, which they shall consider and report upon at the next succeeding meeting of the Association.

Your committee, therefore, offer the following:

Resolved, That a committee of five be appointed by the president to be a permanent committee on safe methods of construction and operation—any vacancies that may occur on the committee from time to time to be filled by the president.

WM. MC DEVITT, WM. BROPHY, T. CARPENTER SMITH, M. D. LAW.

LEGAL INTELLIGENCE.

The Electric Arms and Ammunition Syndicate (Limited).

On Wednesday last, in the Vacation Court, before Mr. Justice Jeune, Mr. Eustace Smith supported a petition presented by the shareholders for the winding up of the Electric Arms and Ammunition Syndicate (Limited), which was originally started to manufacture, under certain patents, firearms which were electrically fired. The petitioners alleged that the patents having turned out to be imperfect the firearms could not be manufactured, and experiments were now being made by the Directors for the purpose of perfecting a battery, which was an essential part of the gun. The petitioners complained that their money, instead of being expended in making and selling guns, was being spent on experiments.

Mr. JUSTICE JEUNE: Do the Company oppose the application?

Mr. MILLAR, Q.C.: Certainly. The bulk of the shareholders considered they had invested their money in what required some experiments and testing, and these were now being made. The application was made by five shareholders, all of whom were in arrears for calls, and therefore, had not complied with their own contract with their co-shareholders. The petition was launched on the footing that it was just and equitable that the Company should be wound up, but insolvency was not alleged. The Directors were honestly engaged in making the business remunerative, which they believed they would ultimately be able to do, and they objected to ruin being brought upon them at the instance of five shareholders who could not, or would not, meet their own obligations to the Company.

Mr. JUSTICE JEUNE thought it was impossible for anyone to say that the substratum of the Company had gone.

Mr. SMITH said his complaint was that he had been induced to join a company formed to manufacture and sell guns under a perfect patent, when no such patent existed.

Mr. JUSTICE JEUNE said misrepresentation might be a ground for rescission of contract, but not for winding up. The terms of the memorandum appeared to be sufficiently wide to justify the Directors in making the experiments complained of.

After some discussion, it transpired that evidence had been filed in support of the petition which had not been seen by those representing the Company, and thereupon it was arranged that the petition should stand over for a fortnight.

CORRESPONDENCE.

THE RELATION BETWEEN THE OHM AND THE "LEGAL OHM."

TO THE EDITOR OF THE ELECTRICIAN.

SIR,—An editorial note in your issue of September 11th, which I have just seen on my return to England, calls for some explanation from me. The point is as follows. It is stated on certificates issued by me as Secretary of the Electrical Standards Committee, with the sanction of the Committee, that "it has been assumed that 1 legal ohm is equal to 1·0112 B.A. units." Again, on another certificate it is stated that "1 ohm is equal to 1·01358 B.A. units"; and you point out that the ratio of these two numbers is not that of 106 to 106·3. The form of certificate referring to the "legal ohm" was adopted by the Committee in 1884 after the Paris Congress. It was then agreed to recommend provisionally the use of the "legal ohm" in accordance with the resolutions of that Congress; and the question arose, were the new "legal ohm" standards to be constructed by direct comparison with mercury units, or by comparison with the B.A. units, making use of the results then existing which connected the B.A. unit and the mercury unit? This latter course was adopted by the Committee, and after discussion it was decided to take the number $\cdot 9540 \times 10^{-4}$ as the specific resistance of mercury in B.A. units. At that date the only exact experiments on this point were those of Lord Rayleigh, which lead to the value $\cdot 95412 \times 10^{-4}$, and of M. Mascart giving $\cdot 95374 \times 10^{-4}$, and it was felt that the number $\cdot 9540 \times 10^{-4}$ represented the mean of these with all the accuracy required. The "legal ohm" standards constructed in England are all based on this number, and from it is obtained the number 1·0112 (1·06 × ·954) B.A. units as the value of the "legal ohm."

Since this date, however, many more determinations of the specific resistance of mercury in B.A. units have been made. A list of the results obtained is given in the Report of the Com-

Digitized by Google

mittee for 1890 (B.A. Reports, p. 137), from which the following is taken :—

Rowland	1884	95349
Kohlrausch	1887	95338
Glazebrook	1888	95352
Wuilleumeier	1890	95355
Strecker	1885	95334
Hutchinson	1888	95352
Salvioni	1890	95354

The mean of all the observations made thus differs very little from $\cdot 9535 \times 10^{-4}$, and accordingly this number was adopted by the Standards Committee of the British Association (Report, 1890, p, 97), and implicitly by the Committee of the Board of Trade in their recent Report, instead of the former value $\cdot 9540 \times 10^{-4}$. Thus we have, according to the resolutions of 1884,

$$1 \text{ legal ohm} = 1 \cdot 060 \times \cdot 9540 \text{ B.A. units},$$

while, according to the best results obtained up to 1891,

$$1 \text{ ohm} = 1 \cdot 063 \times \cdot 9535 \text{ B.A. units}.$$

Hence the ratio of the ohm to the "legal ohm" as constructed in England is not 106·3 to 106. The "legal ohm" coils are all really about 5 in 10,000 too large. This has been pointed out by me in various Papers (see *Phil. Mag.*, October, 1885, July, 1891). The discrepancy to which you refer in your note is thus accounted for. In the future I suppose certificates of "legal ohms" will not be asked for, but only those of B.A. units and ohms.

These two are connected as follows :—

$$1 \text{ B.A. unit} = \cdot 9866 \text{ ohms},$$
$$1 \text{ ohm} = 1 \cdot 01358 \text{ B.A. unit}.$$

The "legal ohm" coils constructed in England do not represent—in the light of our present knowledge—the resistance of a column of mercury of 106 centimetres in length, but one the length of which is $\frac{106 \cdot 3 \times 1 \cdot 0112}{1 \cdot 01358}$, or about 106·05. They only represent the resistance of 106 cm. on the assumption stated on the certificate that a "legal ohm" is equal to 1·0112 B.A. units. This assumption further research has shown to be wrong. The resistance of a column of mercury 106 cm. long is really equal to 1·0107 B.A. units.—I am, Sir, &c.,

R. T. Glazebrook.

TO THE EDITOR OF THE ELECTRICIAN.

Sir,—As I have been favoured by you with a proof of Mr. Glazebrook's letter, I should like to say a few words in reply. The way in which the discrepancy was noted is somewhat to the point. My firm sent a true ohm to Cambridge to be certified, and it came back some ·05 per cent. wrong as compared with "legal" units, from which it had been derived on the basis 106·3 : 106, and it was only after much cross checking that the reason was found to be in the difference of definitions. Mr. Glazebrook's letter certainly explains the apparent discrepancy between the two definitions of the ohm, but it emphasises a very strong objection to the introduction of mercury at all. It amounts to this: that, during its life, the "legal ohm" changed its value; it was always 106cm. Hg., but varied according to the latest accepted value of the specific resistance of that metal.

What more cogent reason against a mercury definition could be wanted? If the accepted value of $\cdot 9535 \times 10^{-4}$ is right it has little value, as I presume it would be the very last way anyone would use to reproduce the ohm if the standard is lost. If wrong, it makes the definitions contradict one another. And if only taken as an approximate value it is not required in the presence of a much more exact one.

The "C. L." stamp is accepted not only in England but throughout the civilised world. The only definition really required is a reference to the standards over which Mr. Glazebrook has so long and so ably presided, *i.e.*, the imperial ohm = 1·01358 B.A. units. There is this much to be said for retaining the 10^{-4} definition, that it is what we think and hope is the resistance of the actual standard coil. The mercury definition as mentioned in the report to the Board of Trade (but not, I am glad to say, in the draft order in Council) makes there its last official appearance.—I am, Sir, yours, &c.,

C. W. S. Crawley.

16, Red Lion-street, Clerkenwell.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

Now Ready.—"The Electrician" Primers (38 in all. Vol. I., 20; Vol. II., 18), in two volumes. Price per volume 2s. paper covers, 2s. 6d. cloth; post free, 2s. 2d. and 2s. 9d. respectively. Single copies, 3d.; post free, 3½d. Prospectus on application to the Publisher.

Tenders, &c. Invited.—The Festiniog Local Board are advertising for plans and estimates for the supply of electricity for lighting and power purposes to the village of Festiniog and district of Tan-y-Grisiau. Further information may be obtained from Mr. R. Walker Davies, solicitor, Blaeneau, Festiniog, North Wales.

Results of Tenders.—The following is the list of tenders received for the lighting of the Market Hall, Bilston :—Lancashire and London Electrical Company, Manchester, £800; Siemens Brothers and Co. (Limited), London, £649; Walsall Electrical Company (Limited), Walsall, £625; Manchester Edison-Swan Company (Limited), Manchester, £510; Crompton and Co. (Limited), London and Chelmsford, £500; Scott (A. F.), Chelmsford, £315.

Sale by Auction.—There will be sold by auction to-day (Friday), at 132, Horseferry-road, a quality of electrical engineering plant, including engine, boiler, cable, &c., &c.

New City Offices.—Messr. Laing, Wharton, and Down, have opened new branch and City offices at 17, Gracechurch-street, London, E.C.

Messrs. Rashleigh Phipps and Dawson.—This firm informs us that they have taken possession of their manufactory for electric light fittings at Stanhope-street, Euston-road, N.W., which they claim now forms one of the largest art metal shops in London. The new manufactory is to be used in addition to the one at present occupied by the firm in Wells-mews, W.

Bankruptcy.—Under the failure of C. J. Allport, described as an electrical engineer, of Woburn-place, Russell-square, accounts have been filed, showing liabilities £14,880 19s. 1d. and assets £43 10s. The debtor states that he commenced business in 1882 as an electrical and mining engineer, with about £200 borrowed money. In the following year he entered into an agreement with others for the purchase of concessions and the right of working various lead, silver, and other mines in Servia, and he attributes his failure to loss in connection with these mines.

Messrs. Charlesworth, Hall and Co.—We are asked to notify that Messrs. Ewen and Co. have ceased to act as the London agents of the above firm; and that all communications, inquiries, &c,, should for the present be sent direct to the works at Oldham.

Messrs. Drake and Gorham.—As the result of the lighting which has been carried out at Alnwick Castle by Messrs. Drake and Gorham, it has been decided to introduce electric light to the Duke of Northumberland's town house, 2, Grosvenor-place.—The County Council have decided to introduce the electric light throughout the Newington Weights and Measures Offices, and have entrusted the work to Messrs. Drake and Gorham.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

September 10, 1891.

15,321. E. A. Claremont. Manchester. An improved electrical regulator or governor.

15,337. A. Muirhead. London. An improvement in standard electrical condensers.

15,363. H. C. E. Jacoby. London. Improvements in alternating current motors.

September 11, 1891.

15,377. J. Whitehead. Birmingham. An improved electric globe gallery and shadeholder.

Digitized by Google

15,403. W. S. Boult. Liverpool. An improved method of actuating electrically propelled tramcars, partly applicable to other purposes.
15,407. G. Cohen. Manchester. Improvements in galvanic batteries.
15,432. T. Parker and W. Armistead. London. Improvements in electrical igniting apparatus.
15,440. Improved apparatus for periodically passing currents of electricity through a conductor.

September 12, 1891.

15,480. W. P. Thompson. Liverpool. Improvements in or relating to dynamo-electric machines. (L. Dahlmann and F. Kirster, Germany).
15,483. J. C. Mewburn. London. Improvements in electric lighting and in the means therefor. (P. Sée, France).

September 14, 1891.

15,522. G. B. Lückhoff. Croydon. Improvements in or relating to conductors for dynamo-electric machines, electric motors, and alternate or direct current transformers.
15,529. E. J. Starr. Crawley Down. Indicating the direction of the wind on a dial by means of electricity, called "an electric ane."
15,542. D. Urquhart. London. Improvements in telephones. (L. H. Despeïssis, France).
15,575. A. D. Meritens. London. Improvements in galvanic batteries.
15,579. O. March. London. An improved arrangement of automatic electric switch and cut-out for use in charging secondary cells and for similar purposes.

September 15, 1891.

15,597. C. U. Fisher. London. An improved battery. (R. H. Thompson, United States).
15,621. S. C. C. Currie. London. Improvements in the method of making the plates or elements of a secondary or storage battery.
15,645. E. T. Greenfield and C. J. Kintner. London. Improvements in and relating to ceiling blocks or roses and cut-outs for use in connection with electric light and other circuits.

September 16, 1891.

15,697. J. Graham. London. Improvements in electric telephonic transmitters.
15,705. J. Watkinson and G. Prince. Leeds. Electric signalling on railways to trains in motion or otherwise.

September 17, 1891.

15,740. W. H. Akester. London. Improvements in electric arc lamps.
15,768. C. J. Hall. Bradford. Improvements in the method of and apparatus for distributing electricity.
15,794. F. W. Dickenson. London. Improvements in electric arc lamps.

September 18, 1891.

15,834. B. M. Drake and J. M. Gorham. London. Improvement for carriers for conical shades for electric or other lamps.
15,868. H. Hegner and L. Lenczewski. London. Improvements in electric arc lamps.
15,872. The American Elevator Company. London. Improvements connected with electric motors and elevators. (Otis Bros. and Co., United States).

September 19, 1891.

15,882. H. Hearthfield. Croydon. An improved switch-holder for incandescent electric lamps.

12,455. Welter (Bonneau). Electric locomotives. (Price 6d.)

COMPANIES' MEETINGS & REPORTS.

The Direct Spanish Telegraph Company (Limited).

The thirty-sixth ordinary general meeting of this Company was held on Tuesday at Winchester House, Old Broad-street; Mr. Edmund Etlinger presiding.

The MANAGER (Mr. Charles Gerhardi) having read the notice convening the meeting,

The CHAIRMAN said: Gentlemen, before commencing the business of this meeting I wish to state—and I do so with the utmost regret—that the absence of our Chairman is caused by a sad domestic affliction, probably the greatest affliction that could have befallen him. His wife, Lady Anderson, died on Friday last. I am sure that you will all regret the cause of his absence, and will feel the deepest sympathy with Sir James Anderson in the great loss which he has sustained.

The MANAGER then read the minutes of the last general meeting, which were approved as correctly entered; and the report and accounts for the half year ended June 30, 1891, were taken as read.

The CHAIRMAN: Perhaps, gentlemen, you will allow me to go through the report, and make a few observations on the various paragraphs. The second paragraph states that "The traffic receipts show a decrease of £1,620. 10s. 6d., as compared with those of the June half of 1890." Well, gentlemen, I am bound to say that this paragraph does not quite do justice to the Company's position. It is absolutely true that we have lost £1,620, or rather that we have made less revenue to that extent than in the corresponding period of the previous year, but I must explain to you that the year 1890 was quite an exceptional year in our history. Ever since the Berlin tariff came into operation in 1886 we have had a regular steady increase in our receipts—in fact, so regular that we can say there has been a normal increase year after year, and that went on until 1890. In 1890, for reasons which I need not go into now, there was an enormous bound in Spanish traffic, and our normal increase was not only exceeded slightly, but three times over, and the consequence was that our receipts in 1890 were not normal, but were entirely abnormal; and therefore, in order to make a comparison of how we stand, we must exclude the year 1890, otherwise we shall not have a fair conception of the good position the Company occupies. Now, in 1889, as you remember, we had a very good year, but the receipts of this half year of 1891 far exceeded those of 1889, although they were behind those of the exceptional year of 1890. 1889 was better than 1888, 1888 was better than 1887, and 1887 was better than 1886. I make a stop here, because that was when the Treaty of Commerce with Spain came into operation; but as a matter of fact the half year now under review, which ended with June, 1891, shows larger receipts than any which this Company has had since its commencement in 1873, with the sole exception of the abnormal year of 1890. Therefore I take it that the shareholders may be perfectly satisfied that the Company is in a very sound and healthy position, although there is the decrease which I have mentioned in the receipts compared with those of last year, which, as I have said, was an exceptional year. Now, the question is, how shall we get on in the future? There is no doubt that our volume of traffic will keep on increasing. The trade with Spain seems to be in that state that it appears to be going up year after year; out last year, as you are aware, the Paris Conference again reduced our tariff, and from the 1st of July last, when the reduced tariff came into operation, we started, if I may say so, in a new position. We do not know, and cannot know at the present moment, how this reduction of ½d. per word will affect us. In the first place, one would naturally suppose that if people could telegraph at a cheaper rate they would telegraph more. The proportion is this: that formerly one could for a certain amount of money send eight words, whereas he can now send nine; or, to make it more practical, one could formerly send sixteen words compared with eighteen now for the same money. If, therefore, one chooses to increase his telegram slightly for the sake of clearness, we shall be in the same position as we were before; but how far that consideration will influence people it is impossible to say. Another idea that strikes me is this: that coding is naturally based on the principle of saving expense. If you go to extremes, and if you were to assume that the word-tariff was made extremely low, a point must be arrived at where people would not take the trouble to code; so that, theoretically reasoning, the reduction of the tariff will tend to reduce the coding of words from which telegraph companies suffer very much. Still, how far this will work out in practice no one can tell at present. I take it that what we have to rely on is the normal increase of traffic between Spain and England. We have no cause to believe that that will not continue, and so the point will be arrived at when the loss which we sustain by the reduction in the tariff will be counterbalanced by the increased number of words we shall be asked to transmit; but when that will come I cannot say. I now come to the next paragraph, which says, "The working expenses are £284. 11s. 9d. in excess of those for the corresponding period of last year." Although that increase is not much I should like you to see how it arises. As to £100 of it, you will remember that last year the shareholders voted to the Directors an additional remuneration in the way of salary of £200 per annum, instead of their taking a share in the profits of the Company over and above a certain dividend paid to the shareholders, to which they were entitled under the articles of association. That share of profits the Directors gave up, and thus became entitled to additional remuneration. This £100 represents half of that increased sum for six months. The difference of £184 represents the net difference on the various items of expenditure, some being more and some less; but stated roughly you may say that this £184 is the cost of the additional assistance we have required at the various stations to carry on the increased traffic and the duplex working.

Digitized by Google

The duplex system, I may say, has been in full operation and does remarkably well. We are in this position—that the average time occupied in the transmission of a message between London and Bilbao is three minutes, and between London and Madrid twenty minutes. Considering that this message has to go overhead from London to Falmouth, under water from Falmouth to Bilbao, and overhead from Bilbao to Madrid, I think it is good work; and as a proof that others consider it good work, I may mention to you what you may regard as an interesting fact—that people in Paris frequently send messages to London to be transmitted to Bilbao by the Direct Spanish cable, and occasionally people in Paris also send messages *vid* London to be transmitted by the Direct Spanish Company to Madrid, whereas they could send by direct wire from Paris to Madrid. Sending these messages *vid* London they must travel over twice as much distance. I think this will prove two things to you. One is that your cables, instruments, and property generally are kept in good order, and secondly that your manager and staff do their work admirably well. The next paragraph reads as follows:—"With the exception of the interruption of the Barcelona cable from April 3rd to 14th, the Company's cables and the land-lines in connection with them have continued in good working order throughout the half-year. The entire cost of the repairs of the Barcelona cable, amounting to £1,695. 1s. 2d., have been paid out of the 'contingencies account.'" I have very little to say on this paragraph. Cables do occasionally break, but in this case there is a remarkable statement to be made, viz., that excepting the actual kink where the break occurred, our Barcelona cable, which has been under water since 1874, was found in very perfect mechanical condition—in fact, I understand that it is just as good mechanically as it originally was. We may therefore hope that it has a long life before it and that we shall not have much to lay out on it in the future. I think that we owe our thanks to the Eastern Telegraph Company for the promptitude with which they put at our disposal one of their telegraph ships, the Amber, which at the time was at Gibraltar. It was despatched to us almost at once, and the interruption only lasted 11 days. I think we are very much obliged to the Eastern Telegraph Company, for a Company like ours cannot keep a ship, and years ago it used to be weeks before we could engage a repairing ship, and we thus sustained considerable loss. The cost for these repairs, as the report states, has been paid for out of the contingencies account. You will remember that last year 1890 was an exceptionally profitable year. We paid a dividend of 6 per cent., plus a bonus, making 7 per cent.; but the shareholders agreed with the Board that it would be very wise to start a contingency fund which was to be applied for such contingencies as occurred this year—a break of the cable or any expense of that kind—a fund out of which we could meet these things without trenching on our reserve fund. We all agreed a year ago that the great thing was to build up our reserve fund, so that when the time came for renewing our debentures or laying an additional cable we should be in funds to effect either object. The last paragraph of our report deals with the dividend. We put, as usual, £2,500 to our reserve fund, to which is also added the interest of that fund, which is invested in securities. We next pay our debenture interest and then provide for a dividend of 10 per cent. on the preference shares. There then remains a sum with which to pay a dividend on the ordinary shares at the rate of 5 per cent. per annum, leaving us with a small sum of £270. 4s. 10d. in hand. This balance we propose to carry again to the contingencies fund. We have taken the whole of the cost of the repairs—£1,600 odd—out of this fund, and the sooner we build it up again, so as to have a fund in hand for future contingencies, the better. It is quite true that we could have paid 6 per cent. by appropriating this £270 to the purposes of dividend, but I think it would have done us more harm than good. The present moment is—I will not say critical, but one requiring a great deal of consideration and forethought. We are now working at the reduced tariff, and how that will operate on us, it is impossible to say. Naturally if you get less for what you do, you must suffer a loss, and the only way we can recoup ourselves is by getting an increase of traffic, and that is a matter which we have no control over. I think, therefore, you will agree with me in the wisdom of paying a dividend of only 5 per cent., and of carrying this odd amount to the contingency fund. I have nothing farther to say regarding the working of the past half-year. You would be glad, perhaps, to know how the three months' working from the 1st July under the new tariff has affected us. I am, however, rather reluctant to make any observation on that point, as three months' working is not enough. As you know, there have been in Spain dreadful calamities lately, and all that has caused a great deal of business for us. We have carried more words than in 1889—I again leave out 1890—but the tariff is lower. As far as money is concerned we are still losers: that is to say, the increased traffic at the reduced rate has not quite compensated us for the loss of ½d. per word; but it seems that we have a right to expect that before long the two will balance each other. I do not think I have anything further to say, and I will now propose:—

"*That the Report and Accounts now presented be, and they are hereby, received and adopted.*"

Mr. JOHN DENISON PENDER seconded the motion, which was at once unanimously adopted without discussion.

The CHAIRMAN: The second resolution which I have to propose is as follows:—

"*That the dividend at the rate of 10 per cent. per annum, less income tax, on the preference shares, and a dividend at the rate of 5 per cent. per annum on the ordinary shares, free of income tax, both for the half-year ended June 30, 1891, be and are hereby declared.*"

Mr. J. D. PENDER seconded the motion, which was unanimously carried.

The CHAIRMAN having intimated that that closed the business,

Mr. WALTER BARNETT said he thought it would be only right before the shareholders separated to pass a vote expressing their sympathy with the Chairman of the Company in his sad bereavement, for he was sure that the shareholders all sympathised most deeply with Sir James Anderson. He then proposed the following resolution:—

"*That the shareholders of this Company, assembled in general meeting, beg to tender to Sir James Anderson and his family their sincere sympathy and condolence in their sad bereavement.*"

Mr. DAVID LOWE seconded the resolution, which was carried unanimously.

The CHAIRMAN: We will forward this resolution to Sir James Anderson as soon as possible.

Mr. CHARLES BURT then proposed a vote of thanks to the Chairman and Directors for their management of the Company's affairs in the past half-year. The Chairman had given them a full explanation of their affairs, and it was always a good thing to have a Chairman who could make such a statement, as it showed that he knew all about it.

Mr. J. P. CREASEY seconded the motion, which was unanimously adopted.

The CHAIRMAN briefly acknowledged the compliment, and the proceedings then terminated.

City of London Electric Lighting (Pioneer) Company (Limited).

An extraordinary general meeting of this Company was held at Winchester House, Old Broad-street, on Wednesday, for the purpose of considering, and, if thought fit, passing the following resolution, that is to say: "That the Company be wound up voluntarily." The Lord Mayor (The Right Hon. Sir Joseph Savory, Bart.,) presided.

The SECRETARY (Mr. J. Cecil Bull) having read the notice convening the meeting,

The CHAIRMAN said: Gentlemen, you will have heard from the notice which has just been read by the Secretary, the object for which this meeting has been summoned. It is my duty to tell you that the object for which this Company was formed has now been realised, and we have sold the concern to the City of London Electric Lighting Company for the sum of £75,000, clear of all deductions. I think this must be, and will be, satisfactory to the body of shareholders, and I feel no doubt that you will unanimously pass the resolution which it is intended to place before you to-day. Any question which any shareholders may like to ask I shall be very happy to answer, but I will now formally propose—

"*That the Company be wound up voluntarily.*"

Mr. J. B. BRAITHWAITE, Jun.: I have great pleasure in seconding the resolution. I think you will all agree that the shareholders of this Company will be fairly well satisfied with the result of their investment in the Pioneer Company, and still more satisfied that they have succeeded in their object, which was to undertake the efficient lighting of the City of London. This Company stepped into the breach in February last, when things were very dull, and it was necessary to make an early start and take up the matter pending the working out of the engineering and other details, and the making of the financial arrangements necessary to enable the formation of a Company adequate for the lighting of the City of London. I have much pleasure in informing the shareholders that the formation of a company with an adequate capital to light the city of London has been successfully carried out. The object for which this Company was formed has, therefore, been attained, and the shareholders will receive back the money they embarked, with a bonus of 50 per cent.

The CHAIRMAN then put the motion to the meeting in the usual way, and declared it carried unanimously. He afterwards said: I have now only to add that another extraordinary general meeting will be held in about a fortnight, and that cheques will be made out as soon as possible after the confirmatory meeting.

Mr. LEE said he thought they might fairly and properly pass a vote of thanks to the Lord Mayor and the Board of Directors for bringing the affairs of the Company to so happy a termination. He thought it must be very gratifying to the Lord Mayor, occupying his position in the City of London, to feel that his efforts had been crowned with success in bringing about the lighting of the City in the manner which had been contemplated. There was no doubt that the point had been mooted that Lord Mayors had no right to put their names upon prospectuses, or even to become Chairmen or Directors of public Companies; but this was an exceptional case and an exceptional Company. The Lord Mayor, as head of the City, had acted almost as a philanthropist in his desire to serve the City by heading the Board of Directors in promoting the Pioneer Company, which at the time was contemplated not only for the benefit of its shareholders, but also for the whole of the City of London. He thought they would agree with him that the Lord Mayor and the Directors were entitled to the shareholders' thanks.

Mr. FOSTER MACGEAGH said he had great pleasure in seconding the resolution. He felt sure that the citizens fully appreciated the fact that in a very short time they would have the advantage of the electric light in the City, especially during the dark evenings.

Mr. LEE put the motion to the meeting, and it was carried unanimously.

The CHAIRMAN: Gentlemen, I am extremely obliged to you for the vote of thanks so kindly proposed by Mr. Lee and seconded by Mr. MacGeagh; and on behalf of my colleagues I beg to thank you most sincerely for the kind expressions which you have been good enough to use with respect to our endeavours in connection with this Company. It was my firm resolution when I entered upon my term of office to join no public company; and it was only through very exceptional reasons, and through the pressure brought upon me from very high quarters, that I was induced to so far waive my resolution as to join this Company. I can assure you that it is a satisfaction to me that I am able to announce to this meeting that the work which we have in hand has progressed so satisfactorily, and that we have so far carefully protected the interests of the shareholders.

The proceedings then terminated.

Brush Electrical Engineering Company (Limited).

The second annual general meeting of the Brush Electrical Engineering Company (Limited) was held at the Cannon-street Hotel, on Friday last, under the presidency of his Grace the Duke of Marlborough.

The SECRETARY (Mr. B. Broadhurst) having read the notice convening the meeting, the report of the Directors was taken as read.

The CHAIRMAN said: It is a somewhat difficult position that I occupy to-day, having assumed the position of Chairman of this Company for what I may say was a broken year. I have had the pleasure of being connected with the Company for three years, and have watched its progress and seen the difficulties it has had to contend with; and when we, unfortunately, lost the valuable services of our late Chairman, Lord Thurlow, the Directors were kind enough to ask me to carry on the business of the Company as Chairman for the remainder of the year; and that duty I was very pleased to accept. Perhaps, personally, it is a fortunate circumstance for me that I should be able to bring to your notice so favourable a balance-sheet as that which is now before you. It is some years since the Company was able to feel that its position was one of commercial stability, and therefore it is very fortunate for me that I should be the spokesman of the present very much improved condition of affairs. The history of your Company is a peculiar one. It was founded in 1879, and has therefore been about twelve years in existence. At that time there was an idea that the electric light was going straight away to sweep away the gas companies, and, in fact, completely revolutionise the conditions of our homes and also of our industries. That anticipation was not fulfilled. We found out, as electricians could have told the public at the time, that although there was great hope in the future, yet hundreds of problems still remained unsolved, and that not only with respect to the production of the electric light itself, but also as to its distribution, it would take years before we could place the industry on a commercial basis. At the inception of your affairs you had many valuable patents, which you sold for large sums, and your dividends were enormous. One year you absolutely paid a dividend of 100 per cent. Well, it was not to be supposed that such a state of things as that could exist without turning men's heads, and making them go beyond the limits of prudent enterprise. The consequence was that in a very few years the Brush Company got into very considerable difficulties, and the then Chairman—I think it was Sir Henry Tyler—resigned. At that time Lord Thurlow became the Chairman of the Company, and it really was a terrible time to have undertaken the chairmanship of the Board and the direction of the affairs of the Company. Not only was there the difficulty of discouragement created by the failure of early promises, but there was the extreme difficulty created by the character of the early electric light laws, which were of such a nature that it was impossible to capitalise undertakings where there was no security to shareholders that they would not be bought out at a price which would in no way pay them for their investment. To amend the Electric Lighting Act was quite an undertaking. Your late Chairman, Lord Thurlow, in conjunction with other gentlemen, was very largely instrumental in getting this Act amended and in getting other measures passed; and it is through these amendments that the electrical industry has become possible in this country in the form of public lighting. I think, therefore, that we owe our late Chairman a great debt of gratitude for having—perhaps somewhat unobtrusively—worked at this question, as he did, in the House of Lords, and for having, as he did, carried out the affairs of this Company for four or five years of considerable depression, times when we were able to pay no dividend. I think it was only in one year—1885—that a dividend was paid at all, and so matters went on, and, as you are aware, it was necessary to bring about a reconstruction of the Company. That period is now passed, and I am able to put before you quite a different prospect for the future. The turning point in the affairs of the Company was, first of all, its reconstruction; and, secondly, as I have said, the amending of the Electric Lighting Act. The object of this Company is not to do small work—what I should call retail work; but to carry out large industrial enterprises. Electric energy has many features and many sides for its development. There is electric traction, there is electric mining—in fact there are numerous ways in which the energy called electricity can be employed, but the principal reason for the existence of your Company is for the purpose of developing electric lighting centres. Now, you are going to have a gradual and, by slow degrees, an immense demand for the establishment of these large electric companies. What the gas companies did in former times electric lighting companies are going to do in the future, and there is a large field open to a Company like ours. The obtaining of the Electric Lighting Act was, therefore, invaluable to this industry. In order to be able to carry out the work of the Company, the Directors decided that it would be very advantageous to obtain some large manufacturing premises, and negotiations were carried out by which you obtained the Falcon Works, at Loughborough, in Leicestershire. Your Board have visited these works on several occasions, and have great pleasure in reporting to you that you are possessed of some very splendid manufacturing works, where you can make dynamos and engines on a large scale—in fact, as large as any works of the kind in this country. They have begun in a conservative spirit, but as the industry developes, I am sure you will approve of these works being extended. To-day the particular feature of your Company is that you are looking forward to acquire large and important orders for the carrying out of electric light centres, and that you possess the Falcon Works, where you are able to manufacture the plant for carrying out those enterprises. The policy, in fact, has been to concentrate our energies, and to get rid of outside obligations. I will mention some of those features a little later on, in a few remarks which I shall make to you then; but I will turn my attention now just for a moment to one or two small features of the report placed before you. Another of your Directors, Mr. Braithwaite, will speak on the subject of the Report itself, and analyse the particularly favourable character, financially, of the figures. The only point, perhaps, which it is my duty to insist upon with regard to the balance-sheet, is that it includes nothing except that which is fair, honest trading profit of the year. There is no profit from the City undertaking carried into this year's figures, nor anything connected with our having disposed of the Bournemouth station, nor with respect to the money we have received for the sale of certain land to the South Eastern Railway Company It is nothing more than a trading account, and it shows that in the year under consideration we have made a gross profit of £39,915, as compared with £36,698 in the previous year. This brings me to say a few words on the City undertaking. Perhaps, our shareholders do not all realise what an extremely important thing this is. Probably there is no undertaking in the whole of Europe at the present time which represents an exact parallel to the undertaking which you are concerned in carrying out. This is the only town, so far as I am aware, where the whole of the private and public lighting has been intrusted to one big Company, the City of London Electric Lighting Company, which, for the period of 40 years, thus has a monopoly. If you consider the conditions in regard to other parts of London, where Provisional Orders have been given, you will see the advantage which the City Company possesses. In every other district the Board of Trade have decided to give two Provisional Orders in every district—one, as a rule, for the continuous current, and the other for the alternating current system. That is undoubtedly, in the long run going to create complete confusion and cause disappointment to shareholders. What is going to take place is this: One company will start with one system, and when it has got a certain way towards lighting the district, another company will be formed and will put down another system, and there will be competition. It will not be fair competition, but of the character of trying to bounce one system with threatening it with competition by another. The reason it cannot be fair competition is that the streets of London do not admit of laying two sets of cables—that is, when you have laid out the system of cabling necessary to supply one central system of energy, you cannot find room to lay another network. It is exactly as if you had two telegraph companies trying to run their wires over the same district. There is, however, nothing of that sort in the City. Here you have a perfectly clear field, and there can be no competition. So long as the City Company fulfils its duties and carries out its work it has a monopoly. You will see what advantage that is to this Company when I tell you that we are interested to the extent of two-thirds in this matter. The City being divided into three parts, we have got two parts, while another group of gentlemen, who are representatives of an American firm of some position—Messrs. Thomson, Houston and Co.—have been able to obtain the other portion. However, that has nothing to do with us at the present moment. The point for our present consideration is that we are interested in two-thirds of this large undertaking; and if the City of London Company succeed in carrying out their work satisfactorily and avoid the mistakes made in some of the earlier electric lighting enterprises, your Company will get the credit of all that success, and that must eventually lead to the development which I pointed out just before, that is, the development of central lighting business, which is the main feature of our industry. I think I cannot impress on you too strongly what an immense advantage it is to you to have obtained this valuable order; and in passing I cannot help saying that I think you ought to know that you owe it entirely to the services and the persistent labours of your Managing Director, Mr. Garcke. Although your Directors have given every attention to your affairs, it would have been impossible for them to have negotiated this enterprise, but for several years Mr. Garcke has been working at this matter, and has succeeded in carrying it out. I must say that I think it is largely owing to his successful labours in connection with this matter that we are able to come forward and make such a very favourable report—not simply with respect to the balance-sheet, but with respect to the prospects of your Company generally. The next point I will allude to is the question of Bournemouth. You are aware that it was considered advisable to establish the Bournemouth business for the purpose of demonstrating what the electric light could do. There has been so much ignorance in former times as to the electric light, and it has been so necessary to push this industry, that we have been very much puzzled at certain times to know what policy to adopt; and it was considered advisable, at one period, to push a business at Bournemouth. This was successfully done. This matter ended by our obtaining a Provisional Order, and the Company carried on the work themselves—that is to say, we became the electric lighting agency under the Provisional Order. That was an unsatisfactory position, in the opinion of your Board, for a manufacturing company to be placed in; and we thought it would be more advisable, if we could to realise the values there locked up, and place ourselves in a freer position. Negotiations were, therefore, set on foot for this purpose, and they ended successfully in floating the Bournemouth Company, and the terms of that arrangement were not at all unprofitable to us. We were repaid a fair profit on our plant, and we have taken the payment of £17,275, partly in cash and partly in shares in the Bournemouth Company You are, therefore, free from any difficulties or any engagements with respect to Bournemouth; and this matter is now in the hands of a Local Board, composed of gentlemen who have local interests, and with intelligence, energy, and determination to make that business succeed. The capital of the Company formed there is £30,000, and your Company have guaranteed a dividend of 5 per cent. on that amount for a period of three years; but I do not think, judging from the returns at Bournemouth and the demand for the electric light there, that you are really incurring any risks by giving that guarantee. I now come to another feature of our industry—that is, our business at Vienna and Temesvar. At one period during the past five years it was considered advisable to acquire the Vienna business. It was acquired at a very cheap price, and a great deal of time and energy has been devoted

Digitized by Google

to developing this Vienna business. We have a factory there which was of a temporary character, but it has been extended by our permanent works, which are now nearly finished, and a large business is being done there. Temesvar is a place whose situation is something like that of Bournemouth. We undertook the lighting of that town, and are still carrying out the business, but negotiations are going on both with respect to the Temesvar business and the Vienna factory, which may very likely end in your Company disposing of your interest in those places on favourable terms to yourselves. There is a great deal to be said against what I would call "long-arm management"—trying to manage an industrial enterprise abroad, especially in such a city as Vienna. Where you are interested as sleeping partners in a concern managed by others you need not be alarmed, but where you are responsible for the expenditure and for all mistakes you cannot manage, as successfully as people on the spot, a business like the electric light in such a city as Vienna. From my knowledge of the circumstances, if an arrangement can be carried out financially advantageous to yourselves by which you can dispose of the Temesvar and Vienna business—which has grown largely during the time it has been in your hands—you will be adopting a wise and prudent course in transferring it to others. I have only one or two other matters to touch upon. One is as to our sale of land to the South Eastern Railway Company. Negotiations went on for a long time with that Company respecting a portion of the ground on which our Lambeth works stood, and they resulted in an agreement being made for the sale of a portion of a strip of land. The agreement was carried out and the purchase money has been paid; but unfortunately the sale of that strip of land has interfered with some of the offices of the Company, and we have, therefore, been obliged to take offices for the Directors and for the commercial department elsewhere. These offices have been taken in Queen Victoria-street, near the Mansion House Station, and in the same block is a shop which belongs to the Company, in which there is a large exhibit of our manufactures. For the next few years you are possessed of these offices on lease, and the premises generally where the commercial part of the Company's affairs will be carried on. Meanwhile, the Victoria Works at Lambeth will remain as they are, so far as the construction department goes; and the technical and draughtsmen's offices will remain there. I now come to the question of the Australian business. You know that you have a branch of business in Australia, and a great deal of trouble and thought has been devoted by the Board, and also by your Managing Director, to its development. We have a manager, Captain F. Rowan, who represents us there, and does all he can to develope our interest on that side of the world. It might seem that there was not a great deal to be gained just at present by establishing such a branch of our industry, and yet when we think of it, we must see that it cannot be our Colonies that will develope this new business unless we go in first and start it. There is no doubt that the Colonies will largely require all the things which we can supply them with and which they will not be in a position to provide for themselves; and although there is not at present a very large demand, there is a satisfactory demand springing up, and the business is a growing one. I therefore think that in a few years time you may hail with great satisfaction the fact that your Board were inspired with the idea of getting early into the Australian field and obtaining a large amount of the custom of our cousins on the other side of the world. I think that, although the profit on the first year's work is not large, it affords us an indication of what the working of this business may eventually tend to, and I think we may fairly look forward with hope to the development of a very considerable business in Australia and in the Colonies in the course of the next few years. We are really only at the commencement of the development of this marvellous invention. Ten years have gone by, and manufacturers on one side, and men of science on the other, have been trying to thresh out this question of electricity. It has been in the hands of mathematicians one day, and "chucked" at the heads of engineers the next; but we are now getting out of that state of things. The engineers—that is, the men of business—and the professors are agreed, and have come to the conclusion, practically, that we now know where we are moving. It is simply now a question of expense. When the public can afford to find the money for the lighting of their towns by electricity, we, the Brush Company, and other companies are in a position to solve the problem for them. There is no doubt about that. Ten years ago, when this Company paid its 100 per cent. dividend, we were not in that position. To-day you have an established industry. It is in an essentially conservative sense that your Directors do not recommend that the thing should be pushed or "boomed" in any way; but they feel, on the other hand, that it is simply a question of time and expense when they will be able to obtain any number of orders they require, and to be able to do a thoroughly good business, and one very remunerative, in every sense of the word, to the shareholders of the Company. I feel no hesitation, therefore, in speaking in the most hopeful way with respect to the future. I may just say, in passing, that, as compared with the average of five years preceding the reconstruction of the Company, the volume of business has increased in the ratio of 100 to 288—that is, nearly 200 per cent.—while the standing charges have only increased in the ratio of 100 to 113, or, say, 13 per cent. You see that the policy of your Board has been to keep down, as far as possible, the standing charges, and not to let them run ahead of our business. The gross volume of our business has increased, and the fixed charges have been very stationary. You will observe, therefore, that I am right in saying that our policy has been an essentially conservative one. I think I need not keep you any longer, but I will leave to Mr. Braithwaite and other Directors to point out the financial features of the balance-sheet. I think I may conclude by saying that you have before you every prospect of a successful year, and I hope that the next time we meet we shall be able to present quite as successful and prosperous a report as the one laid before you to-day. You are aware that we have not only lost the services of Lord Thurlow as Chairman of the Board, but we have also lost, I am sorry to say, the invaluable services of Mr. John Sellon, who was for so many years connected with this Company. It was with great regret that his co-Directors lost his help; but he was unable, owing to his many engagements and the large amount of business which he has to conduct, to continue to give his personal attention to the affairs of the Company. It is now my duty to conclude by moving:

"That the Report of the Directors and the Statement of Accounts to the 30th June, 1891, as now presented to the shareholders, be received, and the same be hereby approved."

Mr. J. B. BRAITHWAITE, jun., in seconding the motion, endorsed the remarks of the Chairman that the balance-sheet was purely a trading, and not in any way a speculative one. The results shown had been entirely derived from their ordinary trading, and not one penny of credit had been taken in the balance-sheet in connection with the City of London Order, or from the sale of the Bournemouth business or the sale of land at Lambeth to the South Eastern Railway Company. It would not have been right to have included such items, but he merely desired to point out that the profits shown were entirely from the business. If they concluded that that was a favourable balance-sheet, drawn up on such lines, they might look forward with considerable satisfaction to any future balance-sheets the Directors might present. There was one great change in the balance-sheet this year, and it had been made at the suggestion of their auditors. They had rendered a separate balance-sheet connected with their foreign and colonial branches, and it showed a balance of assets over liabilities of £64,530, which they brought into the general balance-sheet. In the general balance-sheet itself it would be noticed that their capital had been increased in the year by £5,000, which was the remaining payment they had had to make to acquire the Australian business. There was an item on each side of the balance-sheet connected with the City of London Electric Lighting (Pioneer) Company. On the debit side the item was £34,892, which represented money they had received from the Pioneer Company and others, as advances in order to go on with the City of London work; and on the other side of the balance sheet the item of £21,070 was the amount which, up to the date to which it was struck, they had spent on this work. Now that the City company had been formed, these items would disappear in future from the balance-sheet. The £21,070 was the amount spent on the work, and did not include any item of profit—not even ordinary trading profit. They had begun the formation of a reserve fund—a fact which he was sure they would be glad to hear, and he hoped that every year it would be increased. Perhaps some of them might think that the amount, £4,275, was so small that it was not worth while to have shown it; but he regarded the entry with much satisfaction; and the amount represented a portion of the money they had received from the sale of the properties. They might call this a cash reserve to start with, and it would be the policy of this Board to increase this fund as opportunities offered, until it amounted to such a sum that they felt they had attained a position of financial stability. The property account was largely reduced as compared with last year, but the details of this were given in the report. Passing to the profit and loss account, he stated that it would be seen on the credit side that the gross profit, including the net profit of the foreign and colonial branches, had amounted to the very respectable sum of £39,915 during the year, in spite of the fact that the Managing Director and a good many of their officers had had a great deal of their time taken up in connection with the City lighting, the results from which would not appear until next year. Their standing charges had been reduced compared with those of last year, almost every item showing a reduction. There was a new item on the debtor side of the profit and loss account to which he thought their attention should be directed—he referred to the item of "staff bonuses," £759, and he hoped they would all agree with the policy of the Board in this matter, which represented, in fact, the adoption by them of the profit-sharing scheme. As far as it had gone they had every reason to be satisfied. They commenced the scheme by placing on it all their chief officers. They had now put on another series, and this year they would be able to still further extend the benefits of the scheme to all their foremen, and possibly to all the men who had been any length of time with them. Eventually they hoped to extend it to every man in their employ. In view of the nature of their manufacture, and how much depended on the care and skill of their workmen, he regarded it as not only right but also expedient to give every man an interest in the profits. With reference to the appropriation of the profits, they proposed to distribute a dividend on the ordinary shares amounting to £7,018. To show how thoroughly honest and business-like the balance-sheet was he desired to call their attention to the fact that in addition to paying this £7,018 in dividends, they had written off against revenue other items equal in amount to it. It was perfectly right to have done this, but he thought the shareholders ought to see that if the Board had cared to do so they could easily have paid another £7,000 to their shareholders, but he thought they would agree with him that the amount written off was right. They wrote off, first, £3,000 against property, and then £630 against preliminary expenses, reducing them to about £630, which would be finally extinguished next year. There then remained £306 to carry forward, and in the profit and loss account they wrote off against the revenue the whole cost of maintenance of plant and buildings, £2,184, and of the patents £480, as well as the whole of the loss incurred by closing the Cardiff Station, £447. The closing of that station was not owing to the fact that it was not answering, but to the fact that the Corporation of Cardiff refused to let the Company apply for a Provisional Order for lighting the town, and that the Board of Trade declined to allow them to continue their lighting without the consent of the local authorities. They had, therefore, been in the position of not being able to light the place themselves, while no one else had been willing to do so. They therefore had no alternative but to close the Station. If the Corporation of Cardiff should ultimately decide

Digitized by Google

to undertake the lighting of the town it was by no means unlikely that they would come to the Company. They had thus written off against revenue in connection with these items, an amount equal to the sum they would distribute on the ordinary shares. It gave him great pleasure to second the motion for the adoption of the report.

Mr. E. K. SMART said he thought that instead of saying in the report that they recommended a dividend at the rate of 6 per cent. per annum for the half-year, it should have been 3 per cent. for the year, for there was no doubt that the dividend proposed by the Directors had been earned in the whole twelve months. With reference to the Debentures, he hoped that as the Company was in a much firmer position, an effort would be made to reduce the interest, 6 per cent. being too much for a stable company to pay on debentures. He thought that the amount of property and plant should be stated separately from the goodwill and the amount paid for patents. With regard to the gross profits, the Company had been in active operation for the whole twelve months, and had done as much business as possible, and yet the gross profit was only 9 per cent. on the capital of the Company.

Mr. WEIR wished to express his great satisfaction at the condition of the Company. He was an original shareholder of the Brush Company, and had followed the career of the Company for ten years. They now appeared to have passed through the experimental stage, which was always a very trying stage, and they had arrived at the producing stage. He hoped they would continue to have plenty of work to keep their machinery engaged. He was glad they had adopted the profit-sharing system among the heads of departments, and that they were going to extend it, for he was sure that that was the way to avoid strikes. He had been glad to hear the Chairman speak so highly of the services of Mr. Garcke, and he thought the shareholders ought to congratulate themselves on seeing that that gentleman occupied the position of their Managing Director. Mr. Garcke had stood by the Company throughout, and he hoped that he would continue to do so, and that he would share very handsomely in the profits. With respect to the previous speaker's observations regarding the dividend, it mattered not whether it was for three months or twelve months so long as they received a fairly-earned dividend. He desired to ask whether any progress had been made in the use of electricity for light railways and tramways, and whether their machinery was suitable for light railways, such as were now being constructed by the Government in the West of Ireland.

The CHAIRMAN: With respect to the few remarks that have been made, and the few questions asked, I will reply to them *seriatim*. As to the question about the dividend, I think that the last speaker answered it. The dividends are paid half-yearly, and the dividend has been paid practically for the last half-year. If you like to say that it is 3 per cent. for the whole year instead of, as we say, 6 per cent. per annum for six months, it is a matter of opinion. As to the rate paid for debenture interest, undoubtedly I think that the day will come when we shall be able to fund that debt on more favourable terms; but when these debentures were issued the conditions were totally different from those now prevailing. It is of no use counting your chickens before they are hatched, but I hope that our position will improve considerably as time goes on in this respect. With regard to the gross profits being only 9 per cent. on the whole capital of the Company, you must remember that the Company has gone through some very considerable vicissitudes, and that as to a great deal of that capital, though it will earn a dividend in the future, it has, to a great extent, been spent on building up the enterprise you now possess. It was not to be supposed that every shilling of expenditure would be remunerative. You have had to pay for litigation, you have made mistakes, and there have been all sorts of things to contend with; and you will have more mistakes. I hope you will have less litigation. It is impossible not to have mistakes, but the industry promises to grow, and it will carry all the money it has required to acquire the experience that we have gained. I think you will see less capital expenditure in future, and larger returns. With respect to the division of the item of "property, patents, and goodwill," you must remember that that item of £266,270 represents what has been paid by you for these things. It is no use to divide these items out into the numberless headings they represent. We could put out the money paid for patents, for premises, and for goodwill; but in a statement of this sort we cannot distinguish, and it appears as one item. We took this all over from the old company, and we have it entered at that figure, but we have not set it out as so much for patents, so much for premises, and so much for goodwill. It is a bargain that we have made, and it will not look any better if we divide it out. As to the question of the tramway business, that is a very important feature in electrical industry. We are very anxious indeed to develope the electrical traction business. We have one contract which we are carrying out, which I hope will be successful; and some of our technical staff have only lately returned from America, where they have been giving close attention to this question. Mr. Mordey has only just returned from America, and has brought us full details with respect to electrical traction there. In America electrical traction has taken an immense start. There is sure to be a large demand grow up for light railways on electrical principles in outlying districts, such as in the West of Ireland. The Falcon Works we took over were originally a car company, and the car-making feature has been preserved by us. We are making cars, and our technical staff are giving as close attention as they can to the development of electricity for tramways, and we shall try and obtain a fair proportion of the orders given by the public for tramway cars and light railways in the future. That answers all the questions asked, and it is now my duty to put the motion to the vote.

The resolution was carried unanimously.

The CHAIRMAN proposed:

"*That the interim dividend at the rate of 6 per cent. per annum paid upon the preference shares of the Company for the six months ended December 31st, 1890, be confirmed; and that a dividend be declared upon the preference shares and upon the ordinary shares of the Company at the rate of 6 per cent. per annum for the six months ended 30th June last, and that the same be paid on 1st October, 1891.*"

Mr. BRAITHWAITE seconded the resolution, which was unanimously agreed to.

On the motion of Mr. B. H. VAN TROMP, seconded by A SHAREHOLDER, the Duke of Marlborough and Mr. Aymor H. Sanderson were re-elected to their seats at the Board; and the Auditors (Messrs. Cooper, Bros. and Co.) were subsequently re-appointed.

Mr. WEIR then proposed and Mr. DURRANT seconded, a vote of thanks to the Chairman and Directors.

The resolution was unanimously passed.

The CHAIRMAN: As Chairman, and as representing the Directors, it is my duty to thank you very sincerely for your kind acknowledgment of our efforts on your behalf. You may be quite sure we shall continue them, and, in fact, increase our efforts to produce the success which we are certain will attend the operations of the Company during the present year.

The meeting then terminated.

NEW COMPANIES, STATUTORY RETURNS, &c.

ATLAS CARBON MANUFACTURING COMPANY (LIMITED).—This Company was registered on September 24th, with a capital of £2,000 in £1 shares by Slaughter and May, 21, Great Winchester street, E.C. The objects are, to manufacture, sell and deal in carbons, glass, india-rubber, vulcanite, iron, copper, and other metals, electric conductors and non-conductors, and all machinery, plant, apparatus and appliances necessary for the generation, distribution and accumulation of electricity; to enter into an agreement with W. J. Woodward; to enter into any contracts for the supply of electric light and energy; to acquire the right to use, manufacture, or put up telegraphs, telephones, phonographs, electric bells, and all kinds of electric apparatus. Registered without special articles.

JEWISH COLONISATION ASSOCIATION.—This association, which was registered on September 10, 1891, with a capital of £2,000,000 in £100 shares, includes, among the objects of its incorporation, the forming of Jewish colonies in various parts of North and South America and elsewhere, for agricultural and commercial purposes, and the construction, establishment, and maintenance of all roads, tramways, railways, bridges, harbours, fortifications, gas and electric light works, telegraphs, telephones, and other works of a public or private character. The management of the association will be under the control of a "Council of Administration," with offices at 17, Old Broad-street, London, E.C.

LAW'S ELECTRICAL APPLIANCES COMPANY (LIMITED).—This Company was registered on the 23rd September, 1891, with a capital of £4,000, in £5 shares, by Davidson and Morriss, 40 and 42, Queen Victoria-street, E.C. The objects are: To enter into an agreement with Edward F. Law, and to work the inventions, patents, and rights (particulars of which are not given) mentioned in a draft of the agreement, to enter into an agreement with William Clowes and Sons, Limited; to carry on the business of type setters and compositors, by machinery and otherwise, printers, lithographers, telegraphists. The first Directors are Major E. F. Law, Sinclair Macleay J. T. F. Otway and S. H. Isles. Solicitors, Davidson and Morriss.

TRENT CYCLE COMPANY (LIMITED).—This Company has been registered with a capital of £10,000. The chief object of the Company is to manufacture and deal in cycles, and, in addition, to carry on the business of mechanical and electrical engineers, machinists, wire-drawers, tube-makers, galvanisers, electro-platers, and other businesses incidental to the manufacture of cycles.

JOSIAH WADE (LIMITED).—This Company has been registered with a capital of £20,000, and included in its objects are those of mechanical and electrical engineers, machine and tool makers, boiler makers, iron founders, printers' furnishers, &c.

CHARLES WALMSLEY AND COMPANY (LIMITED).—This Company was registered on September 25, 1891, with a capital of £30,000, in £5 shares, by Hooper and Son, 69, Ludgate Hill, E.C. The objects are to acquire and take over as a going concern and carry on the business of a mechanical and electrical engineer and machinist, now carried on by J. Smethurst, under the names of Charles Walmsley and Co. and the Atlas Ironworks Company, at Elton, Bury, in the County of Lancaster. The first Directors are: C. Walmsley, J. Byrom, J. Cronshaw, T. Thornley, and T. Holt, all of Bury. Qualification, £500. Solicitors, Butcher and Barlow, Bury.

CITY NOTES, &c.

ANGLO-AMERICAN TELEGRAPH COMPANY.—At a meeting of the Board of Directors of this Company on Friday last it was resolved to declare an interim dividend for the quarter ended September 30th of 12s. 6d. per cent. on the ordinary stock, and £1. 5s. per cent. on the preferred stock, less income-tax, payable on October 31st to the stockholders registered on the books of the Company on September 30th.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the past week were £4,915.

CALLENDER'S BITUMEN TELEGRAPH AND WATERPROOF COMPANY (LIMITED).—An interim dividend of 5s. per share has been declared by the Directors of this Company, payable on October 31st.

Digitized by Google

CITY AND SOUTH LONDON RAILWAY COMPANY.—The traffic receipts of this Company for the week ended September 27 amounted to £708; aggregate receipts for half-year to date, £8,917.

THE HALIFAX AND BERMUDAS CABLE COMPANY.—A private meeting of this Company was held on Wednesday last, to which reporters were not admitted.

SUBMARINE CABLES TRUST.—Notice is given that on and after the 15th inst. the balance of the coupon due in April last (£2) will be paid by Messrs. Glyn, Mills, and Co., of Lombard-street, E.C., between the hours of 10 a.m. and 2 p.m. The coupons should be left with the bankers for examination four clear days before payment. The certificate holders are requested to present the coupons for April only, and not those payable on October 15, 1891.

THE RISE IN ELECTRIC LIGHTING SHARES.—The *Observer* of the 27th ult., commenting on the recent rise in the price of electric light companies' securities, says:—In 1882, electric light companies, with a combined nominal capital of 25 million pounds, were introduced to the public, and a boom in electric light shares generally took place. The results obtained in the way of dividends by those companies who started business were not encouraging, and the shares steadily declined in popular favour, until the Board of Trade, after a long inquiry into the claims of the various companies for lighting certain Metropolitan districts, divided London into suitable areas. From that time certain of these undertakings have been quietly receiving the attention of investors who believe in the dividend-earning possibilities of the electric light. Prices have thus steadily advanced and show a considerable rise on last year's quotations. Below are the highest and lowest prices of the shares in 1890 of the electric light companies quoted in the official list and the price to-day:—

	Paid on shares.	Price 1890. Highest.	Price 1890. Lowest.	Price Sept. 26th.
Brush Electrical	£3	2 15/16	1¼	3⅜
Electric Construction	£10	8½	7⅛	6⅛
Metropolitan Electric	£10	*8½	5¼	10½
Swan United	£3½	4 1/16	5⅜	5½
Westminster	£5	—	—	6¼

* £8 paid.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended September 25th, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £3,833.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 699.—Vol. XXVII. FRIDAY, OCTOBER 9, 1891. Price Fourpence.

NOTES.

Mr. Denny Lane, the manager and secretary of the Cork Gas Company, is one of the few gas engineers who do not labour under the delusion that we are bitterly opposed to gas and everything connected with it. Where would electric light be if we had not begun by hundreds of small jobs run with gas engines? Where should we be without a little healthy opposition? Mr. Lane's article which we print in the present issue is worthy of the careful consideration of electrical engineers. At the first glance it seems to threaten an intrusion upon the work of electrical engineers; but if towns like Cork find that they can use electric light if distributed by means of their existing gas mains, so much the better for the electrical trade.

The method of measuring the heat developed by magnetic hysteresis, which is described by Prof. Ewing on p. 631 of the present issue, seems, as he says, to admit of no doubt. So long as this matter depended on complicated arrangements of dynamometers and other more or less accurate modes of determining the power given to and the power yielded by a transformer, it was generally felt that the quantity to be detected was hardly to be distinguished among errors of observation or of correction. But the simplicity of Prof. Ewing's method cannot fail to carry conviction of the results—when we get them. We were in error last week in saying that he has already employed it; for the coils are wound, but he has not yet experimented with them. The fact that the heat is generated in the one case by the current in exactly the same part of the transformer that is heated in the other case by hysteresis, is a great improvement over the method of warming one of the conductors, and the balancing can be checked by rearranging the connections of the two coils. We have received a letter from two correspondents who have studied the magnetism of iron with more care than they perused Prof. Ewing's article last week, and they draw attention to "a serious fallacy underlying Prof. Ewing's explanation;" but yesterday morning's post brought an urgent appeal that the communication might on no account be published, as there was a "nigger" in their argument.

It would be unfair to hold a man responsible for the utterances recorded in an interview, since the victims of this development of journalism are often more surprised than anyone else when they see the "interview" in print. But, however much the opinions of Mr. Massey may have been garbled by an evening paper last week, it is evident that he is but little satisfied with the present supply of electrical energy in London. He is reported to advocate "three big stations, each as large or larger than Deptford; one should be situated at the waterside, at, say, Bermondsey or Wapping, another near the water at Hammersmith, and the third somewhere in the neighbourhood of the Regent's Canal." It is not clear whether the existing stations are to be swept away, or whether they will be allowed to attempt to continue their work. The motive power for the Metropolitan and District Railways is to be thus supplied, among other things; and the main point of his remarks was that "in certain portions of London there is ten times the demand for power there is for light;" and he dwelt strongly on the advantages of doing away with boilers and machinery for printing. "Think of the hoists, lifts, ventilators, tramways, and a thousand and one things we could work by electricity, all part and parcel of one big scheme! These little bits of central stations over which so much fuss is now made are as nought to it." So far, the "scheme," if so it can be called, is interesting; but we fail to see where the economy is going to come in.

There are a few engineers, Mr. Ferranti being one of them, who hold that great economy can be obtained from large steam engines; and it is generally agreed that no appreciable advantage is to be obtained by building engines of greater power than about 300 H.P. It is manifest that no improvement is possible in dynamos as far as efficiency is concerned; and the question resolves itself into one of distribution and general expenses. Mr. Massey is reported as having remarked that Deptford "is said to have proved itself not exactly a success, but that is probably because there is a loss in the conversion of high into low tension currents by apparatus that is always at work, whether lighting is being done or not, and they have not attempted to supply power." This is news to us, for we thought that the chief trouble of the London Electric Supply Company was a lack of demand, and that this is largely due to the unfortunate fire at the Grosvenor Gallery, when old customers went over to other companies, and new ones were reluctant to come on for fear of more mishaps. This Company, moreover, is the only one which systematically uses sub-stations, and adapts the number of transformers in use to the load. It would appear that Mr. Massey advocates a low-pressure or a continuous current supply.

It appears that Mr. Massey thinks that the cost of these huge stations, of the distributing mains, and of the expenses

Digitized by Google

of management will compare favourably, when reduced to the horse-power-hour delivered, with the rent and expenses of separate machinery. It would be very interesting to our readers to hear from him how this can be shown; we fail to see how it can hope to compete. The cost of a brake horse-power-hour to a large printing-house cannot differ very widely from that generated in a supply station; and yet it is out of this difference that the whole cost of distribution and management is to be paid, to say nothing of the losses of conversion in the dynamo and motor, for these are but trifling compared with the expenses which Mr. MASSEY overlooks. Some idea of this expense is to be gathered from the "little bits of central stations." They can generate an electrical unit for from 1d. to 1½d., and have to charge 7d. or 8d. for delivering it, and make no great profit at that. We are sure that Mr. MASSEY would not make rash and unconsidered statements, and we should be glad to hear how he supports those to which we have alluded.

ANOTHER instance of the neglect of interest on first cost is to be found in the rather roundabout way of lighting Edinburgh by electricity which has been suggested to the councillors of that city by Prof. G. FORBES. It has been proposed to generate steam by refuse destructor furnaces, and to pump water into reservoirs on Arthur's Seat or Calton Hill, and this would be used for driving turbines as occasion demanded. The *Scottish Leader* is very indignant at "the conversion of their historic and beautiful eminences into mere receptacles for bilge-water." We thought that this was no more than an off-hand suggestion, for the single merit that it offers is the small and indeed negative value of the fuel, Prof. FORBES being very fond of refuse destructors; but we learn from the *Edinburgh Evening News* that a conference of the members of the Town Council was convened at which the details were explained. If coal is worth 15s. a ton, and it costs 2s. 6d. a ton to get rid of refuse, the saving may no doubt be put at 17s. 6d. But the unfortunate element of first cost insists on intruding such schemes as this and that of Mr. MASSEY in the shape of interest and depreciation; and a very little figuring will show in this case, as in most tide-mill, windmill and many water-power schemes, that it is on the whole cheaper after all to put down an ordinary steam engine and burn coal than to buy refuse destructors, boilers, steam-pumps, water-mains, tanks excavated in the rock, turbines, and the necessary pipes and gear, with mains back to the town.

REPLIES to the criticism of a contemporary would be, as a rule, uninteresting to our readers, especially when the journal is one so little likely to be read by them as *Electricity* of Chicago. But, in the tenth number of the latest, but valuable, addition to American weeklies, our views are repeatedly and deliberately misrepresented. Our leading article of August 14th dealt with the question of exhibiting at the Chicago Exhibition; and we failed to find any reason why English manufacturers should take the trouble to send their goods so far when they are so plainly informed by the McKinley tariff that they are not wanted. We are, however, twice accused of having stated that Englishmen have nothing to learn in America. This accusation is easily refuted by turning to the article in question, which contains no such statement, but does contain the words, "There will be much to learn, and, perhaps, something to unlearn, and a harvest of knowledge will be reaped in a few hours, which, without the Exhibition, would require months of journeying in palace cars." This forms the theme of an article in our contemporary, and it is only with the desire to put ourselves right with our many American friends that we take any notice of it.

New Cable.—A submarine cable will shortly be laid between Pernambuco and Senegal. The project is promoted by an English company, and, unless unforeseen difficulties arise, within six months the line will be open.

Lahmeyer's Direct Current Transmission System.—We learn from the *Elektrotechnisches Echo* that the plant for transmitting power from Offenbach to the Frankfort Exhibition on Lahmeyer's continuous current system, which at first was working at 1,250 volts, has now for three weeks been working satisfactorily at a pressure of 2,000 volts.

Bray.—The principal streets of this town are to be lighted with arc lamps and the rest with incandescent, and the mains for the supply of current for private lighting will be laid at the same time. The electricity will be generated by water-power situated in the town. Direct current with motor transformers and storage batteries will be used. The contract was secured by Messrs. J. E. H. Gordon.

Electric Railway Concessions forfeited.—Mexican mail advices state that the Public Works Department has notified the forfeiture of a concession for an electric railway in Mexico City, granted to an American citizen. The concession has been cancelled owing to the required guaranteed deposit of $50,000 in Government Bonds not having been made by the concessionnaire in the time stipulated.

Inverness.—The committee of the Police Commissioners of the burgh of Inverness are gathering all the information possible with regard to the proposal to light Inverness by electricity. They agreed to recommend the appointment of Mr. Frederick Nell, hydraulic engineer, London, and Mr. James Fraser, Inverness, to prepare a joint report as to the water-power required for electrical purposes and the probable cost.

A New Use for Search Lights.—The gamekeepers on an estate near Bournemouth found that poachers were in the preserves, and by the aid of occasional flashes from the search lights at Hurst Castle they were able to recognise two men, who were subsequently arrested from the descriptions given by the keepers. Hurst Castle is, according to the *Daily Telegraph*, several miles distant from the place where the men were identified.

Train Lighting.—In reply to an enquiry, the General Manager of the London, Brighton, and South Coast Railway informs us that there is no truth in the report that the Company has decided to discontinue the electric lighting of their trains. They have some trains lighted by electricity, and the number may be slightly added to; but they cannot do much more, as most of their main line trains are divided at Croydon for Victoria and London Bridge, and in those they cannot economically use electricity. For all trains where they cannot use that mode of lighting they intend to use gas instead of oil, and perhaps this accounts for the report which has been circulated.

Swiss Telegraph Statistics.—The Swiss telegraph returns for 1890 show that the traffic remained practically stationary, the total number of telegrams of all sorts being 3,695,988, or an increase of only 2·03 per cent. In spite of the great development of inter-urban telephonic communication, however, the inland telegraph traffic has increased somewhat faster than the international and transit traffic, the augmentation being 2·79 per cent. With regard to foreign telegrams the total number ex-

Digitized by Google

changed in 1890 amounted to 1,219,653, Germany taking 400,706, or 33 per cent., and France 378,201, or 31 per cent. During 1890 46·5 miles of new telegraph lines, comprising 82 miles of wire, have been erected; 209 miles of wire were also added to existing lines. The total length of line existing in Switzerland at the end of 1890 was 5,170 miles, of which 84 per cent. belonged to the State. There were 1,251 interruptions during the past year, of an average duration of 3·47 hours. Some 1,672 Morse and 41 Hughes apparatus are in use.

Mexican Telephone Company.—The Mexican *Two Republics*, of September 13th, says that the Mexican Telephone Company is about to undertake very extensive improvements and alterations in its plant, &c., in accordance with the terms of its concession. When the concession was granted, it was decided that after the Company had been in existence for a certain time (which has now nearly expired), it should adopt the cable system in place of the wire system now in use. At present, the Company has 850 wires, extending over 100 miles in length; and, while the long wooden poles are alleged to be unsightly, it is complained that the present system is liable to accidents and disarrangement. The Company has, therefore, decided to replace the existing poles and wires by cables containing 25 to 200 copper wires. This cable will be placed overhead and will be sustained by iron supports instead of the wooden poles now in use. The cost of replacing the old by the new system is estimated at $60,000, and the work will take about a year and a half to complete.

Conduits in Minneapolis.—The feeders of the Minneapolis Street Railway are buried underground in conduits which are built as follows:—Two-inch plank, first treated by boiling in fernoline, is used for constructing a long trough of the desired size. This trough is so nailed together as to be continuous and without joints from manhole to manhole, a distance of 408ft. The trough is placed below the surface at such a depth that the top is six inches below the paving blocks. The conduit proper consists of a number of heavy paper tubes of the Interior Conduit and Insulation Company's make. The tubes employed are 1in. and 1¼in. inside diameter, laid in the trough in 10ft. lengths and separated from each other and the sides and bottom of the trough by rings or spaces. The tubes are made continuous from manhole to manhole by use of a telescopic joint. After the tubes have been properly put in place, pitch is poured in, filling the interstices and leaving a series of highly insulated raceways with a solid insulated filling, impervious to moisture, around them. A large amount of this conduit has been in service since September, 1890, and has not as yet developed a single fault.

Reducing the Internal Wastes of the Steam Engine.—Some time ago, says *Industries*, we directed the attention of our readers to a proposal by Prof. Thurston for reducing the internal wastes of steam engines by reducing the heat-conductivity and the heat-storing power of the internal surfaces of steam-engine cylinders. The same thing had been attempted many times before, but without very much success. Prof. Thurston believed that he had discovered that it would be possible to form upon these surfaces a non-conducting stratum, integral with the material of which they were composed, with the metal of the cylinder itself, that should intercept the heat tending to pass away without transformation in any appreciable degree into work. This he had proposed to bring about, first, in any convenient and inexpensive way, effecting a partial solution of the superficial portion of the metal, leaving a spongy layer; then by the impregnation of this sponge with a resin or other non-conducting material produced by the painting of this surface with drying oil or with any available substance that should thus be found able to permeate and cling to the porous surface. Prof. Thurston's proposals were based only on laboratory experiments, but since they were made they have been tested on a larger scale, and he now thinks the matter fully settled.

New India-rubber Drying Processes.—In the September number of the *Bulletin Technologique de la Société des Anciens Élèves des Arts*, M. Ph. Rousseau publishes an interesting monograph on india-rubber. In the course of his remarks on the various methods of coagulation, M. Rousseau examines the chemical process recently introduced on a large scale by the Orinoco Company. This process merely consists in mixing the milk of the *hevea* with sulphuric acid and carbolic acid. Commercial sulphuric acid coagulates 55 times its volume of gum, and carbolic acid acts as an antiseptic to the coagulated juice, improving its keeping qualities. The chemical process of coagulation has the undoubted advantage over the method of smoking of diminishing the proportion of inferior rubber collected, the dust and vegetable dirt inherent to the old process being in a large measure avoided. The labour requisite is also less. Nevertheless, M. Rousseau is in doubt whether the rubber treated in this way will prove as elastic and acid-resisting as that coagulated by smoking. He argues that the molecular grouping of the rubber coagulated by the old Indian evaporative process, by the smoke of fires and by chemical action, is very different, and cannot but result in marked differences of physical and chemical properties. M. Rousseau is in favour of "barattage."

Continuous-Current Transformers.—Herr Lahmeyer, whose name is well known on the Continent as a dynamo designer, has, as was recently chronicled in these columns, severed his connection with the Deutsche Elektricitäts Werke of Aix-la-Chapelle, in order to devote himself to the development of a system of continuous-current transformer distribution. Temporary premises have been secured at Offenbach, pending the completion of a large factory at Frankfort-on-the-Main. According to *La Lumière Electrique*, Herr Lahmeyer proposes to build four-pole drum armature machines, the low-pressure conductors being placed in deep grooves cut in the periphery of the drum, and the high-pressure conductors being wound on the surface. The grooves are lined with vulcanised fibre, which projects above the top of the grooves, and helps to insulate the portions of the primary circuit from each other. The top of each groove is closed with a strip of iron sandwiched between two pieces of fibre. The system of distribution adopted by Herr Lahmeyer consists in continuous-current transformer sub-stations, the primaries of the transformers being supplied with current at about 1,000 volts pressure, and the secondaries feeding an ordinary low-pressure network at 100 volts. Herr Lahmeyer proposes to run powerful motors and arc lamps in series off the high-pressure mains. A 120 H.P. central station on this system will shortly be laid down at Brockenheim.

An American Water Power Station.—The new station of the Brush Company at Rochester on the Genesee River is a three-story stone building. The turbine capacity consists of 15 double 15-inch horizonal Lesner turbines under 90 foot head, with 14 foot draft tubes, a total of 3,360 H.P., using 6·95 cubic feet of water per minute per horse-power. The amount of floor space occupied by all of the turbines is 4ft. × 38ft. The weight of each turbine is 196 pounds, less than one pound to a horse-power. The dynamos are belted directly to the turbine shafting. The shafting runs at 800 revolutions per minute, with 25-inch pulleys on the turbine shafting and 24-inch on the dynamos. There are three iron penstocks 6ft. in diameter and 80ft. high, built of three-eighth inch boiler iron, with a gate to each penstock. There are five elbows to each penstock leading to as many turbines, with an iron slide gate to each elbow; in addition, each turbine has a register gate, thereby permitting the repairing of any one turbine without interfering with the running of the others. A turbine can be taken out and another put in its place in 25 minutes. There are three tail races extending under the entire length of the main building. As a reserve power, when making repairs and cleaning the race-way, there is a 600 H.P. Cooper Corliss engine; in the past year it has been necessary to use it but a few days. There are nine men employed at the station, five of them in the dynamo department and four in the water-power department. There are 30 dynamos; three of them are run without any stoppage, and the balance of them on an average of 13 hours per diem.

Mr. Ferranti and Niagara.—According to the *Street Railway News* of New York, Mr. A. P. Brayton, President of the Pelton Water Wheel Company, has just returned from a trip to Great Britain and Paris. Mr. Brayton met Mr. Ferranti, and refers to the latter's boldness in his plans and designs as unequalled. Mr. Ferranti has secured a concession from the Canadian Govern-

Digitized by Google

ment to utilise the Canadian side of Niagara Falls for the purpose of the production of electrical power. The concession grants his company the privilege of using all the water it may need. It purposes taking the water from above the Falls and discharging it below, thus obtaining 140 to 150ft. fall. For this purpose Mr. Brayton can furnish a wheel capable of developing 5,000 H.P. if necessary. Mr. Ferranti expects to use dynamos of 2,500 H.P. capacity, and the Pelton Water Wheel Company will furnish wheels of 5,000 H.P.—two of 2,500 H.P. each, connected directly to the shaft of each dynamo. The works will start with a capacity of 20,000 H.P., necessitating the use of eight water-wheels. On asking for confirmation of this, we learn from Messrs. Ferranti, Limited, that the available fall is about 128 feet, and the proposed plant at starting is five dynamos, each of 1,500 E.H.P., and each driven by four small Pelton wheels mounted direct on the dynamo shaft. Probably for ultimate extensions dynamos larger than this will be wanted.

Manchester.—The arrangements for the installation of the electric light in the central portion of this city are now in a forward state, and the specifications will be prepared and the erection of the station and the laying down of the mains will be proceeded with without delay, the City Council having selected a site near Gloucester-street on Wednesday last. By the terms of their Provisional Order the Corporation are compelled to have the mains laid within the compulsory area before next August. In addition to electricity, hydraulic power will be transmitted, and, wherever possible, the hydraulic and electric mains will be laid together. One engine of about 400 horse-power, with a large dynamo, will generate at the station 250,000 watts, at a pressure of 400 volts. It is proposed to have three such sets of plant in the first instance, two working and one in reserve, and the building will be so arranged that the plant may be readily increased to a total of twelve sets. From the generating station the electricity will be conveyed on the five-wire system. Burnt in ordinary burners, as is usually the case, Manchester gas gives about 2½ candles per cubic foot per hour, whereas electricity takes about four watts to produce one candle. Hence, one cubic foot of gas per hour is equivalent to about 10 watts. To provide the compulsory area with electric light, machinery will be needed capable of delivering 900,000 watts, and to supply the whole area machinery capable of delivering 5,000,000 watts. It is proposed that the price shall be about 6d. per unit of 1,000 watts.

Steam Engine Efficiency.—Prof. Thurston contributed a valuable Paper, entitled "Steam Engine Efficiencies; the Ideal Engine compared with the Real Engine," to the recent meeting of the American Society of Mechanical Engineers. The ideal engine he defined as one having a non-conducting cylinder and frictionless rubbing parts. The real engine would approach this in proportion to the improved conditions of construction and operation. He thought wastes could be reduced "by drying or moderate superheating of the steam, and by adopting high speed of engine to one-half these proportions." It ought to prove practicable to bring the water consumption by the adoption of these high pressures, and by further dividing the wastes by the use of three or four cylinders in series, and by properly supplying dry steam to the engine, down to within 10 per cent. of the best figures here obtained for the ideal case. "The real measure of the useful power of an engine is not the indicated power, however, but the dynamometric power, as measured by the brake, or at the point at which the engine delivers its energy to the machinery of transmission. A well-built non-condensing engine should have an efficiency of machine at least as high as 92·5 per cent., and engines have been constructed doing better than this. An equally well-built condensing engine should approximate 90 per cent. efficiency of machine, though 85 is a much more common figure." The author then concluded: "It is apparently doubtful whether a vacuum will be found desirable, with its concomitant costs of the air-pump system, when we come to the utilisation of these high pressures; unless we can at the same time find a way to reduce the waste of power and the tax thus imposed upon the engine."

Gas Engines.—In a Paper recently read before the Société Technique du Gaz, the following remarks occur:—"The inventor turns his mind to the economy of fuel, which is of great but not of capital importance. Motors ought to be planned so that the ordinary workman can understand them, take them to pieces, clean them, and generally deal with them, without it being necessary to send for a person of special skill. Besides, gas engines do not work continuously; French statistics show that the average daily consumption of gas in gas engines is no more than 106 cubic feet per horse-power, and an extreme economy in gas is therefore practically of secondary importance. Lubrication, again, is of very great importance in the question of economical working. What good does a second cylinder or a very long cylinder do if its use involves a non-remunerative expenditure of oil? The mode of ignition is of importance. Flame ignition is incompatible with compressions beyond 2½ atmospheres; and the speed of travel of flame limits the speed of the machine, while the efficiency of the engine increases with the speed of the machine within certain limits. Electricity produces a small spark which may happen to go out in a poor stratum of gas or even in air or burned gas, and then the charge is lost. The best method appears to be ignition by incandescence; the incandescent mass does not go out suddenly, and a speed up to 500 explosions per minute has been attained under this method. The regulator ought to be very sensitive to the least variation of speed, for which purpose it ought to be light and to form an integral part of the machine, its movement being conveyed to it by rigid gearing, such as eccentrics, and it ought to be adjustable by hand while the machine is running. The piston should be of iron: steel cuts the cylinder too much; bronze is too soft and wears out, and it is often attacked by the oil. The horizontal shaft is often at fault in gas engines. The fly-wheel shaft, which is exposed to violent stresses, and has to support a heavy wheel, is often so badly supported that it bends and rapidly causes the wearing out of the bearings."

Differential and Integral Calculus.—A special course of evening instruction for beginners, on the differential and integral calculus and its application to the practical problems of mechanical and electrical engineering, will be given by Prof. John Perry at the Technical College, Finsbury, Leonard-street, City-road, E.C. A good working knowledge of the elementary principles of algebra and trigonometry is expected in students. Students who are unable or unwilling to devote at least two hours at home to working the exercises which will be set will not derive much benefit from this course of instruction. A lecture will be delivered every Tuesday evening from 7:30 to 9 p.m. commencing October 13th. The following syllabus is subject to alteration:—Oct. 13th: The uses to which a knowledge of the calculus may be put. The use of squared paper. One quantity a function of another. The notion of a differential coefficient; velocity; acceleration; electro-magnetic induction; self-induction; the study of a curve; examples. Oct. 20th: Fundamental rules of differentiation; examples in differentiation. Oct. 27: Examples in differentiation. Nov. 3rd: Ohm's law as extended to currents which are not constant. Alternating currents. How the practical rules employed by electricians are derived. Nov. 10th: Simple harmonic motion. Vibrating bodies. The compound-interest law in problems on belting, atmospheric pressure, electrical condensers discharging through great resistances, long pump rods. Vibratory motions which are damped. Hertzian vibrations. Nov. 17th: Conditions of maxima and minima examples. The strongest and stiffest beams cut from a tree. The most economical conductor for an electric current. Output from dynamo. Cut-off in steam-engine cylinder and other examples. Increased importance in engineering of this kind of calculation. Nov. 24th: The use of integration. Obtaining a list of simple integrals. The rules for integration. Examples. Dec. 1st: Finding the areas and length of curves, and areas and volumes of surfaces. Dec. 8th: Problems on steam and gas engine indicator diagrams and efficiency of engines. Dec. 15th: Further problems on areas and volumes and moments of inertia. Jan. 12th: The stiffness and strength of loaded beams. Jan. 19th: The use of Fourier's theorem. The electric dynamometer illustration. The effect of self-induction.

THE DETERMINATION OF CURRENTS IN ABSOLUTE ELECTRO-MAGNETIC MEASURE.

BY G. F. C. SEARLE, M.A.

(*Continued from page 576.*)

§ 18. Magnetic Potential of a Small Magnet at a distant Point.—Let O (Fig. 18) be the centre of the magnet A B, A its north pole, m the strength of each pole, $2l$ its length, $M = 2ml$ its magnetic moment, P the point at which the potential is to be found, $OP = r$, angle $POA = \theta$. Draw AK perpendicular to OP, then $OK = l\cos\theta$, and since OP, AP are very nearly parallel $AP = r - l\cos\theta$, and similarly $BP = r + l\cos\theta$. Hence the potential of the magnet, which is the sum of the potentials of the two poles, is—

$$V = \frac{m}{AP} - \frac{m}{BP} = \frac{m}{r - l\cos\theta} - \frac{m}{r + l\cos\theta} = \frac{2ml\cos\theta}{r^2 - l^2\cos^2\theta}$$

Now, we are considering the case in which r is very large compared with l, we may therefore neglect l^2 in comparison with r^2 and write $V = \frac{2ml\cos\theta}{r^2} = \frac{M\cos\theta}{r^2}$

Our expression for the magnetic force in terms of the magnetic potential enables us to write down at once the magnetic force at P along and perpendicular to OP. We saw (§ 13) that $F = -dV/dS$, where F is the magnetic force along S in the direction in which S increases. If F_r is the magnetic force at P in the direction OP, then $F_r = -\frac{dV}{dr} = \frac{2M\cos\theta}{r^3}$. In finding F_θ the magnetic force at P perpendicular to OP in the direction in which θ increases, we must put $r\,d\theta$ for dS, and thus obtain

$$F_\theta = -\frac{dV}{r\,d\theta} = \frac{M\sin\theta}{r^3}$$

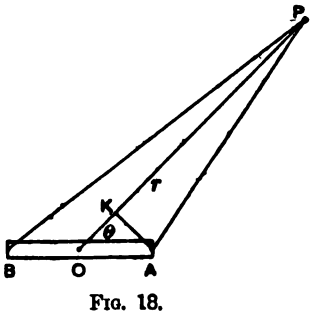

FIG. 18.

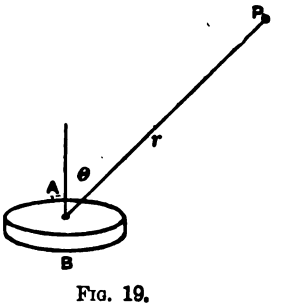

FIG. 19.

§ 19. We are now in a position to investigate the magnetic potential of a *magnetic shell*. Imagine a sheet of steel magnetised so that the whole of one side is North and the whole of the other South. If such a sheet can be imagined to become indefinitely thin, and at the same time to remain magnetised, it will constitute a magnetic shell. The strength of a magnetic shell is the magnetic moment of a square centimetre of the shell. We shall denote the strength of the shell by i. Let A B (Fig. 19) be a small portion of the shell, A being the North side, and its area being a. The portion A B constitutes a small magnet of magnetic moment ia. Let P be the point at which we wish to find the potential, and let $AP = r$ make an angle θ with the normal BA. By the last paragraph the magnetic potential at P is $v = ia\cos\theta/r^2$. But we have seen (§ 8) that $a\cos\theta/r^2 =$ solid angle subtended by the area a at P. Let this solid angle be denoted by ω. Then $v = i\omega$. The solid angle is positive when the North side of the portion is towards P. If the shell is uniform, and of any size or shape whatever, so that it subtends a solid angle Ω at P, then, by adding the potentials of all the elementary portions, we find for the potential due to the whole shell $V = i\Omega$. Now the solid angle subtended by the shell at P, and, therefore, its magnetic potential at P, depends only upon the boundary or edge of the shell, and not otherwise upon the shape of the shell. As long as the boundary remains the same we may fill it up with a magnetic shell of any form without producing any change in the potential due to it. The fact that the potential of a magnetic shell of given strength depends only upon the shape of its edge is exceedingly curious; it is of fundamental importance in the theory of electro-dynamics.

A very important result is easily obtained. Let the curve A B (Fig. 20) represent any section of a magnetic shell, A and B being points on the edge. Let P, Q be two points very close together, one on each side of the shell, the side of the shell next to P being the North side. We wish to find the work which must be done in taking a unit magnetic pole from P to Q, or in other words the difference of potential between P and Q. Let P describe the path $P P_1 P_2 P_3 Q$, which does not cut through the shell. The magnetic potential at P is $i \times$ (solid angle A P B). Describe a sphere of radius 1 cm. about P; the solid angle at P is measured by the area in square cms. of this sphere intercepted by the cone A P B. As P moves let it carry the unit sphere with it, and let us attend to the changes of the area on the sphere intercepted by the cone A P B. When P has moved to P_1 this area has diminished, and at some point between P_1 and P_2 will vanish; at P_2 the South side is turned towards P, so that the solid angle must now be reckoned negative. This solid angle gradually increases negatively, until, when the point has arrived at Q, it has the value $-(4\pi - A Q B)$. But since P and Q are indefinitely close together, the solid angles A P B and A Q B are indefinitely nearly equal. Thus the increase of magnetic potential in going from P to Q is $i\{-(4\pi - A Q B) - A P B\} = -4\pi i$. Hence we find that, whatever the shape of the magnetic shell, and whatever the form of the path along which we take the unit pole, we expend $-4\pi i$ ergs of work in taking the pole from a point very close to the North side of the shell to a point very close to the South side. If we take the pole from the South side to the North side, we do $4\pi i$ ergs of work. But if we make the path $P P_1 P_2 P_3 Q$ such that P and Q have no part of the magnetic shell between them, then it is easily seen that the whole change of solid angle in passing from P to Q is zero when P and Q are indefinitely close

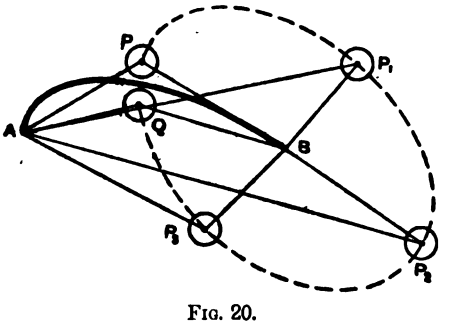

FIG. 20.

together. Thus, in this case, on the whole no work is done in taking the unit pole from P to Q.

If, in the first case, we make a very small perforation through the shell, and make the pole return absolutely to P again, then we can easily show that we must expend $4\pi i$ ergs upon it in bringing it from Q to P. Thus, when the path is absolutely complete, the total work done is zero. Any other result would be at variance with the law of the conservation of energy.

§ 20. We can give another interpretation of the expression $V = i\Omega$ for the magnetic potential due to the shell. If we bring up a pole of strength m, from a great distance to any point P, near the magnetic shell, the work spent upon it is $mi\Omega$, Ω being positive when the north side of the shell is seen from P. But $m\Omega$ (*see* § 11) is the number of lines (or tubes) of induction which would pass from m through the boundary of the shell if the shell were not magnetic. Thus the mutual potential energy of the pole and shell = strength of shell × number of lines of induction, which would pass from m through the boundary of the shell, if it were non-magnetic, in the opposite direction to those actually proceeding from the shell. If, instead of a single magnetic pole, we have any magnetic system, we can decompose it into a number of magnetic poles. The potential energy of each of these due to the presence of the shell is proportional to the number of lines of induction it would send through the edge of the shell if the shell were non-

Digitized by Google

magnetic. By the principle of the superposition of magnetic fields (*see* § 12) we see* that the whole number of lines through the edge due to the magnetic system is the sum of those due to each separate pole, of which it may be considered to be made up. Thus the mutual potential energy of any magnetic system and any magnetic shell is equal to the product of the strength of the shell by the number of lines of induction due to the magnetic system which would pass through the boundary of the shell, if it were non-magnetic, in the opposite direction to those actually due to the shell itself. Since lines (or tubes) of induction are always closed upon themselves, the only way in which a line which was not passing through the boundary of the shell can pass through it is by having cut

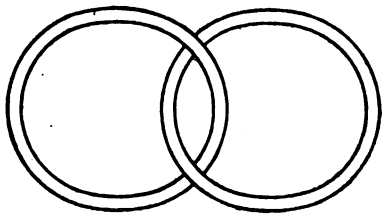

FIG. 21.

through the boundary. When a line of induction passes through the boundary of the shell, we may say that it is linked with the edge of the shell. We have thus been led to perceive that every additional line or tube of induction which is linked with the edge of a shell of strength i has involved the expenditure of i ergs of work if the line passes in the opposite direction to those due to the shell. We shall return later to some considerations about this linking.

(To be continued.)

DISTRIBUTION OF ENERGY BY GAS.

BY DENNY LANE.

There was a time when the proprietors of gasworks were so much alarmed by the advent of the electric light that they parted with their shares at a heavy loss. Experience has proved that their fears were ungrounded, and, in fact, the consumption of gas has increased more rapidly in the last decade than it had in any previous period. The very stir that was caused by the threatened competition roused the energies of gas engineers, who were waxing fat, and perhaps growing lazy, after many years of unbroken prosperity. I always alleged that the electric light would never injure the shareholders in gas companies. On the contrary, it has conferred benefits on them, which may, in my opinion, be considerably increased. As I have devoted a good deal of time and thought to the connection between gas and electricity, I will endeavour to point out a mode by which each may be made to help the other. A celebrated old theological treatise is called "*Concordantia Discordantium Canonum.*" In the same spirit I would wish to evoke harmony out of the discord which is supposed to exist between those two brilliant rivals.

The subject naturally divides itself into three heads: the generation, the storage, and the distribution of the agents to be employed.

With respect to generation of illuminating gas, there is not much hope for any substantial improvement. The practice of three quarters of a century has naturally developed highly an industry which yields residuals that return a large proportion of the first cost of raw material. I believe that the cost of labour in gas making will certainly be reduced to the extent of two or three pence per 1,000 cubic feet, but beyond this I see no probability of further economy. With reference to heating gas, it is, however, a different question; I believe such gas can be produced at a price lower than that of 16-candle gas, but, of course, would require separate mains.

With respect to the generation of electricity from motive power we cannot hope for any improvement. With the many admirable dynamos of all kinds which are now procurable, it is a proud thing for electricians to say that they have left no room for improvement. When dynamos convert 90 to 95 per cent. of mechanical into electrical energy, they have far exceeded the results obtained in every other analogous transformation, and by so doing have endowed their favourite science with one of the brightest of the jewels that adorn her crown.

Next, as to storage. The gas engineers have this immense advantage that their hourly production need not be more than the *average* demand of 24 hours of mid-winter, while the electrician, who does not use storage cells, must have producing power sufficient to meet the heaviest hour, or, in fact, *minute* in the year, although that may require five or perhaps ten times the average consumption. On the other hand, if he employs accumulators, he has to meet a heavy first cost and a depreciation which, with a fair interest on capital, will run up to 15 or 20 per cent. per annum. Nevertheless, I believe that for those hours (and in summer they are long ones) in which the demand for light is low, great economy will result from the partial employment of these most useful garners of energy.

The third point to be looked into is distribution; and when I first worked out the problem I own I was surprised at the low cost of the distribution by means of gas supplied to gas engines. My surprise was increased and confirmed lately on reading the excellent lectures which Mr. Kapp has delivered on the transmission of energy. I saw more clearly than before the great losses incurred by the transfer of energy in every other case, except that furnished by gas mains. In many cases the existing mains are capable of transmitting as much gas as would in all probability be required for electric lighting at present prices. I think it fairer, however, to calculate what would be the expense of separate mains laid to supply electric sub-stations I do so for four reasons:—

1. Because this gives the total cost of distribution.

2. Because it gives an opportunity of supplying cheap gas of good heating, but low illuminating power, which might also be used for stoves and cooking.

3. Because it affords the means of increasing the supply of gas as the demand for electricity increases, without throwing undue pressure on the service pipes of ordinary consumers.

4. Because the unaccounted for gas would be very small. In fact, gas companies get paid for what is delivered at the consumer's meter, a quantity considerably less than that supplied at the inlet of the distributing mains. But the loss can easily be accounted for by minute leakages in the innumerable joints of the service pipes and connections to the meter—each small in itself, but, when multiplied by myriads, making up an important aggregate. With a good main, carefully laid, and not tapped for services, the leakage would be small, and should not amount to 1 per cent. of the quantity delivered. In such a case the pressure can be increased considerably without causing any notable loss, or any inconvenience to ordinary consumers.

Of course, gas will not travel through a main without some propelling force, but the amount required is extremely small, as may be judged from the following example. As water weighs about 62½lbs. per cubic foot, the weight of a column of water of 1ft. area and 4in. deep is under 21lbs. This gives what is called "four inches pressure." In a good gas engine the consumption of gas should not be more than 24 cubic feet per brake horse-power when at full work; but I will allow one-fourth more, thus making a more than ample provision for the extra proportion of friction, which exists when the engine is not working up to its full capacity. We therefore have for the power employed to force enough of gas through the mains for one horse power $30 \times 21 = 630$ foot pounds. As a horse power for one hour means $(33{,}000 \times 60 =)$ 1,980,000 foot pounds, our

* We can make this clearer as follows:—Let a be a small area on the shell. Let $f_1, f_2 \ldots\ldots$ be the magnetic forces at the centre of a due to the poles $m_1, m_2 \ldots\ldots$, and let $f_1, f_2 \ldots\ldots$ make angles $\theta_1, \theta_2 \ldots\ldots$ with the normal to a. The number of lines of induction through a, if m_1 is the only pole in the field, is easily seen to be $f_1 \times a \cos\theta_1$ and so on for the other poles. The sum of all these quantities is $a \times \Sigma f \cos\theta$. But $\Sigma f \cos\theta$ is the resultant magnetic force at right angles to the shell and, therefore, $a.\Sigma f \cos\theta$ is the number of lines of induction through a. From this the statement in the text follows at once.

Digitized by Google

propelling power is only 1,980,000 ÷ 630, or the $\frac{1}{3145}$ part of a horse power. In other words, 1 H.P. employed at works would force through the mains as much gas as would supply over 3,000 H.P., at 4in. difference of pressure.

Of course, the quantity of gas that can be sent through a main depends on the size of the main and on its length, varying in practice directly as the square of the diameter, and inversely as the square root of the length. But I will give a practical example; taking my figures from Barlow's Tables, I find that a 6in. main one mile long will deliver 9,000 cubic feet of gas per hour at the difference of pressure of 4in., which I have given above; and if we divide this by 30 cubic feet, we get 300 H.P. delivered at this moderate difference of pressure.

Let us see now what the cost of such a main would be. At £5 a ton (in many places the price is less), a 6in. main costs 4s. a yard or £352 a mile. If with turned and bored joints, the cost of laying would be 1s. 6d. a yard in a paved road, or £132, making in all £486, let us say £500, a mile. The interest on this at five per cent. would be £25, or 1s. 8d. per H.P. per annum. If, however, the pressure was increased to 16in., double the quantity would be delivered, while the motive power absorbed would be considerably under 1 H.P. at the time of the maximum delivery of 600 H.P. for one mile. I believe no other instance can be given of so moderate a cost for the transference of energy.

Counting the cost of gas at 2s. 6d. we have in the first case 300 H.P. transferred one mile by the expenditure of 300/3,000, equal one-tenth of a horse-power or one-tenth of a penny. In the second case we have 600 H.P. carried a mile at a cost less than one halfpenny. But besides this remarkable economy, we have also the following advantages. The cartage of coal to and of ashes from a station is done away with. No nuisance is caused by the escape of smoke or of steam, and, if the foundations are properly arranged, and the base of the engines isolated from the surface of the ground, no damage will be caused by vibration. The whole space occupied by boilers will be saved, and where space is of value a building of three floors—the two lower containing gas engines and dynamos, and the upper storey giving room for attendants and regulating gear—can be employed.

But, again, a most important saving would be made in attendance. Practically a good gas engine requires no continuous attendance. A daily supply of oil and an inspection which need occupy only a quarter of an hour is all that is necessary. I can say this from several years' experience. Formerly there was some difficulty in starting gas engines. Now several contrivances enable this to be effected without any trouble.

Again, the wear and tear of gas engines is extremely small. At works here a small engine has run for over 36,000 hours; at the end of that time it required a new lining to the cylinder, which cost 2½ per cent. of the first cost of the engine. The slide valve required to be scraped occasionally, but the slide valve has been dispensed with in engines of modern make. This engine, although working continuously night and day, is looked to only twice in the 24 hours, in order to give a supply of oil, and take the index of the meter. It is working in a yard where it is exposed to some extent to the dust of coke, one of the most active grinding materials we know, and but for this it is probable the cylinder lining would have lasted longer. Now, if a station is supplied with a small proportion of storage cells, I think I may assume that the dynamos will not be required for more than five hours a day on an average, say 1,800 hours a year. If my data, therefore, be correct, a gas engine should work for 20 years, and then may require a new cylinder lining, which would come to 2½ per cent. of the first cost. To this must be added the insignificant cost of new piston rings required occasionally.*

Compare this with the wear, tear, and maintenance of steam engines, remember the wages of stokers and engineers, and I think a remarkable economy in the up-keep and attendance of the gas-motor must be admitted. Again, with the best boilers, it takes a considerable time to get up steam, and in work necessarily intermittent the heat accumulated in the boiler and setting is wasted. We are thus burning the candle at both ends *without deriving any light* from it. It is this cause which runs up the cost of coal for electric light stations so very high. Dr. Fleming estimates it at from 9 to 22lbs. per unit sold. In one case in the North of England I find the consumption is 23·4lbs. per unit.

On the other hand, a gas engine can be started in less than a quarter of a minute; as soon as it is stopped all consumption of fuel ceases. Hence its great economy whenever the demand for power is intermittent. Next as to the chance of break-down or interruption. The steam engine and boiler form a very complex arrangement. If any serious injury to any of the essential parts takes place, the whole system is made inoperative, and in most cases the boiler must be stopped occasionally for cleaning, examination and repairs. On the contrary, the gas engine is extremely simple in construction.

Of course, "accidents will happen in a family as well regulated" as that of the gas engines, but fortunately these are very rare. I will conclude by giving a singular example. At a large printing establishment in Cork, a gas engine worked very irregularly, and finally struck work. Messengers were sent to complain "that the gas was bad," "that there was no pressure," "that the meter was out of order," "that the service was choked"—in fact, the whole litany of complaints was recited. One of our engineers immediately attended, and found nothing wrong with the supply, or apparently with the engine, which, however, refused "to do a stroke of work." On examination he found that the supply of air to the engine was derived from a pipe which was carried up outside the building to a height of about 8 feet; the object of this arrangement being to take air at a high level, and so avoid dust, &c., which might be drawn in and injure the cylinder, piston and valves. This air inlet pipe was found to be choked, and what, think you, was the nature of the obstruction? It was composed of *thirteen boys' caps*. In fact, there is a school close by, and the Cork boy, being of a scientific, ingenious, and inquiring disposition, noticed that there was a considerable indraught at each inspiration of the engine, and having being taught that "Nature abhorred a vacuum," he endeavoured to secure a "plenum" by tossing another boy's cap close to the end of the pipe, where it performed the pleasing conjuror's trick of suddenly vanishing. Of course the other boy returned the compliment; and so it went on, and would have gone on, until all the caps of the school were absorbed, were it not that the air fiend got so gorged that he lost all appetite, and "died of shortness of breath."

You will, of course, notice that I have said nothing of the cost of gas used in gas motors; but as this communication is already too long, I will, with your permission, reserve my remarks on this subject for another occasion. I have only dealt with the distribution through feeders. The present practice seems to depend on distributing from sub-stations at a low pressure, whether the alternate or the continuous current be employed. Of course, the system I advocate dispenses with banked transformers, and would probably use storage cells for a certain portion of the delivery, although equally well adapted for the alternating current.

* I have just heard of a case where a gas engine has been running 168 hours a week for 11 years, without any renewal of cylinder lining or of piston. The last piston rings were put in three years ago.

Celluloid.—In view of the tendency to employ celluloid for several electrical purposes the following particulars may be of interest. Celluloid is simply made up of nitrocellulose, camphor, and water. It was invented in 1869 in America. In 1876 the industry was introduced into France. Germany also possesses two large factories, whilst the largest in the world is in London. Crude celluloid is a horn-like transparent mass of a slightly yellowish colour, and of specific gravity 1·25-1·45. Heat softens it and renders it capable of taking impressions. At 90 deg. it becomes very plastic. It readily kindles. Sulphuric acid rapidly decomposes celluloid on heating, whilst hydrochloric acid attacks it much less vigorously. Nitric acid slowly attacks it in the cold, very rapidly on heating, and the same is true of caustic soda. Acetic acid dissolves it, giving a solution from which water precipitates camphor and nitrocellulose; it is also soluble in ether, acetic ether, acetone, fatty oils, alcohol, and turpentine.

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

Advertisement Rates, &c., forwarded on application as above.

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday. Renewals of expiring advertisement orders and alterations to standing advertisements should be in Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday.*

SMALL PREPAID ADVERTISEMENTS *accepted up to 4 p.m. Thursday.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, 1891, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with well-written Biographical Notices of leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1891 should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Prospectuses free.

ELECTRICAL BOOKS AND PUBLICATIONS

All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad*

"THE ELECTRICIAN" *Series at present consists of—*

THE ALTERNATE CURRENT TRANSFORMER IN THEORY AND PRACTICE. By Dr. J. A. FLEMING. Vol. I. Price 7s. 6d., post free.

THE ART OF ELECTROLYTIC SEPARATION OF METALS (Theoretical and Practical). By Dr. GEORGE GORE. Price 10s. 6d., post free.

STEEL-PLATE PORTRAITS

Of W. H. Preece, F.R.S.; Michael Faraday (out of print); Sir John Pender, K.C.M.G.; Sir William Thomson, F.R.S. (Past-President of the Institution of Electrical Engineers); C. H. B. Patey, C.B. (Late Secretary of Telegraphs, G.P.O.); Dr. John Hopkinson, F.R.S. (Past-President of the Institution of Electrical Engineers); Dr. Oliver J. Lodge, F.R.S.; Prof. William Crookes, F.R.S. (President of the Institution of Electrical Engineers); Willoughby Smith (out of print); and Prof. von Helmholtz, have been issued as Supplements to "THE ELECTRICIAN."

A few Copies of these admirably-executed Steel Engravings can be supplied, price 1s. each, post free on roller, 1s. 2d. Or framed in neat Black Pillar or Brown Ornamental Frames, price, 4s. 6d, carriage paid (U.K.)

REPORTING THE DEBATES OF SCIENTIFIC SOCIETIES.

At a recent meeting of the Société Internationale des Électriciens an enterprising member, M. J. A. MONTPELLIER, proposed that stenographers should be admitted at the monthly gatherings of the Society, in order that a *compte rendu intégral* might be taken of the proceedings. Such a course seemed to M. MONTPELLIER to possess many advantages, and he cited the example of several similar institutions in his support. The President, M. JOUBERT, was, however, of opinion that there was but little to be gained by preserving what he called the "physiognomy" of scientific discussions, where the bases upon which the paper superstructures were reared were not likely to be upset in the course of casual controversy. M. MASCART supported this contention, and the proposal was thereupon politely referred to a Committee, to be heard of no more.

With us in England there is the usual characteristic diversity of practice. Each society does what seems good in its own eyes, without as a rule troubling itself about the mode of procedure adopted by its neighbours. The whole gamut between the rigid secrecy of the Institution of Civil Engineers and the unqualified publicity of the various gas associations is played. One institution, with the desire, we believe, to afford its members the fullest opportunity for revising their remarks, postpones any publication whatever for many months. Another welcomes the reporter, technical or otherwise; in some cases, indeed, the non-technical stenographer is rather preferred, being more likely to take copious notes of the commonplace generalities of the eminent advertiser, and to "cut down" to a minimum the more abstruse remarks of the modest investigator. Other learned bodies act on the principle of here a little and there a little; they adopt one rule from this society and another from that, and are thus in

Digitized by Google

a position to defy the criticism of all those who respect precedents. The general tendency of such a policy is, however, to limit the sphere of usefulness of those who pursue it; they become enamoured of their precedents and fail to see that a new science may be none the worse for a little initiative. The principle is, indeed, an excellent one, but only on the assumption that what is intrinsically good is imitated, and that which merely possesses the prestige of long use is critically examined and, maybe, rejected. The aversion of corporate bodies, whether scientific or other, to the publication of their proceedings has, we suppose, for its ultimate root the natural antipathy of every individual member for anything approaching publicity in connection with his own private affairs, although we need hardly point out that the two things are not exactly on all fours. There are, however, but few who would in these days be bold enough to openly argue in support of the thesis that scientific societies exist for the delectation of those who have the good fortune to be able to attend their meetings or who possess the pecuniary means to purchase their often expensive journals. The reasons alleged for the exclusion of reporters are, therefore, usually that verbatim reporting and prompt publication in the technical press tend to promote prolixity and playing to the gallery. Now, verbosity and advertising are certainly to be deprecated, and especially so in the discussions of scientists and engineers. But while granting this much, it does not follow that one must admit the premiss.

It is now more than two years since the Council of the Institution of Electrical Engineers after due deliberation came to the conclusion that the welfare and dignity of the Institution required the exclusion of reporters from its debates; yet we have not observed any marked diminution in the average length of the speeches, on the contrary we can call to mind several instances of inconvenient prolixity, and one or two amusing attempts at advertisement. The precautions which were taken in the early part of 1889 do not, therefore, appear to have been entirely successful in effecting a cure. The question may well be asked whether the disease is not inherent to our fallen state, and whether a milder remedy would not prove just as efficacious without entailing any undesirable consequences. One result of the system at present in vogue is that many who are interested in electricity both on its practical side and from the point of view of pure science are to all intents and purposes excluded from participating in the benefits to be derived from learning what is thought on matters of current interest by those best qualified to offer an opinion. The Institution of Electrical Engineers, notwithstanding the powerful traditions of the *doyen* of engineering societies, has already done well in permitting the prompt publication in full of all Papers read before it. Why not do better still, and revert to the old system of allowing its debates to be equally promptly and fully reported? To exorcise the evil spirit of prolixity the ten minutes' rule might well be made automatic and inexorable. It is surprising what a vast amount of valuable information it is possible to impart in ten minutes, after a little practice; if a speaker has previously made up his mind what he intends to say and how he means to say it, something like one thousand words can be easily emitted in that brief period of time. In parliamentary debates attempts at eloquence, and in scientific discussions attempts to speak without due preparation, are responsible for the major portion of the time that is wasted. Whenever a speaker rises at the Institution of Electrical Engineers the President might start a time-glass, which, when run out would ring a bell, and after this peremptory summons everyone would have to throw himself on the mercy of the meeting, while members dropping into the anecdotal vein or persistently wandering away from the subject under discussion into "green fields and pastures new," might perhaps be more sternly brought back to the point than has hitherto been customary.

With these innovations, and with all Papers printed and in the hands of members well before each meeting, the arguments against the admission of technical reporters would lose what little force they may once have had. Indeed, a return to the old order of things would, under the circumstances, prove the reverse of harmful. With the speakers in full possession of the facts there would be less excuse for straying from the point, and when ample time has been given for the detection of erroneous statements, their demolition within the allotted period of ten minutes ought not to be impossible. The discussions might be expected to gain in utility, and the individual speeches in conciseness. The statements of the readers of Papers and the counter-statements of those holding contrary opinions would appear side by side, a desideratum which the authorised abstracts, promptly and well done as they are, cannot be held to adequately fulfil. Abstracts can at the best only give the barebones of a debate.

A METHOD OF MEASURING THE HEAT DEVELOPED ON ACCOUNT OF MAGNETIC HYSTERESIS IN THE CORE OF A TRANSFORMER.

BY PROF. J. A. EWING, F.R.S.

I have arranged the following apparatus to measure the heating effect of magnetic reversals in the core of a transformer under various conditions as to frequency, intensity of magnetisation, and load (that is, output on the part of the secondary coil). The experiments are specially intended to test, in a manner which will admit of no doubt, whether the loss of energy that occurs through magnetic hysteresis is less, per cycle, when the transformer is loaded than when the secondary coil is open or is closed through a high resistance.*

A small transformer is wound, the core of which consists of an "anchor-ring" of soft iron wire, cotton covered so that the turns of the core are completely insulated from one another. Over this a primary is wound in two layers, uniformly distributed round the whole circumference of the ring. Over this, again, a secondary is wound, also in two layers, and uniformly distributed. Before winding the primary and secondary, a thermo-electric junction is imbedded in the insulated core. To avoid circumlocution, we shall call this transformer A.

A second coil, B, is then wound, which has the same dimensions and number of turns as A in its core, its primary, and its secondary, and is exactly like A in every respect, except this—that the two layers of the "primary" in B are joined so as to oppose one another, and therefore to produce no magnetising effect on the core, and the two layers of the "secondary" in B are also joined so as to oppose one another. Any current passing through either the "primary" or the "secondary" of B exerts no magnetic force on the core. A thermo-electric junction, a duplicate of the one in A, is imbedded in the core of B.

The two coils are now connected with the primary of A in series with that of B, and the secondary of A in series with that of B, with an alternator in the primary circuit and an adjustable resistance (to vary the output) in the secondary circuit. The thermo-electric junctions are connected so as to oppose each other; and a galvanometer, put in circuit with them, serves to detect any difference of temperature which may come to be developed between the two cores.

When alternating currents are sent through the primary of A, inducing secondary currrents, and making it act as a transformer, its core suffers reversals of magnetism, the heating

* See *The Electrician*, October 2, 1891, p. 597 and p. 602.

Digitized by Google

effect of which we wish to measure; but though the same currents traverse the primary and secondary of B, the core of B remains inactive. The Joule effect, due to both primary and secondary currents, is precisely the same in both A and B. The difference of core temperature, which soon shows itself in the thermo-electric circuit, is therefore due to the heating effect of hysteresis alone.

Finally, I balance this heating effect by passing a continuous current through the insulated iron core of B, adjusting the strength of the current until the core of B is heated by this current at just the same rate as the core of A is heated by the reversals of magnetism which are going with uniform frequency in it. The adjustment is correct when there is no progressively increasing deflection of the galvanometer in the thermo-electric circuit.

Knowing the strength at which the steady current has to be maintained to keep up this balance, and the resistance of the iron core, we find the energy expended by it in the core of B, which is equal to the energy lost by magnetic reversals in the core of A.

THE FRANKFORT EXHIBITION.—XII.

(FROM OUR SPECIAL CORRESPONDENT.)

Kummer's dynamometer, of which we give some illustrations, is a convenient instrument for measuring the power supplied by an engine when it is possible to connect the driving engine with the driven machine by means of belting, in such a way that one belt runs from the driving engine to one pulley of the dynamometer and another from the other pulley of the dynamometer to the machine driven. The dynamometer is thus the connecting link between the two beltings, and measures the power transferred from the one to the other.

The following is a short description of the mechanism and the mode of measuring.

Figs. 1 and 2 show the machine in perspective, Fig. 2 showing it with one of the pulleys removed.

Figs. 3, 4, and 5 show the mechanism more clearly. It will be seen that the axis a' which lies in the bearings in o, o', carries three arms d, d' and e; the first of these, d, (Figs. 3 and 5) has bearings at its ends for an axis i, which is parallel to it and which (Fig. 5) carries at its lower end the lever g. This is provided at q' with a long slit, into which fits one end of the double lever ff'; this lever is capable of turning on the pivot w, which is fixed on the extremity of the arm e.

The axis i is provided at its upper extremity with the double lever $k\,k'$, (Fig. 4) whose extremities fit into the two projections, $n\,n'$, $v\,v'$ of the pulleys c c', and it is this lever which transfers the power from the one pulley to the other.

The inner extremity of the lever ff' (Fig. 5) is in close contact with the rod b (Fig. 3), which fits loosely into a hole in the axis a, and rests with its outer extremity in contact with the pointer r. The arm d' is simply to keep the centre of gravity of the system in the diameter of the axis; and for small adjustments the moveable weight e' is screwed on.

The pointer r is pressed forcibly against the rod b by means of the constant weight u acting at various positions of the lever arm r' (Figs. 3 and 4) or a variable weight in a scale, which is the method most recently employed (Figs. 1 and 2).

The dynamometer works in the following manner.

The belting from the driving machine is placed on c, and that to the driven machine on c'; the power from the first pulley c is consequently transferred to c', and c' tends to lag behind c, a wrench being brought into play between the two, which is transferred to one between the two ends of the double lever $r\,r'$ by means of lever $k\,k'$, axis i, lever g, double lever ff' and rod b.

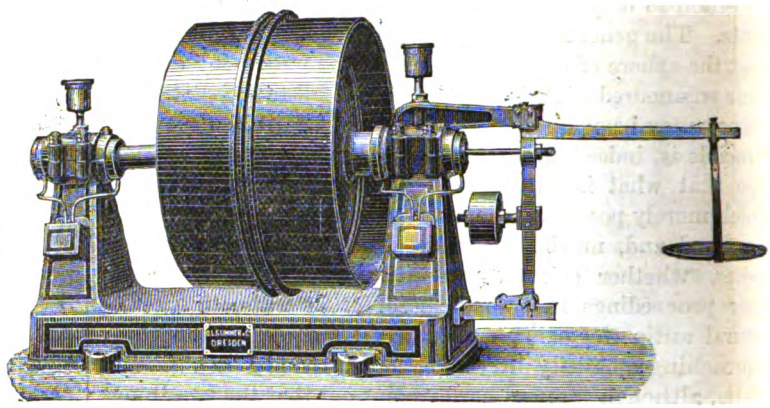

FIG. 1.—Kummer's Transmission Dynamometer.

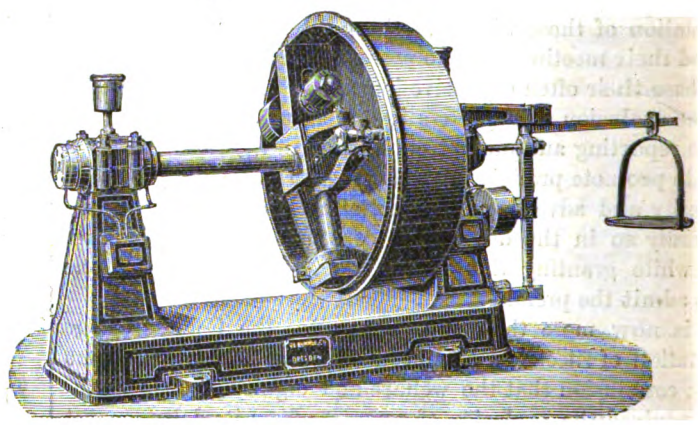

FIG. 2.—Dynamometer showing Driven Pulley removed.

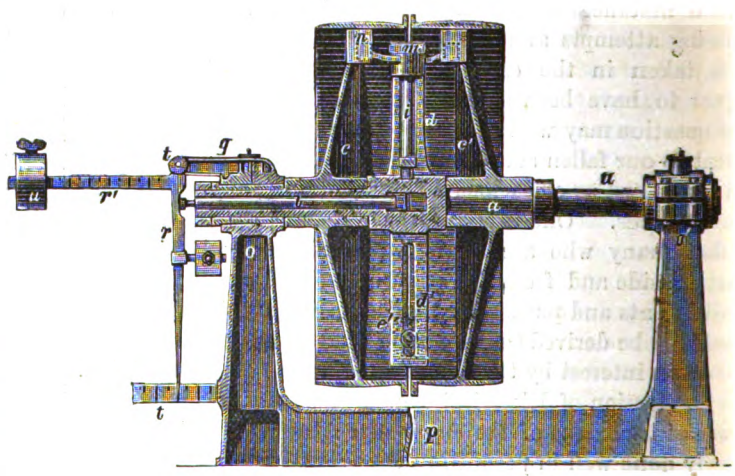

FIG. 3.—Sectional Elevation, longitudinal.

SCHUCKERT 320-H.P. DYNAMO, COUPLED TO KUHN COMPOUND ENGINE, FRANKFORT EXHIBITION, DESCRIBED IN "THE ELECTRICIAN," AUGUST 21, p. 443.

Digitized by Google

The measurement consists simply of shifting u or loading the scale till the pointer r stands at zero on the scale t. The result of the measurement expressed in H.P. is found by dividing the product of the number of kilogrammes indicated by the pointer and of the lineal velocity of the belts in metres per second by 75. From this it is seen that when once the instrument is set up, the work of measuring is very simple, being reduced to an adjustment, if necessary, of the pointer to zero, before setting the instrument in motion, this being done by means of the moveable weight on r (Fig. 3), and an ordinary weighing process. The adjustment of the centre of gravity of the revolving parts prevents the centrifugal force having a disturbing influence on the measurements. The instrument is at present made in five sizes, ranging from measurements of 24 H.P. up to those of 300 H.P., all at a belt speed of 30 metres per second.

It should be mentioned that to prevent a sudden throw of the lever g (Fig. 4) against the sides of the pulleys two adjusting screws $h\,h'$ are introduced.

The astatic volt dynamometer for recording pressure of Siemens and Halske is the result of a long series of experiments, and the example shown in their laboratory at the Exhibition is a highly finished and well-made instrument. It is intended chiefly for the use of linesmen, and is provided with a scale reading directly in volts, so that there is no need to take the square root or multiply by a constant, which in this instrument is made as nearly as possible unity.

The instrument depends, of course, on the same principles as those of the well-known electro-dynamometers of this firm. It consists of two sets of coils, the two moveable ones being wound in opposite directions, so as to cut out the effect of external fields.

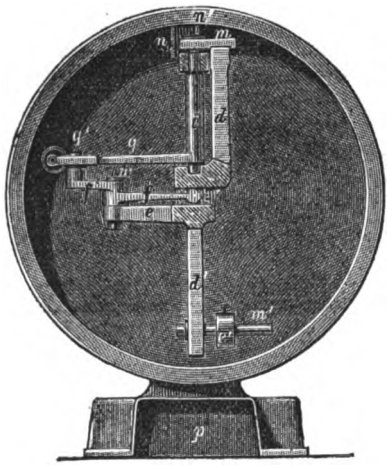

FIG. 5.—Sectional Elevation, transverse.

The fixed coils can be either placed in series or in parallel, the divisions of the scale then denoting either 1 volt or $\frac{1}{2}$ volt. Thus the instrument can be used for pressures up to 90 volts or to 180 volts, and, of course, works equally well with continuous and alternating currents.

Siemens and Halske "band" lamp forms one of their latest novelties; its name is due to the long copper band which supports the upper carbon. It is wound on a drum whose axis is horizontal and connected with an escapement which on being let loose by the action of the electromagnet or magnets, gradually releases the band and with it the upper carbon. The armature is on the same axis as the drum, and is acted on by two spiral springs, of which the upper is the more powerful, but is, however, prevented from pulling home by the end of the armature, which presses against a fixed support. As soon as the magnetic attraction overcomes the force of the upper spring, the escapement is let loose and the band and carbon descend till the spring again overcomes the magnetic force. A spring is set on the interior of the drum and this is wound up by the action of the descending carbon, so that when the carbon is again lifted the drum revolves under the action of the spring and winds the copper band on to it.

Mr. C. H. Stearn, who was formerly director of the Swan United Electric Light Company, has now removed to Zurich, and started the manufacture of glow lamps there, in connection with the Zürich Incandescent Lamp Company. He has taken with him from England the engineers and others who were associated with him there, and is now turning the Zurich natives into skilled glow-lamp makers. The lamps have to pass many tests before being declared ready for sale, among them being a very severe one for vacuum with an induction coil. The lamps are largely used at the Exhibition, about 5,000 being used in some 23 different installations. The following are some data relating to the lamps manufactured by the above firm.

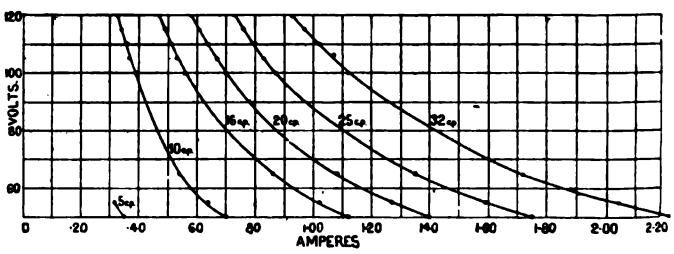

FIG. 7.—Curves showing the Relation of the Candle-Power with the Voltage and Current.

MAGNETIC CIRCUITS AND THEIR MEASUREMENTS.*

BY H. E. J. G. DU BOIS.

Ten years ago, when the first amazement produced by the wonders of electricity had subsided, engineers set themselves to detail work, and attempted to design reasonable dynamos and motors. The history of steam engines began to repeat itself. For this they wanted a theory; but in the literature of electro-magnetism, though voluminous enough, nothing was found that could be utilised. Since then, the two principal worthies of science, British and Continental, have stated that, in their concordant opinion, all that was wanted might at the time have been found ready by diligent searchers. Allusion was made to writings (in the reverse of chronological order) of

* Translated and abridged from a Paper read in Section I. of the Frankfort Electrical Congress, September 11, 1891.

Digitized by Google

Maxwell, Sir Wm. Thomson, Faraday, as far back even as Euler.

However this may be, engineers, finding no assistance from science, helped themselves. History will give them due credit for this; science can do no better than annex the ground covered on that side, in a state, however, modified to suit her wants, and cleared from much that is superfluous or even wrong.

During the last decennium, investigations appeared by Bosanquet (1883), Rowland (1884), Werner v. Siemens (1884), Gisbert Kapp (1885), Pisati (1890), in which closed electromagnetic systems are considered analogous to electric circuits, and have Ohm's law applied to them. However, I hold the latter to essentially involve that the ratio of E.M.F. to current is constant, irrespectively of the amount of current. Now, the magnetic flux of induction (alias number of lines of force) is neglecting hysteresis, a single-valued function of the so-called magnetomotive force; but these quantities not being in the least proportional, it seems to me unwarrantable to introduce their ratio as a resistance in the sense of Ohm's law. This would lead one to divide the argument of any function by the latter, and introduce the quotient as a mathematical resistance against the increase of the function. In physics we would then have none but ohmic laws.

The conception of the magnetic circuit is doubtless a fruitful one, and the introduction, for practical purposes, of an (essentially variable) resistance may be recommended. But I think the use of Ohm's name is sufficiently widespread already, and should not be tolerated in connection with our present subject. Still less should magnetic shunts be treated under the auspices of Kirchoff and his rules, such treatment giving nothing but false results.

These criticisms do not apply to the Hopkinsons' classical Paper, which marks the modern epoch of the subject. In fact, they never mention an ohmic law; they simply start from two absolutely safe propositions, viz.: (1) The many-valued lamellarity of H; (2) the solenoidality of B; the latter is, of course, *the* theorem in the "tubes-of-force" theory. Their Paper is often considered a practical one, on account of the dynamo experiments in it. But science claims it as hers for the essentially scientific method followed.

I would now principally show how we may manage without tubes of force, the importance and elegance of which is not in the slightest degree denied. We may go as far by considering, in the old-fashioned way, magnetisation at individual points in the iron. We need not even be physically ultra conservative to prefer this method to looking at the magnetic circuit as a whole, because recent experiments teach us to consider magnetisation as the quantity physically more fundamental than induction. However, within the range occurring in practice, these quantities do not differ by more than the factor 4π.

I was glad to find that Prof. Ewing to a certain extent follows my method in his latest paragraphs on the magnetic circuit, published in *The Electrician*; on the other hand, I regret that after so excellent an exposition my present remarks may appear rather superfluous.*

I.

In terms of the old theory of magnetic induction, as classically expounded in Maxwell's treatise, the behaviour of an ellipsoid of revolution is determined in the now well-known manner by the factor N; we might appropriately call this the "self-demagnetising factor," though a shorter name would sound better. Such an ellipsoid with the closed tubes-of-force surrounding and pervading it, may, of course, be conceived as a magnetic circuit; however, in the present case, this would certainly not lead to so simple a mode of representation.

As regards magnetic circuits in the more usual sense, their simple type is a thin ring, uniformly and peripherically magnetised and provided with a radial air gap. This case is reducible to the preceding one as soon as the factor N is known. It is found that

$$N = \cdot 035\ a \text{ or } = \tfrac{1}{8}\ p,$$

where a is the width of the slit in degrees, p the same in hundredths of the mean periphery. This result is most simply obtained by considering the line-integral of the self-demagnetising force which must vanish when taken around the ring; it is deduced for an infinitely narrow gap. The result may be put somewhat plausibly by considering the gap as a magnetic shell; for this we may substitute the equivalent current almost uniformly counteracting the rest of the uniform winding. The action of such local coils on rings has been experimentally investigated by Oberbeck in 1878.

The amount of deviation of the above equation from the truth with increasing width of the gap must be determined by experiments. These are now being made by Mr. H. Lehmann in the Berlin University laboratory. This ring (shown to the audience) is turned out of Swedish plate; it is uniformly wound with three primary and one secondary layers. The gap now covers $\frac{1}{4}$th per cent. of the circumference; preliminary experiments gave good agreement with theory for intense magnetisation. When the latter is less (as would occur in practice) a sufficiently constant value of N was found; this is smaller than that given by theory in a ratio which must be related to the leakage coefficient of the tubes of force theory. Details will be published after the completion of the experiments.

The two typical cases, ellipsoid and ring, have now become entirely comparable. The curve of magnetisation, I = funct. (H) for endless pieces (infinitely long ellipsoids or closed rings) I shall call the normal curve. From it we find the curves for shorter ellipsoids or for rings gradually opening out by Ewing's "shearing" of the diagram. We soon see the curves merging into a characteristic form adapting itself to two straight lines. The first of these passes through the origin and forms an angle, $\tan^{-1} N$, with the axis of ordinates. The second runs parallel to the axis of abscissæ at a distance corresponding to the maximum values of the magnetisation. The first straight line depends upon the shape of the magnetised body only, the second upon the material, whereas the point of intersection is determined by both. The same holds for the parts of the curve near each of the straight lines. Now we may, at least as an approximation, consider these as the asymptotes to an hyperbola, th equation of which is found to be

$$x = N\,y + \frac{P}{1-y} \text{ or } x = \frac{N\,y + (P - N\,y^2}{1-y},$$

here P is a second constant; the unit of ordinates is the maximum magnetisation.

It is interesting to compare this with the old well-known hyperbolic curve of O. Frölich, the equation of which (in the above convenient unit) may be written:

$$y = \frac{1\,Q\,x}{1 + 1\,Q\,x}, \text{ or } x = \frac{Q\,y}{1-y},$$

Here Q is that value of k for which y becomes $= \frac{1}{2}$; *i.e.*, the iron is "semi-saturated" or, as Prof. Silvanus Thompson has it, reaches its "diacritical point." The equations are seen to differ by the term $P - N\,y^2$ in the numerator. Frölich's curve has a different flatter shape than the one deduced above, and it is always impossible to give Q a value so as to fulfil the conditions prescribed. From the purely electro-magnetic point of view, I therefore prefer my own hyperbola, leaving it to competent judges to decide on the practical applicability of Frölich's curve of "effective magnetism."

In conclusion, I remark that the "shearing of the diagram" is not restricted to ellipsoids and rings, but may be applied (approximately) to bodies of any shape. The mean factor, N, for a given shape may be found by experiment. Lord Rayleigh's original construction is thus generalised to the utmost.

II.

A few applications remain to be mentioned.

In the first place a question exists, the solution of which may now be attempted. It is the construction of electro-magnets for producing fields as strong, as uniform, and as extensive as possible. The problem is well-defined; its conditions essentially differ from those which have to be fulfilled, say, in a dynamo; still a rational solution must be feasible with our

* The original German paper was prepared before these articles appeared; so far as the ground is already covered by Ewing, the present English translation is therefore considerably cut down.—d.B.

Digitized by Google

theory. In any case something better may be expected than the purely empirical types now used. It is hardly necessary to dwell upon the importance of such improved apparatus for further experimental advance in magnetism.

In the air-gap of the ring above mentioned we may obtain a field of almost 20,000 C.-G.-S., with a current of 20 amperes. By general theorems of Sir Wm. Thomson's on similar electromagnetic systems, we get the same on magnifying the whole arrangement, say, to five-fold linear dimensions, and using the five-fold current of 100 amperes. By conical pole-pices, bored if necessary (Fig. 1), we may considerably concentrate the field, though its extension and uniformity are thereby reduced. We know more about such cones now from late investigations by Stefan, Ewing, Czermak, and Hansmaninger. We have still to cut through along C (Fig. 1), in order to be able to vary the distance of the poles within certain limits. Such an electromagnet is being built at present from my designs by Messrs. Siemens and Halske.

In conclusion, I have to demonstrate an instrument intended to meet the want of a rapid and simple method for determining magnetic curves of materials used in machine construction. The existence of a demand seems to be proved by the number of attempts made to supply it. We have Hopkinson's bar-and-yoke, Swinburne and Bourne's differential inductive method, Silvanus Thompson's permeameter, Rœpsel's open-circuit torsion apparatus, Eickemeyer's differential magnetometer, Corsepin's siderognost, Bruger's bismuth spiral apparatus. It appears that in America Edison and others proposed various other arrangements, about which we never heard much. It would

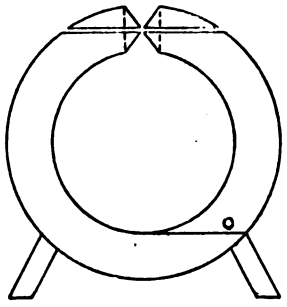

Fig. 1.

lead too far to enter into a description, or even a critical discussion, of all these more or less known instruments. I restrict myself to shortly describing a new solution of the problem and showing the apparatus.

The leading constructive principle was to insert the cylindrical test sample as the principle resistance into a magnetic circuit. As it is quite impossible to reduce the rest of the resistance so as to make it negligible it must be capable of being simply corrected for. It therefore consists for the greater part of air, for the smaller of Swedish iron of large cross section. The induction B in the circuit has to be measured, and it is very tempting to do this by means of the considerable tension of the lines of force in the air-gaps, which amounts (in kilogrammes) to very nearly $(B/5{,}000)^2$.

The tension might be measured in different ways, *e.g.*—1. By sucking in an iron ribbon. 2. By manometrical determination of the hydrostatic pressure in a liquid filling the "interferric" spaces.* 3. By compensating the tension by weights. I chose the latter method as the simplest, though not direct-reading.

The practical application is realised in this magnetic balance (of which Fig. 2 gives a rough idea). The test sample T, which need not necessarily be circular, is cut to a length of 15cm., and automatically clamped between the two massive vertical uprights U_1 and U_2. It may be subjected to fields up to 500 C.-G.-S. by the coil C, of length, 4π cm., so that field $= \frac{1}{10} \times$ ampere-turns. Above the uprights a yoke, Y, is eccentrically supported; magnetic attraction, equal on both sides by symmetry, therefore produces a resulting moment on account of the unequal leverage. This is compensated by a weight, W, sliding along a scale.

* French, *entrefer* (Hospitalier).

The yoke is balanced and adjusted so as to make its purely static equilibrium almost neutral. On magnetising it then becomes unstable; the position of the weight is read on the scale, which just pulls the yoke off the insulated contact screw I. The instant of breaking contact is best determined through having a galvanoscope, bell or telephone in circuit; it is perfectly well defined. The iron surfaces are, of course, prevented from touching by the stops I and S, over which the yoke plays like a Morse key; its motions, of very small range, do not appreciably affect the magnetic resistance of the whole circuit.

The apparatus was calibrated by means of a sample of 1 sq. cm. cross section cut out of the same Swedish plate as the ring above mentioned; its normal curve was, therefore, known. With a small secondary coil and ballistic galvanometer the flux of induction, G, in the central part of the test-piece, was measured for different values of the magnetising field. If the percentage leakage of the circuit be made sufficiently independent of the magnetisation, the scale-reading is proportional to the square of the flux, as above determined. By adjusting the weight and screws the factor of proportionality may be made a round number. The magnetic curve, as found with the sample in the balance, was drawn beside the normal curve, and from the differences of the abscissæ the factor N was at once known. This remains a constant characteristic of the balance, provided the cross-section of the samples afterwards tested does not differ too much from 1 sq. cm.

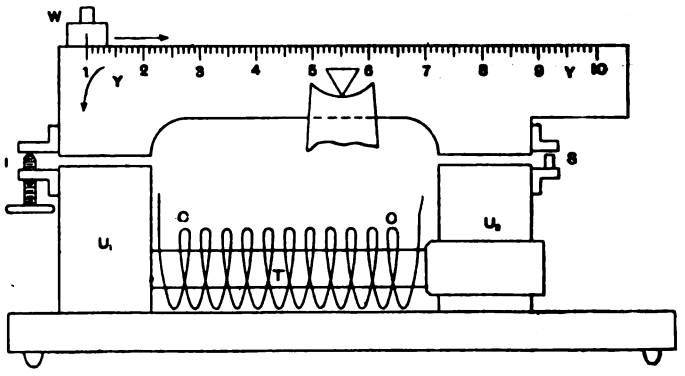

Fig. 2.

Magnetic curves may afterwards be obtained simply by measuring the current in the coil and balancing the beam. They are best drawn directly from an axis of ordinates inclined towards the left through an angle equal to $\tan^{-1} N$. The balance exhibited was made from my working drawings by Mr. W. Oehmke, of the Berlin Physiological Institute; it has the following constants:—

H Field (C.G.S.)	... ...	$= 50 \times$ Current in coil. (amperes)
G Flux of induction (C.G.S.)		$= 1{,}000\,\pi\,\sqrt{\text{scale-reading.}}$
or B Induction (C.G.S.)	...	$= \frac{1{,}000\,\pi\,\sqrt{\text{scale-reading.}}}{\text{cross-section.}}$
or I Magnetisation (C.G.S.)	...	$= \frac{250\,\sqrt{\text{scale-reading.}}}{\text{cross-section.}}$
N		$N = 1/60$
Range		$1{,}700 > I > 0$

"L'Industrie."—In order that Belgium may possess "a journal of science and industry comparable with the great industrial publications of other countries" the journals *Ingénieur-Conseil*, *Industrie Moderne*, and *Industria*, have amalgamated; and the result is a new journal called *L'Industrie*, which seems likely to prove superior to either of the constituent journals both in matter and illustrations.

A THIMBLE FOR DRAWING CABLES INTO CONDUITS.

When drawing electric cables into pipes, Callender-Webber cases, or other conduits, it is necessary to make a secure connection between the cable and the rope by which it is to be pulled in. It is also necessary that such connection should be small enough to pass through the pipe or case. The method usually adopted at present is to make a splice by cutting out the centre strands of the conductor and "marrying" the outer strands to those of the rope. A gripping device has been

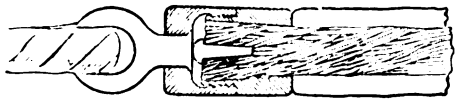

FIG. 1.—Section through thimble, ferrule, and cable.

designed by Mr. A. A. Voysey, of 95, Drury-lane, to avoid the waste of time and material entailed by this method. It consists of a ferrule two or three inches long, tapered inside, and made so that the narrow end fits closely to the conductor of the cable. The ferrule is placed on the end of the conductor, narrow end foremost, the insulation being cut back two or three inches, according to the length of the ferrule. When it is in position, a tapered pin

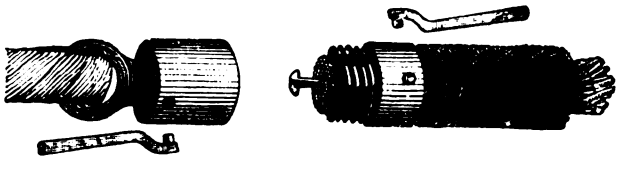

FIG. 2.—Ferrule attached to cable, and spiked. Thimble ready for screwing on.

is driven into the centre of the cable, and this spreads the strands so as to give a tight grip. It is easy to see that any attempt to pull the ferrule off will now cause it to grip the strands more tightly. A cap or thimble is connected to the end of the hauling rope by means of a swivel, and this is screwed on to the ferrule. Thus in two or three minutes a joint (of smaller diameter than the cable) can be made capable of sustaining any strain required.

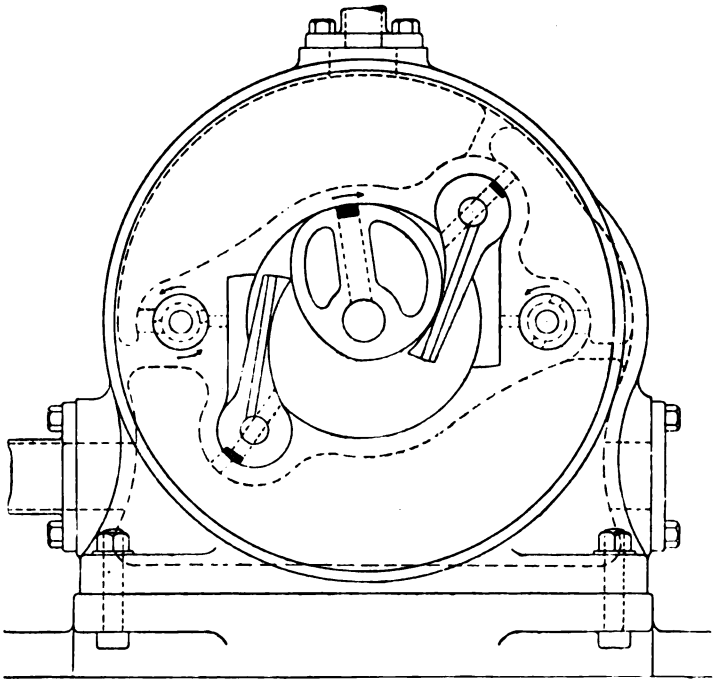
FIG. 3.—Exterior view of connection.

After the cable is drawn in, the ferrule can be easily removed by taking out the tapered pin, which is provided with a small head, so that it can be knocked out without difficulty. This thimble has been used in practice and is found to work well. The saving of time is important, since the cost of keeping the whole gang waiting must be taken into account, and there need be no waste whatever of the cable.

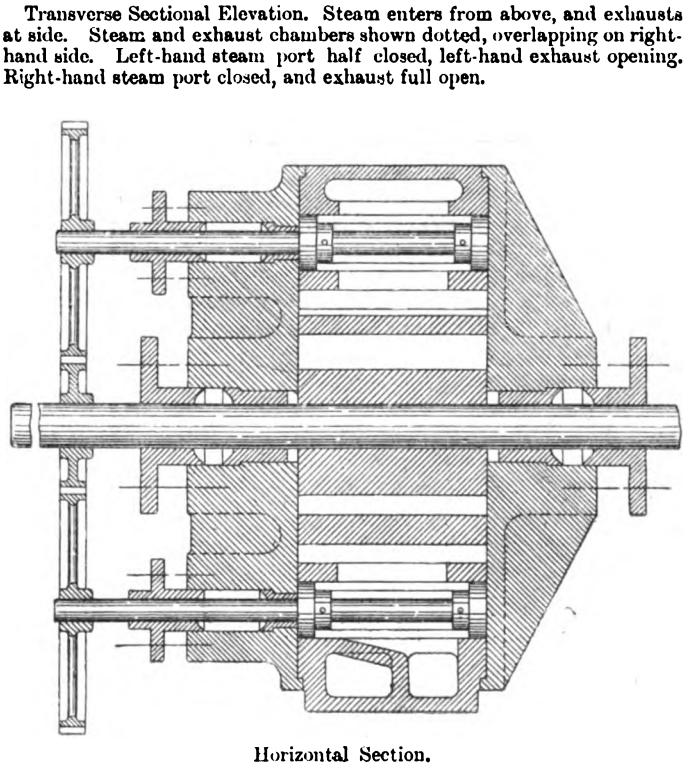
THE BROWN PATENT ROTARY ENGINE.

There is a singular fascination for many mechanical minds in the invention of rotary engines; and it has been observed by the inventor of one of the most successful ones that if his invention would not do for an engine it would work as a pump, or if no good as a pump it would make a good stone-crusher. Reauleaux has classified a large number of "Chamber crank trains," and it is rare to find a rotary engine that is not illustrated in that interesting work. The type of the one which we illustrate herewith is well known, and several attempts have been made to introduce it practically. One of the most recent examples was that of the Hodson Engine, exhibited at the Crystal Palace in 1881, but which has not been heard of again. The piston of this engine is an eccentric drum keyed upon the main shaft, revolving in a cylinder, the contents of which are divided into steam space and exhaust space by means of flaps. The accompanying illustration explains itself.

The novel feature of the Brown engine is the arrangement of admission and exhaust valves. The former are cylindrical, and are driven by gear wheels from the main shaft, and, therefore, revolve continuously. The exhaust passages pass through the flap valves, and this arrangement allows a good steam dis-



Transverse Sectional Elevation. Steam enters from above, and exhausts at side. Steam and exhaust chambers shown dotted, overlapping on right-hand side. Left-hand steam port half closed, left-hand exhaust opening. Right-hand steam port closed, and exhaust full open.



Horizontal Section.

tribution to be obtained. The cylinder is 10½in. in diameter by 8⅝in. in length. The drum occupies nearly one half the volume of the cylinder. The independent adjustment of the steam valves allows the cut-off to be given at any desired point, and effective cushioning to be produced. Prof. Jamieson has made a test of the engine, and found that at a mean speed of 574½ revolutions per minute, and a B.H.P. of 20·8, the feed water per B.H.P. was 37·91b. per hour. The report of Prof. Jamieson contains indicator diagrams, which have been

Digitized by Google

re-drawn with certain modifications from those which were taken during the test. The mean effective piston area and effective stroke of this engine is not readily ascertained, and without a full explanation as to this, much information cannot be obtained from the diagrams. The feed water per indicated horse-power hour is given at 22·72lb. The report alludes to various corrections, which may be introduced into these figures, and says that there is no difficulty as far as the engine is concerned in increasing the speed to 800 or 1,000 revolutions per minute. The engine is remarkably compact, and is, we understand, being further improved.

It was found necessary in the Hodson engine to duplicate the arrangement in order to balance the parts of the revolving masses to some extent, and there was great difficulty in reducing the noise and vibration.

The weak point in this type of engine is the difficulty of maintaining a steam tight fit. The revolving drum has a longitudinal packing piece bearing against the circular wall of the cylinder, and two radial pieces bearing against the ends. The flap valves are also provided with radial bearing strips, but have to make a rubbing contact on the surface of the drum, bearing sometimes on their faces, and at other times on their edges, and being held there by the pressure of the steam. This "high pairing" and "force closure," as it is called in Prof. Kennedy's Translation of Reauleaux, makes it rather doubtful if the arrangement can be kept steam tight.

ON THE RELATION OF THE AIR GAP AND THE SHAPE OF THE POLES TO THE PERFORMANCE OF DYNAMO-ELECTRIC MACHINERY.*

BY HARRIS J. RYAN.

The object of this Paper is not to deal with the subject in a new light, but to add to its literature a limited amount of data, the deductions from which go to establish the correctness of the ideas and the utility of the suggestions put forth in the Papers read by Messrs. Swinburne and Esson at the meetings of the Institution of Electrical Engineers on Feb. 13 and 20, 1890. Up to the

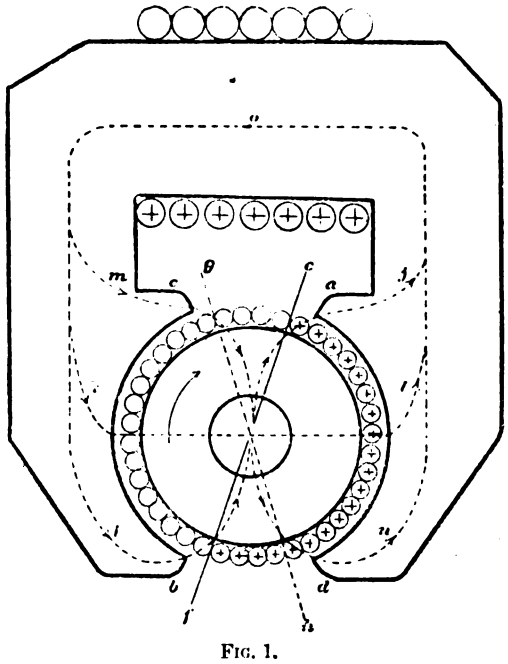


FIG. 1.

time of the publication of these Papers, the air gap was usually treated by contributors to electrical literature as an evil in a dynamo, having a necessary existence, and the smaller that it could conveniently be made the better. The shape of the poles had often been spoken of as having a somewhat decided effect on the performance of the dynamo, while but little had been said regarding the cause of such an effect.

* A Paper read at the 59th Meeting of the American Institute of Electrical Engineers, New York, September 2, 1891.

There exists some difference of opinion as to what should be known as the number of ampere-turns on an armature. For our present purpose we will assume that

$$\text{Armature ampere-turns} = \frac{\left\{\begin{array}{l}\text{The number of con-}\\ \text{ductors on the sur-}\\ \text{face of the armature}\end{array}\right\} \times \left\{\begin{array}{l}\text{Strength of cur-}\\ \text{rent in the arma-}\\ \text{ture conductors}\end{array}\right\}}{\text{Number of poles.}}$$

Referring to Fig. 1, it is evident that when we consider the magnetic forces acting in a working dynamo by the route O, I, J, O, that the entire number of ampere-turns on the armature are directly opposed in action to the ampere-turns on the field. By the route O, M, N, O, all the ampere-turns on the armature except those that lie between the double angle of lead, G, E, are acting with the field ampere-turns, while those between G, E, are opposed to the same. Therefore, by this route the total number of ampere-turns actually aiding the field ampere-turns is the total number of armature ampere-turns, minus twice the number of ampere-turns that lie between the double angle of lead. By the route O, K, L, O, the number of ampere-turns acting is the number of ampere-turns on the field, minus the number of ampere-turns that lie between the double angle of lead. We can then estimate with ample practical accuracy the magnetic density in the air gap at all points, for any given total amount of magnetisation through the armature. The ampere-turns that lie between the double angle of lead are

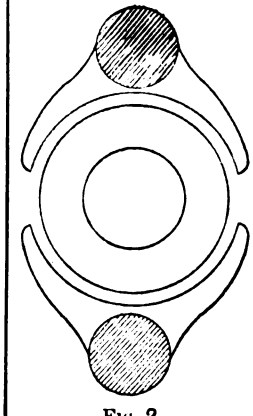

FIG. 2.

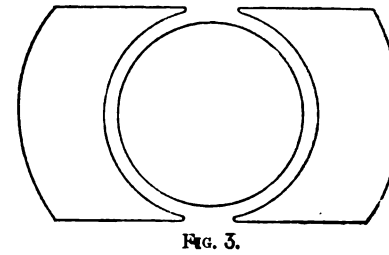

FIG. 3.

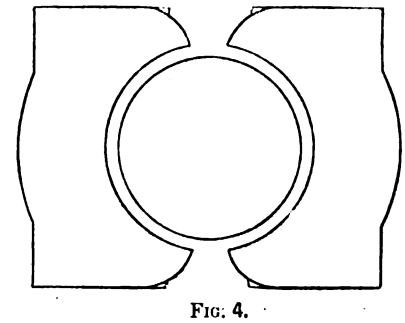

FIG. 4.

opposed to the action of the field ampere-turns at all points. It is evident that the portion of the armature ampere-turns not included between the double angle of lead will increase the magnetisation through the air gap by the route O, M, N, O, just as much as they diminish it along the route O, I, J, O, as long as magnetic saturation does not take place in the strengthened pole corners C, D. If the pole corners are thin, as in the types shown in Figs. 2, 3 and 5, saturation is apt to occur. It is then that the magnetic resistance increases by the route O, M, N, O, and the magnetic density by this route is no longer increased by the same amount that it is diminished along the route O, I, J, O. On the other hand, when the pole corners are fashioned as seen in Figs. 4 and 6, so that saturation in the strengthened pole corners cannot occur in practice, the current in the armature can produce no modification of the total amount of magnetisation through it, other than that which is produced by the action of the ampere-turns that lie between the double angle of lead. This action can always be compensated for by putting an equivalent number of series ampere-turns on the field acting with the field ampere-turns. The double angle of lead can be determined with sufficient accuracy, for with pole corners slightly extended at the centre, see Fig. 11, the diameter of commutation at all loads is very near the weakened pole corners. The pole corners are slightly extended at the centre, so that the coils always enter the field of the weakened pole corners gradually. The E.M.F. developed in the coils as they pass under the poles can never be far different from that actually needed to

Digitized by Google

reverse the current in the coil when passing under the brush. In this way the point of commutation in a dynamo can be kept the same when carbon brushes are used without undue sparking, as long as the armature does not reverse the magnetisation under the weakened pole corners.

From the discussion of the magnetic relations of an armature to its field in a dynamo in connection with Fig. 1, it is seen that the magnetisation in the air gap under the weakened pole corners becomes zero, when the armature ampere-turns are equal to the ampere-turns on the field, whose magnetising force is impressed between its pole faces through the armature. This impressed magnetising force is that due to the difference between the total number of ampere-turns on the field and the number of ampere-turns required to set up the magnetisation through the field cores, from pole face to pole face. In order to commutate the current without spark at the commutator, the magnetisation in the air gap under the weakened pole corners should never be allowed to become zero. It follows, then, that the field ampere-turns impressing a magnetising force between the pole faces must always be somewhat in excess of the maximum number of ampere-turns on the armature. The amount of this excess need only be sufficient to insure a positive field at A and B, Fig. 1, strong enough to reverse the current in the coils as they are commutated. When a certain amount of magnetisation is to be set up through an armature with

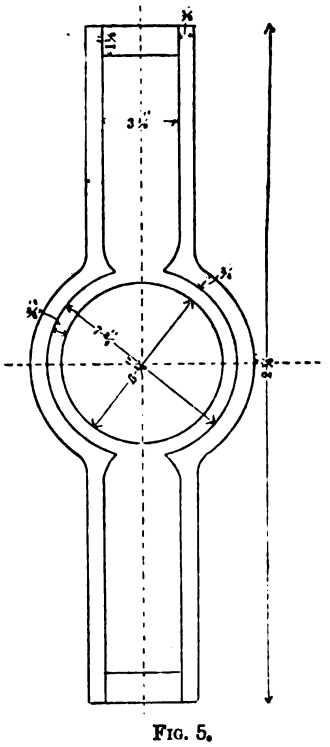

Fig. 5.

the application of the magnetising force of a given number of ampere-turns impressed between the pole faces, we must provide the requisite amount of magnetic resistance between these pole faces. The value of this resistance will have to be such that the impressed field magnetising force will establish the desired amount of magnetisation. This resistance in most cases is best provided for in a proper length of air gap. In general it is found best to avoid heating in the armature core as far as consistent, by the use of comparatively low magnetic densities for wrought iron. The magnetic resistance of the armature core under these circumstances is very small and may be neglected.

The magnetic resistance between the pole faces is occasionally provided for largely, either through a saturated core of a ring armature, saturated lugs on armatures where the wires are placed in grooves, or both. This, in addition to what air gap may be necessary from a mechanical point of view, goes to make up the total amount of magnetic resistance that is provided between the pole faces. Machines of this order have been developed largely through the old and rather expensive method of experimentation. This method has given us some types in which ordinary results are arrived at through rather extraordinary means. Take the case of a machine with a ring armature, wires wound in grooves, a very small air gap, and poles shaped somewhat as shown in Fig. 2. Such a machine operated as a dynamo may require only a quarter of the number of ampere-turns that it will have on the armature at full load for field excitation in order to produce a certain E.M.F. at a given speed. Yet this machine produces a fairly constant potential at the brushes under all variation of load, and without undue sparking at the commutator, in the following manner.

For the production of a constant E.M.F. at constant speed the total magnetisation through the armature must remain constant. At no load one-fourth of the ampere-turns needed on the field at full load are provided by a shunt winding. This shunt winding is sufficient to set up the total amount of magnetisation for the production of the normal E.M.F. of the machine when there is no current in the armature. Now, in order to take the normal current from the armature without reversing the magnetisation under the weakened pole corners, three times as many series ampere-turns as there are shunt ampere-turns must be added to the field. The addition of these series ampere-turns must not increase the total amount of magnetisation through the armature, which is accomplished by the thin pole corners. The strong pole corners become saturated when the armature is furnishing even a small amount of the normal current for which it is designed. For most values of the current, then, the armature ampere-turns tend to diminish the magnetisation under the weakened pole corners, but cannot increase it correspondingly under the saturated pole corners. The action of the series ampere-turns on the field prevents the reduction of the magnetisation under the weakened pole corners to zero, while the saturated portion of the pole-pieces prevents the increase of the total magnetisation through the armature, and thus a constant potential is maintained.

The "armature characteristic" IV. plotted in Fig. 7, was taken from the machine of the above sort, built with cast-iron fields. The cross-section of the field cores proved on trial to be too small, and became strongly saturated at full load,—while they were quite a little under the point of saturation at no load. This curious result for a constant potential generator was due to the increased magnetic leakage, produced as the series ampere-turns on the field came up with the load. Saturation took place as the curve indicates, when the armature furnished a current of about 140 amperes, and no possible compounding could ever make this generator produce even approximately a constant potential, with variation of load. Steel cores of the same dimensions were substituted for the cast-iron cores. Saturation did not occur in them due to magnetic leakage. The pole corners were very thin, as in Fig. 2, and the "armature characteristic" III. was obtained. The machine was then furnished with a shunt winding that produced a slightly

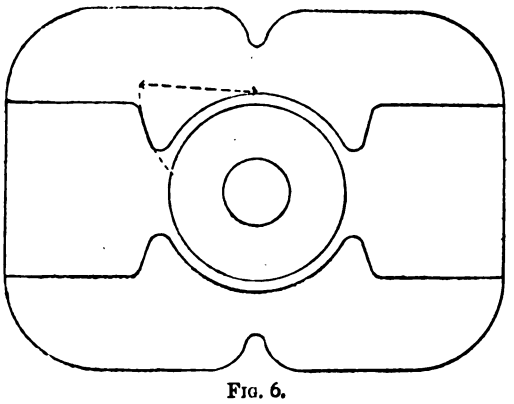

Fig. 6.

smaller number of initial ampere-turns than Curve III. indicates as required to produce 125 volts, and with series turns at such a number that the total number of ampere-turns on the field for any current developed by the armature is shown by the broken line drawn through Curve III. It was under these conditions that the machine performed in the manner described above, did not vary more than 5 per cent. from the normal E.M.F. on either side, or a total variation of 10 per cent. It was then almost entirely rebuilt. The armature was provided with a core that was considerably larger in cross-section, and the maximum magnetic density used in it was 11,000 lines per sq. cm., as against 20,000 used before. The lugs on the core were dispensed with, and the wires wound on the surface of the core. The poles were made of cast iron, and fashioned to accord more nearly with those in Fig. 3. The air gap required ten thousand ampere-turns to set up the magnetisation through it at no load, while the armature ampere-turns were 8,000 at normal output, so that series ampere-turns had only to be added to counteract the action of the ampere-turns on the armature that lie between the double angle of lead, to increase slightly the E.M.F. by the amount equal to the fall of potential through the armature caused by its resistance, and to compensate for the slight effect of the pole corners that still became saturated to a limited extent for the higher outputs. It should be remembered that the magnetic leakage that takes place between the adjacent north and south pole corners, one of which is strongly and the other weakly magnetised, plays an important part in saturating thin pole corners. It is evident that unless the "armature characteristic" is a straight line as in Curve I., Fig. 7, the machine cannot be made to regulate for constant potential with a high degree of refinement. The poles

Digitized by Google

were again changed and shaped as in Fig. 4, when an "armature characteristic" given in Curve I. was obtained, and the proper number of shunt and series ampere-turns for a refined degree of regulation were readily decided upon. These experiments confirm what has been said above, and show how useless have been the attempts to diminish the air gap beyond certain limits.

It was shown on the outstart how we can calculate the actual magnetic densities in the air gap for any total magnetisation through the armature, for any armature current. The results of the following experiments confirm the correctness of these methods. The diagrams in Fig. 8 give the values of the magnetic density at all points of the air gap of a generator producing 125 volts at the brushes and 80 amperes. The following are its dimensions and data :—

Diameter of armature core	6·25 in.
Length of armature core	12 in.
Diameter of bore of poles	7·19 in.
Double depth of air gap	0·94 in.
Armature sections	50
Turns per section	2
Resistance of armature	0·06 ohm.
Poles shaped as in Fig. 3,	
Shunt turns on field	6400
Field current, no load, 125 volts	1·48
Field current, full load, 125 volts	2·10
Speed	1600

Carbon brushes used without lead.

The "armature characteristic" curved considerably, indicating that the pole corners become saturated. It is evident, too, that the normal magnetisation in the pole corners in addition to the magnetic leakage which is greater there than anywhere else, produced saturation in all pole corners, even with no current in the armature. For at full load there were 4,000 ampere turns on the armature, while 4,000 series ampere-turns had to be added to the field that produced 125 volts at no load to keep the E.M.F. the same. Therefore at full load we have the same number of ampere-turns acting through the weakened pole corners as at no load, and the total amount of magnetisation has only been increased 5 per cent., to compensate for the resistance of the armature conductors. The conditions, however, are not the same, for there are just 4,000 more ampere-turns to cause magnetic leakage at the pole corners, so that on the whole the magnetisation in them is increased. This increase of magnetic density in them greatly increases their magnetic resistance, for they are saturated to begin with. It is on this account that we find the magnetisation under the weakened pole corners diminished, when apparently the forces acting have not been changed. The magnetisation under the strengthened pole corners through the air gap is increased more than it is diminished by the effect of the added magnetic leakage, through the 8,000 additional ampere-turns that act to produce magnetisation by this route through the armature.

In Fig. 9 the diagrams show the magnetic action of the armature of a 10 H.P., 110 volt motor, with poles fashioned as in Fig. 6. Measurements of the magnetic leakage were made on this motor, and the results indicate that the shape given to the pole corners avoided saturation in them even at full load. The double angle of lead was almost 60 deg. The ampere-turns embraced by it on the armature were partially compensated for by 9 series turns on each of the consequent fields. The remainder of the armature ampere-turns that lie between the double angle of lead serve to weaken the field by just the amount required to produce a constant speed. The following figures give additional data on this motor :—

Diameter of armature core	8·33 in.
Diameter over all	9·0 in.
Bore of poles	9·38 in.
Double air gap	1·05 in.
Shunt turns on field	2200
Shunt current at 110 volts	3·55
Ampere turns on field at 110 volts	7800
Ampere turns on armature at full load	5750
Armature sections	48
Turns per section	3
Speed	1200

The ampere-turns required to set up 2,600 lines per sq. cm. through a distance of 1·05 in. or 2·64 cms. in open air—

$$\frac{2600 \times 2{\cdot}64}{1{\cdot}26} = 5600.$$

This is the number of field ampere-turns that exerted their magnetising force between the pole faces through the armature. The ampere-turns acting through the weakened pole corners are, therefore, very near zero, which is entirely corroborated by the fact that the magnetisation was observed to be zero at this point. (See full load curve in Fig. 9.) Through the strong pole corners the ampere-turns acting were the 5600 of the shunt ampere-turns, + the 720 of the 9 series turns + the armature ampere-turns, 5750—twice the ampere-turns between the double angle of lead, 2 × [·3 × 5750], or 3400 = 8670 which will produce a magnetic density through an air gap of 2·64 cms. depth of

$$\frac{8670 \times 1{\cdot}26}{2{\cdot}64} = 4100,$$

while the actual magnetic density measured at this point was 3950, an agreement within the possible limit of error.

In Fig. 10 are given curves showing the magnetic performance of an armature, with its conductors laid in deep narrow grooves, as shown in Fig. 12. The clearance on each side was one-sixteenth of an inch, making the double air gap one-eighth of an inch. Additional dimensions are as follows :

Diameter of the armature core	6·0 in.
Length of armature core	6·0 in.
Resistance of armature	·34
Number of sections	64
Turns per section	3
Output, amperes	20
„ volts	100
Speed	1800

Curve I., in Fig. 10, shows the distribution of magnetisation at 112 volts, no current, a speed of 1800, and a field excitation of 2,600 ampere-turns. Curve II. shows the magnetic distribution for an output of 97 volts and 24 amperes, at a speed 1800, and a field excitation of 2600 ampere-turns. Curve III. shows the magnetic distribution at an output of 40 volts and 20 amperes, at a speed of 1800, with a field excitation of 750 ampere-turns. This same excitation, when the armature furnished no current, produced an E.M.F. of 48 volts, at a speed of 1800 revolutions. The poles were shaped as in Figs. 11 and 12, but modified as explained below. In making these experiments carbon brushes were used, and their position maintained at the normal diameter of commutation. An average magnetic density in the air gap of 3400 lines per sq. cm. was required to produce an E.M.F. of 112 volts. The grooves on the armature in which the conductors were placed occupied one-half of the armature surface, so that the actual magnetic density in the air gap was 1·8 times this average magnetic density. The ampere-turns required to set up this magnetic density in the air gap were

$$\frac{{\cdot}125 \times 2{\cdot}54 \times [3400 \times 1{\cdot}8]}{1{\cdot}26} = 1520,$$

which is the number of field ampere-turns whose magnetising force is impressed between the pole surfaces through the armature, when it furnishes 112 volts and no current. The ampere-turns on the armature at a current of 24 amperes are

$$\frac{2 \times 64 \times 3 \times 12}{2} = 2300,$$

as against 1520 impressed by the field. Under these circumstances the magnetism under the weakened pole corners is reversed, as is also clearly indicated by Curve II., in Fig. 10, or the Curve C E D F C, in Fig. 11. This curve also shows that the magnetic density under the strong pole corners was 5,100 lines per sq. cm. Now in building this machine, six longitudinal slots, 1¼ inch deep, were cut in each pole immediately back of the surface, which enables us to be sure of the exact densities in the pole corners for a given distance. For a depth of 1¼ inches immediately back of the pole-faces, these slots took up one half of the cross-section of the poles. Then a density, therefore, of 5,100 really means a density of 10,200, or a strong saturation for a distance of 2½ inches in the cast-iron of the poles. The magnetising force required to produce 10,200 lines per sq. cm. through cast-iron is 200 per centimetre length. Therefore the ampere-turns required to establish this density through 2½ inches are

$$\frac{2{\cdot}5 \times 2{\cdot}54 \times 200}{1{\cdot}26} = 1{,}000.$$

The total number of ampere-turns acting to produce magnetisation through these strong pole corners was the sum of the field ampere-turns that impressed the magnetising force from pole face to pole face through the armature, and the ampere-turns on the armature covered by the poles. The poles covered approximately 85 per cent. of the armature surface, making this value 1,500 × [2,300 × ·85] = 3,400. Of this number, as was just shown, 1,000 were utilized in producing the magnetic density of 5,100 through the saturated portion of the poles. The remaining 2,400 ampere-turns exerted their magnetising force in producing the average magnetic density of 5,100 through the air-gap, and affords another opportunity of checking these ideas of the action of the armature on the field. For the ampere-turns required to set up an average magnetic density of 5,100 through the air gap under consideration were :

$$\frac{[1{\cdot}8 \times 5{,}100] \times {\cdot}125 \times 2{\cdot}54}{1{\cdot}26} = 2{,}300$$

which checks with the above value as well as could be expected. When the armature furnished 24 amperes, the E.M.F. at the

Digitized by Google

brushes was 97 volts, while with no current it was 112 volts. Of this drop of 15 volts, 8 are accounted for by the resistance of the armature, and the extra 7 were caused by the saturated pole corners. By operating this same machine at an E.M.F. at which the pole corners could not saturate with normal output of current, we have demonstrated for us in a very striking manner that the armature ampere-turns cannot change the total magnetisation established through the armature by the field when the pole corners do not saturate. The E.M.F. with the armature current at zero was brought to 48 volts with a separate field excitation of 750 ampere-turns. Then when the armature was allowed to furnish 20 amperes the E.M.F. at the brushes dropped to 40 volts. Of this drop of 8 volts, 7 were produced by the resistance of the armature. Yet the field is powerfully distorted by the armature current, as may be seen by reference to Curve III., Fig. 10, or the

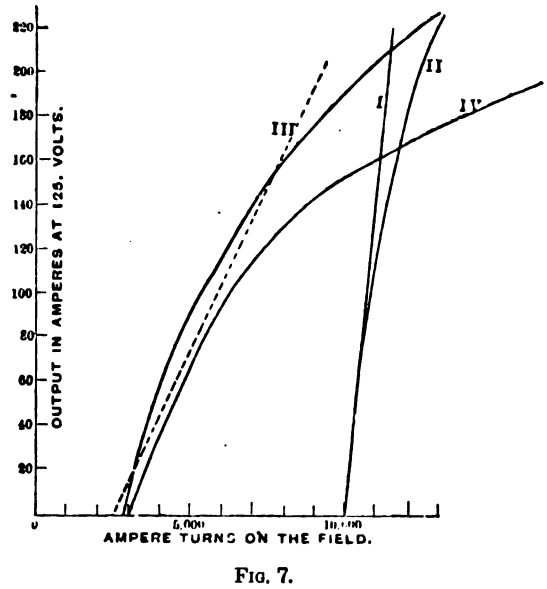

Fig. 7.

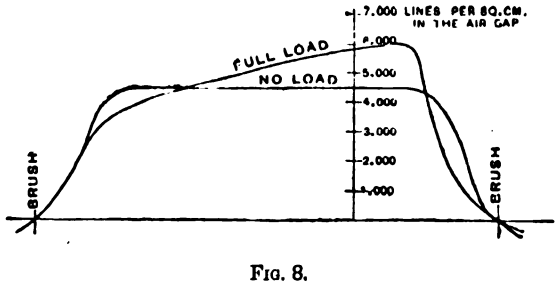

Fig. 8.

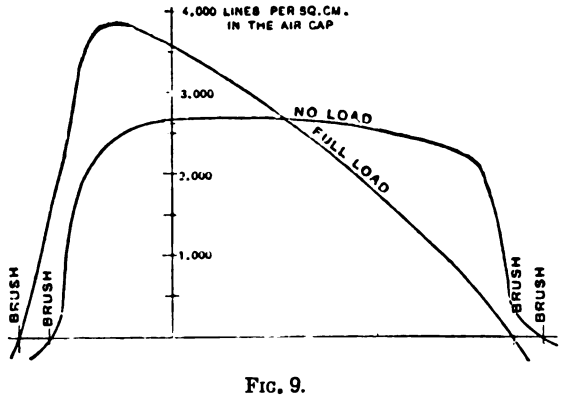

Fig. 9.

curve A, D, C, B in Fig. 12. Even with this very great rearrangement of the magnetisation produced by the armature current, the total magnetisation set up by the field is practically unchanged. The difference of potential on the commutator between the points A, B, Fig. 12, was observed to be 72 volts. This excess of E.M.F. over that which was produced at the brushes, the figure shows clearly to be due to the magnetisation produced by the armature through itself and the strengthened pole corners. The points where the field is zero are at A, B. They mark the diameter through which the ampere-turns encountered on the armature are just equal and opposite in action to the ampere-turns of the field that impress a magnetising force between the pole faces through the armature. A simple computation will show that this is true. The field ampere-turns that impress magnetising force between the poles when the armature produced an external E.M.F. of 48 volts are

$$\frac{1,520 \times 48}{112} = 650.$$

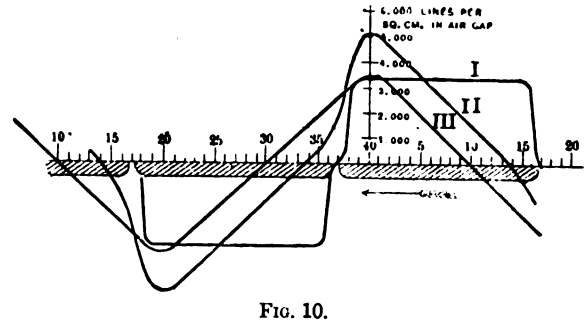

Fig. 10.

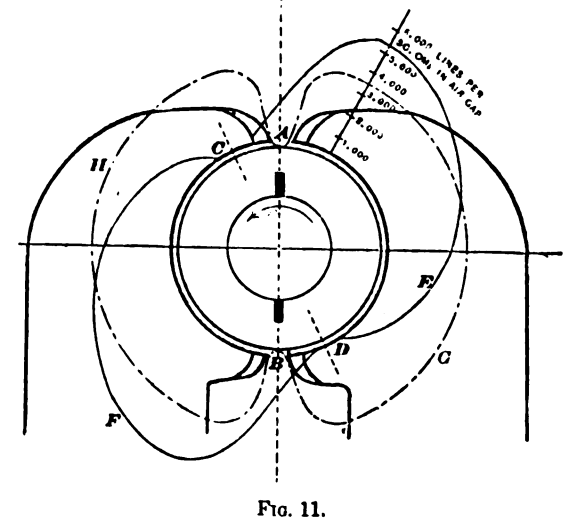

Fig. 11.

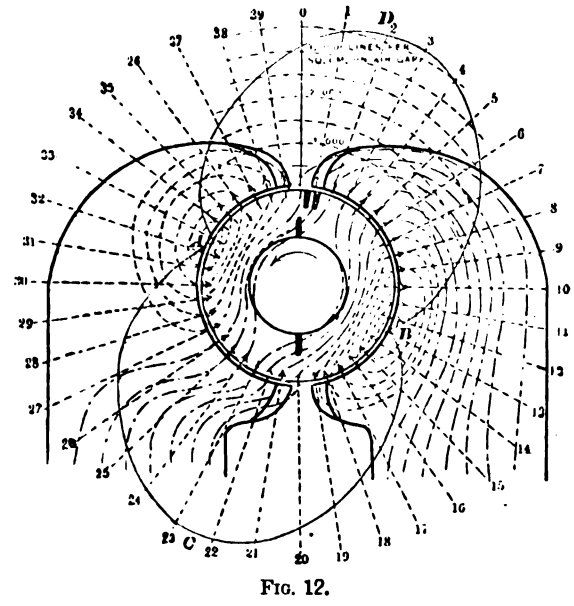

Fig. 12.

The ampere-turns on the armature opposed to the magnetisation set up by the route A B are 12/40 of the total number of ampere-turns on the armature (*see* Fig. 12), or

$$\frac{12 \times 64 \times 3 \times 20}{40 \times 2} = 576.$$

This is a fair agreement when we consider the accuracy with which the original data may be determined.

Mr. Esson, in his valuable Paper above referred to, discussed the requisite features for a generator for constant current, with

Digitized by Google

closed coil armatures, in which regulation is effected by shifting the brushes. He stated that the field should be uniform at all points, under the poles, and that the armature core should be saturated. These statements are a little misleading. The magnetising force impressed by the field ampere-turns must be uniform at all points between the pole faces. This is accomplished by proportioning the poles so that the strongly magnetised pole corners will not become saturated when the brushes have their extreme position for the development of the highest E.M.F. that the machine is to produce. The air gap is made of such a depth that the ampere-turns required to set up the magnetisation through the armature, without current, and for the production of the highest E.M.F. that the machine will be called on to give, shall be a little more than the armature ampere-turns when it furnishes its normal current. Then as long as the brushes are kept under the pole-faces, the non-sparking point will be wherever the brushes are placed. This will be the case whether the armature is or is not saturated. A practical demonstration is found in the following experiment: A Siemens and Halske dynamo, with magnet and armature cores, whose shape and dimensions are shown in Fig. 5, was used.

Length of armature core	7·25in.
Number of armature sections	56
Turns per section	6
Revolutions	1,000
Output in volts	50
„ „ amperes	30

The field was separately excited with 4,000 ampere-turns on each of the sets of consequent poles. Regulation could then be effected for a constant current in the armature of 22 amperes, by shifting the brushes from no E.M.F. to 35 volts without the slightest sparking even when metallic brushes were used. Within this limit the pole corners did not saturate. The field cores were wrought and the yokes cast iron. When the armature circuit was broken it was found that the field excitation of 4,000 ampere-turns produced an E.M.F. of 50 volts. The magnetic density in the field cores, including leakage, was only 11,000 lines per sq. cm. Therefore, of the 4,000 ampere-turns on the field, not more than 200 were applied in setting up the magnetisation from pole face to pole face through the field cores. It is safe to assume, then, that of these 4,000 ampere-turns 3,800 were active in producing a magnetising force impressed uniformly over the pole faces through the armature. The same value is obtained by the method adopted in the previous cases. That is by calculating the magnetic density in the air gap when 50 volts were developed, and then deducting the number of ampere-turns required to establish such a magnetic density through a 1½in. air gap. As to the armature, when it produced 22 amperes its ampere-turns numbered

$$\frac{2 \times 56 \times 6 \times 11}{2} = 3{,}700,$$

or an excess of 100 ampere-turns impressed by the field over and above those on the armature. As long as this same number of ampere-turns was maintained on the field it was not possible to regulate for a constant current of a lower or a higher strength without sparking. The impressed field ampere-turns are in excess of the armature ampere-turns by that amount which is just sufficient to produce a weak positive field that will reverse the current in the coil when its terminal bars at the commutator pass under the brush. When regulation is effected by this means it is seen that all pole corners are alike magnetised, and at the centre of the pole faces the magnetisation is zero when the machine is short-circuited. At full output, at the highest E.M.F., the magnetisation under the one set of pole corners is almost zero, and under the other set it is at the maximum value that is ever obtained. In a generator of this type, when the poles are made stout enough at all points, the total amount of magnetisation through the armature, at all loads, will remain at a constant value. When used for operating long arc lamps a "drooping characteristic" can better be obtained by saturated field cores than by saturated pole corners and armature core.

What has been said of dynamos applies equally well to motors. The only difference being that the non-sparking points are on opposite sides of the diameter at which magnetisation is zero in the air gap. This is due to a well-known cause. In a motor the armature rotates in an opposite direction when field and armature currents remain the same as in a dynamo. The E.M.F. of self-induction caused by the reversal of the current in a current has not changed, while the E.M.F. developed in the coil by the field has changed sign with the change of the direction of rotation. The result is that the reversal of the current in an armature section must take place in a weak field of an opposite sign in a motor from what it does in a dynamo, when sparking is to be avoided entirely.

The action of the current in the armatures of multipolar dynamos and motors will be the same as that found for two pole machines.

PETROLEUM OIL ENGINES.*

BY PROF. WILLIAM ROBINSON.

Since the successful introduction of the oil engine by Messrs. Priestman Brothers, of Hull, in 1888, many engineers have been at work, and not a few attempts have been made to use ordinary petroleum oil at once as fuel and working agent in the internal combustion engine.

Approaching the problem with the knowledge gained in gas engine work, one is led to convert the oil partially into a fixed oil-gas by heat, overlooking the tarry and other products formed, which sooner or later make their presence felt by clogging the valves, passages and working parts to such an extent that the engine soon stops short in the hands of the critical user and forfeits the title of a thoroughly reliable working engine.

Experience then leads to the conclusion that a really commercial and successful oil engine must use the oil as *oil* and not as *oil-gas*, unless the latter be cooled and cleansed. Hitherto, for large gas engines, above 40 H.P., and for small ones too, without gas supply, the heavy intermediate oils have been converted into real gas, by means of a *gas-producer*, and this oil-gas when cooled takes the place of coal gas.

Now, instead of the *gas-producer*, we find in *one class of oil engine* a retort, spiral coil of tubing, or other *vaporiser* in which the oil is heated and converted into *vapour* by a lamp or oil-burner. A mixture of this vapour and air is drawn into the cylinder, and the charge is compressed before ignition—the cycle of operations in the engine cylinder being usually that of Beau de Rochas, as in the well-known "Otto" gas engine.

For example, Messrs. Crossley Brothers, of Manchester, are at work upon an oil engine in which a lamp performs a two-fold function—first, to heat and evaporate the oil as it is pumped into a cast-iron retort or vaporiser, and, second, to heat the tube igniter which is timed by a valve similar to that in their gas engines. This lamp has a separate supply of oil given to it by a pump and an air jet fed from another pump worked by the same lever as the exhaust valve. The current of air carries up the petroleum vapour and makes it burn.

The details of this and several other attempts at workable engines of this class are still in the transition stage.

Again, for the petroleum *spirit engine*, there are many *air-carburetting and heating devices* to evaporate the highly volatile hydro-carbons which make up the lighter products of petroleum, such as benzoline and gasoline. The vapour so formed readily condenses again at moderately high temperatures when subjected to pressure in the engine cylinder. However, the terrible danger and risk in the transport and storage of these light oils prohibit their common use for this purpose.

When considering oil engines the fact should not be forgotten that we have an entirely different condition of things to that connected with steam or gas motors, because the engine has to prepare or gasify the oil for its own use. For instance, a steam engine that will run for a day with good results may be expected to run in a similar manner for a long period. The boiler is relied on to supply dry steam at the desired pressure. The same may be said of the gas engine, where we have simply to turn on the gas-cock, and rely upon the ingenuity and skill of those who manufacture the gas to make it of such quality as to give equally satisfactory results in the motor cylinder, whether used for a short or longer period. But when we come to the oil engine we meet with a different state of things as regards supply of the working agent. The oil must be taken direct from its cistern, thoroughly mixed with the right proportion of air, and passed into the cylinder ready for ignition, at the rate, in some engines, of *four separate charges per second*; so that, unless the arrangement for dealing with these heavy oils is correct and works with precision, the tendency to clog in the cylinder and working parts is very great. In fact, to use a homely example, the engine is like a strong looking man with a poor constitution and suffering from pulmonary troubles, it will run well for a short time and then, getting choked up, refuses to work.

In the Priestman *spray maker* and *vaporiser*, specially designed to avoid clogging of the working parts, we have a neat and practical combination of the two methods of treating the oil. A sprayed jet of oil is first broken up by compressed air playing on it in the inverted spray nozzle, then it is further mixed with air, heated, and completely vaporised by the hot products of combustion from exhaust led round the vaporiser or mixing chamber before being allowed to escape. This is really a *regenerative* and heat-saving arrangement. The oil vapour, thus thoroughly mixed with air in the proper proportions, is drawn through an automatic suction valve into the engine cylinder by the piston in its forward stroke. In order to cleanse the air of dust and dirt it is found necessary to

* Abstract of a Paper read before the Mechanical Science, Section G, British Association, Cardiff Meeting, August 21, 1891.

Digitized by Google

draw it into the oil reservoir and spray-maker through layers of cotton wool, which are renewed from time to time.

The action of this spray-maker (shown) will be seen by the following experiment:—1st. Turn off the air supply, and a flame does not light the unbroken oil jet; next, allow the air under pressure to break up and thoroughly spray the oil; the vapour formed is so intimately mixed with air that it rises in a cloud, and can easily be ignited, burning with a bright flame. On the other hand, incomplete vaporisation takes place, when heavy particles of hydro-carbon are seen falling below the vapour cloud, due to want of air-pressure and consequent incomplete breaking up of the oil jet. Hence the proper proportions of oil and air must be maintained whatever be the strength of charge required, and every spray-maker must be carefully tested, adjusted, and the supply passage graduated for different conditions of running to control the action of the engine in the hands of the user.

The amount of hydro-carbon is diminished or increased, together with the amount of air, so as to form a high explosive charge, or a low one, according to the work to be done by the engine. The action is thus:—A small portion of the air which is slightly compressed (4 to 12 lb. above atmospheric pressure) in the oil cistern of the engine enters the passage to the inverted nozzle and meets the oil which has been forced by the same pressure of air through another passage. The oil jet is thus vaporised by the air forced upon it, and comes out in the shape of a hollow cone or cloud to be still further mixed with a larger body of air admitted by the wing-valve in another passage. The air for spraying and the oil through the centre tube are kept at one regular pressure whether the engine is running light or with full load, but the amount of air through the wing valve-passage is rightly proportioned to mix with the oil which is allowed through the V-shaped slot, cut in the conical plug regulated by the governor. The auxiliary body of air after being drawn into the *mixing chamber*, during the out stroke by the piston in the working cylinder, is prevented from escaping by a small retaining valve. By this means there is a regular explosion and impulse every cycle, giving admirable regularity in running.

The compressed charge in the cylinder is fired by an intermittent electric spark, made to play between the ends of two platinum wires, insulated by porcelain rods in the *igniting plug* and connected to the secondary circuit of an induction coil excited by a storage cell of about 2 volts, which has been known to work more than 1,100 hours.

The *double-cylinder vertical launch engine* is specially designed for running at high speeds. In the 5 H.P. marine type of Priestman engine, each cylinder, water jacketed in the usual manner, is 7″ diameter by 7″ stroke, and arranged to give an explosion or working stroke every revolution of the fly-wheel or heavy disc. The valve gear is admirably simple and ingenious. The movement of the eccentric rod which is timed to open the exhaust valves against stiff spiral springs, on the return of the inner stroke of the piston, is double acting, making it both a thrust and a pull-rod instead of thrust only as in the single cylinder engines. The inlet valves are self-acting, the charge being drawn in by the suction of the piston during its out-stroke. The air pump which forces oil out of the tank is worked by an eccentric from the counter shaft, while the water circulating pump is connected to the same eccentric. The mixer or vapour chamber is supported from the cylinders above the oil cistern. The inlet valve of the spray-maker is fitted to the vapour chamber similar to the horizontal type. The governor is worked by mitre pinions with a belt from the crank-shaft, which regulates the inflow of oil and air. Ignition is by the electric spark, and the contacts can be adjusted to make explosion early or late. The actual horse power at 250 revolutions per minute is 5·7 and 9·1 indicated horse power.

The horizontal type is also remarkably self-contained, and specially adapted for electric lighting installations. The Priestman engine has already been used to great advantage for pumping and hauling in collieries, for rock-drilling in mines, as well as for agricultural and a very large variety of other purposes. In fact, the sphere of usefulness of this oil engine is rapidly extending, because it is found reliable and steady at work, with decided economy of fuel. The only reasonable objection is that of smell, which may be reduced by ventilation.

What has undoubtedly to be arrived at in the construction of oil engines is to get economy of oil and the best mechanical results without clogging of the working parts, so that in the critical hands of the user the engine may run cautiously without attention or frequent cleaning and repairs. Clogging is prevented in the Priestman by thoroughly mixing the oil vapour with a large proportion of clean, atmospheric air, so as always to form an explosive mixture which gives complete combustion and a clean exhaust.

It must be pointed out, however, that during the compression of the charge before ignition a portion of the vapour comes into contact with the walls of the cylinder, &c., and condensing on them *never* gets burned. Still this oil forms, in its heated state, a most excellent lubricant for the piston, thereby dispensing with the need of a more costly oil, and regulating the same without any attention. The perfect state of the piston surface after being months at work affords ample evidence of the advantage gained by this method of self-lubrication with a minimum of trouble.

I have also proved that this slight condensation takes place by comparing the pressure along the compression curves of indicator diagrams with the pressure obtained by experiment from each charge consisting of the explosive mixture of ·015 cubic inch of oil with 191 cubic inches of air at the same temperature as in the engine. Taking the temperature of the charge 170°F. (which experiment has proved the most successful in the Priestman engine) on entering the cylinder, the cards show the highest pressure, before ignition, only 38lb. per square inch. This is kept low for fear of much condensation as well as to give smooth running.

I may here briefly notice my investigation of the relation between the pressure and temperature of the vapours from the different burning oils, intermediate oils, and some heavier lubricating oils, in order to throw some light on their action and behaviour in the cylinder of the common oil engine; at the same time I have tried to find out which oils are best adapted for this use.

My experiments prove that, notwithstanding the complex and varied character of the different oils examined, the law according to which the pressure of petroleum vapour varies with its temperature is represented by a perfectly regular curve for each oil. Moreover, the relative steepness of these curves is somewhat similar to that of the fractional distillation curves of the same oils. "Royal Daylight," the ordinary lamp oil supplied by the Anglo-American Oil Company, distils off gradually through a wide range of temperature. This oil is suitable for oil engines, and can be obtained in almost every village in the kingdom. The wholesale price is, at present, 5½d. per gallon, and there is reason to prophesy that this may be considerably reduced. "Water White" and "Lighthouse" oils give still better results. Crude petroleum, containing, as it does, light volatile hydro-carbons, as well as the very heavy constituents, is extremely dangerous in handling, and unsuitable for use in oil engines.

Another, and by far the simplest type of oil engine is that in which the oil is injected directly as oil into compressed and heated air in a cartridge, which at once acts as a vaporiser and combustion chamber. In this way heavy intermediate oils of specific gravity ·850 can be dealt with equally as well as the ordinary burning lamp oils. This type has not yet got completely beyond the transition stage, since it has been only about a year in a workable and useful shape. Such an oil engine is the invention of Mr. H. Akroyd Stuart, of Bletchley, and is now being made by Messrs. Hornsby and Sons, Grantham A novel feature of this engine is, that the ordinary gear for firing the charge by heated tube, flame or electric spark are dispensed with altogether, and heavy oil is ignited and completely burned when injected into the compressed and heated air in the red-hot vaporiser or cartridge. The cartridge is heated up quickly at start by the fierce flame of a special oil lamp urged by air blast from a small fan driven by hand. This *starting lamp* is merely a small cast-iron pot with contracted nozzle. The lamp is filled with oil up to the level of the fan pipe inlet. A small piece of asbestos or other packing, about ⅜in. thick, by 2in. long, is dipped in the oil, lit, and pushed through the hole with plug (shown) into the oil. Air from the fan is blown on the top of the oil, giving a powerful clear flame, and in from three to five minutes the vaporiser is sufficiently heated, so that a few turns of the fly wheel starts the engine, and then the lamp is extinguished. The cartridge is kept red hot inside by the combustion; and the oil, injected into compressed and heated air containing ample supply of oxygen, burns readily and completely, the exhaust being perfectly clean. There are ribs inside the vaporiser to offer a large heating surface to the oil. A comparatively small opening leads from the vaporiser to the compression chamber at the back of the cylinder, so that there is very little conduction of heat from the vaporiser to the cylinder walls, which are kept cool by the water jacket in the usual way.

The engine is of the simplest design. The working parts are few, and the details are being improved by Messrs. Hornsby, as experience indicates or dictates. The oil is contained in a cistern in the base of the casting, and the supply can easily be replenished at any time during a run by sliding open the top cover and pouring in the oil. Every charge of oil is forced by means of a positive action oil pump, through a thin copper tube and simple nozzle, into the red-hot vaporiser at the proper moment for ignition—just after the air has been compressed into the red-hot cartridge and the piston is on the return stroke. A screw stop adjusts the stroke of the pump to give the right quantity of oil. When the load is thrown off and the speed gets too high the governor lifts a valve and stops the oil supply until the speed is reduced to the normal.

With a large fly and at high speed—about 210 revolutions per minute—the regularity of running of this engine having the "Otto" cycle under full load and then light—was much better than I expected. In order to secure uniform speed for electric lighting, the tendency is in this direction, and as I take it rightly too, to

Digitized by Google

use larger fly-wheels on the internal combustion engines and run at much higher speeds than heretofore. Several of the Hornsby-Akroyd engines may be seen running in London, at Bletchley, and Grantham. I tried a 6 H.P. engine during a run of about three hours, using oil of specific gravity ·854 and flashing point 220°F., and the rate of consumption was less than a pint per brake horse-power per hour—(sets of indicator cards taken). Even heavier oils might be tried, the hot water from the water jacket going to heat up the heavy oil and keep it in a sufficiently fluid state fit for use in winter.

The action in the engine cylinder, although the same cycle, is here very different from that in the Priestman oil engine, inasmuch as there is an excess of air in the cylinder, and this is compressed before the oil is injected. Consequently the combustion is rapid, and will be complete even when heavy oils of great heating power are used. Since the air is dry and there is no condensation of oil the cylinder requires independent lubrication, as in the case of the gas engines.

Safe Storage of Oil for Oil Engines.

A feeling of safety to the public naturally tends to the use of heavy oil, from which the lighter constituents have been driven off or distilled. I have found the loss in weight for some heavy oils by prolonged heating at low temperatures, keeping the oils exposed to the air and allowing free *evaporation*. Known weights of oil were taken in shallow dishes, about 3in. across top, and gently heated in a sand bath by a very small steady flame for three hours, the temperature of the oil being kept constant.

The proportion of volatile constituents present in three samples are indicated :—

EVAPORATION.

The terribly explosive character of the hydro-carbons driven off at the ordinary temperature renders the *safe storage of petroleum* imperative. Instead of the present tank system, Mr. B. H. Thwaite has devised the safety oil tank. It is very much like a gas holder, the cover-plate being kept in contact with the oil and counterbalanced by weights to give only a slight pressure of one or two inches of water on the surface of the oil. The frame moves into an annular water seal stand pipe to draw off any gas that collects.

There is no necessity for the introduction of air to allow the tank or holder to be emptied, and as the oil is kept cool and always under pressure it is impossible for a dangerous explosive mixture to accumulate inside the tank. Any gas given off during the heat of the day is not lost, but may be collected or partly recondensed at the lower weight temperature, since there is no air present.

One realises the danger of *crude* oil, having light volatile constituents on a hot summer's day with sparks or lightning flashes about.

In the case of heavy distilled oil, the danger is very greatly reduced, and there is practically no danger in the use of this heavy oil for motive power in engines.

ELECTRIC MINING-MACHINERY, WITH SPECIAL REFERENCE TO THE APPLICATION OF ELECTRICITY TO COAL-CUTTING, PUMPING, AND ROCK-DRILLING.*

BY LLEWELYN B. ATKINSON AND CLAUDE W. ATKINSON, ASSOC. MM. INST. C.E.

(Continued from page 592.)

The cutter (Fig. 6) consists of a long bar, either taper or parallel, fitted with a coupling to unite it to the shaft of the machine, and having arranged on it a series of steel tools. The bar, revolving on its axis, acts like a long milling tool, each set of cutters sawing its way through the material. The form used in the coal-cutting machine known as the "Economic" was a parallel bar, having holes in it, into which were fitted steel nibs secured in place by set screws. Some years ago Mr. Grafton Jones suggested the threading of star-shaped discs on to a square or polygonal bar, with a nut at the end to hold them in place. The cutter used by Messrs. Bowers in the first machine tried at their colliery (Fig. 7), was upon this principle. A series of star-shaped cutters made of cast steel having an hexagonal hole in the centre, were threaded on to a steel shaft, and secured by a nut at the end, the nut having cutters screwed into it, so as to clear itself. The result was satisfactory except so far as the wear of the points was concerned. In fairly soft or friable coal, it is doubtful whether they can be much improved ; but in coal which contains much dross or is hard, the cutters are soon blunted, and the power required to drive the machine becomes excessive. After some experiments, in conjunction with Mr. Hans Renold, of Manchester, the form shown in Fig. 6 was devised.

The object in view was to provide a bar which would admit of cutters being used of a much higher grade of steel than was possible with the star-shaped castings previously mentioned, which should have more metal for removing heat from the point of the tool, thus preventing its softening and wear, and which should take, if possible, less power, and at the same time give a

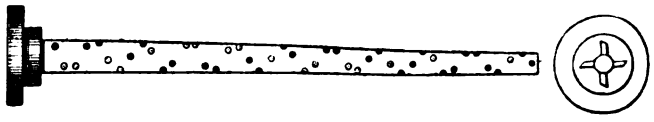

FIG. 6.—Goolden Cutter-Bar.

more steady cutting action, and remove the *débris* which it formed. To effect this, the bar is drilled with a series of holes, each of which is placed in a direction nearly at 90deg. to the next adjacent one, but differing so far from a right angle that one complete turn is made in the length of the bar ; by arranging the cutter in this manner, a left-handed spiral is produced, having a pitch equal to the length of the bar, which serves to equalise the cutting action, and also a right-handed spiral, which has a pitch equal to about one-sixth of the length of the bar, and forms, as it were, a cork-screw to draw the dirt out of the cut. These holes are tapered to about 1 in 30, and pieces of round steel are turned to fit them, the heads being shaped to form the cutter, the exact nature of which depends on the material to be cut.

The proper form to give these tools is a question to which considerable attention has been devoted. Square-shaped, flat-faced tools were tried, of such a width as to overlap one another and remove the whole of the material ; it was found, however, that the power required was excessive. Both square and pointed tools of various widths were then tried, with the result that the form indicated in Fig. 6 has been found to be, on an average, the best. This cutter is of a V-shape, and is placed in the bar with a gauge, so that the surface farthest in the coal is set in such a direction as to clear itself. The edge nearest the machine slopes across the cut, so that when the tool has entered to a depth of about ⅛ to ¼ inch, a wedging action commences, and the ridge of coal left between two

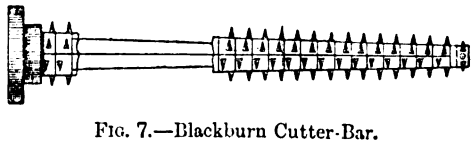

FIG. 7.—Blackburn Cutter-Bar.

succeeding cutters is split off. By this means only about a quarter of the total quantity removed is actually cut away, the remainder being broken off by a splitting action, and the power required for working the machine has been reduced to one-quarter of what it was. Various speeds for operating the bar have been tried, but for fairly hard coal from 400 to 500 revolutions per minute is enough, although in soft and friable coals a higher speed may be adopted. The diameter over the points of the cutters varies from about 5in. at the front of the cut to about 3in. at the back. The tools when blunt are driven out with a hammer, and ground on an ordinary stone in a tool-holder, in which they are set in a taper hole, the holder being mounted eccentrically, so that in grinding the proper backing is given. These cutters are made of an exceedingly high quality of steel, which is tempered dead hard, so that it will easily scratch glass.

The average length that can be cut without changing the bar may be taken in hard coal to be about 40 yards, though as much as 80 yards, in hard gritty coal, has been effected without any stoppage. The blunting of the tools, however, when the edge is once really gone, proceeds rapidly, and out of proportion to the work done, and it is bad economy to force the amount cut to too great an extent. One man or boy attends to the winch, one man follows the machine, spragging and putting up props, whilst a third devotes his attention to the cutter itself, and to clearing the road in front of it.

*Abstract of Paper read before the Institution of Civil Engineers.

Digitized by Google

The amount cut by the machine varies according to the nature of the seam, and the experience of the men working it ; but it may be taken that on the average, all stoppages being included, 20 to 30 square yards per hour may be cut in fairly hard coal. As a matter of actual maximum performances, the following results may be cited. At Lord St. Oswald's colliery at Nostell, 55 yards were bared to an average depth of 3ft. 8in. in 75 minutes, and lengths up to 20 yards, where the road is clear for running without stopping, have been often cut to this depth at the rate of a yard a minute. And at Messrs. T. and R. W. Bowers' collieries, where a less powerful motor is used, 110 yards have frequently been bared to a depth of 3ft. 6in. in four hours. The length of cutter-bar usually adopted is from 3ft. 6in. to 3ft. 9in, ; but it is a matter of interest that in a trial at Messrs. Briggs and Co.'s collieries at Normanton, a bar of 5ft. in length was used, cutting underneath to that depth, an amount exceeding considerably the best performance of any previous machine.

The actual horse-power developed by the motor has varied in different cases from 6 H.P. to nearly 15 H.P., but, in the author's opinion, it is a mistake to reduce too far the power available, and 10 or 12 H.P. would seem to be a fair average amount for working rapidly and effectively, with a reserve enabling obstacles to be overcome, without straining the machinery.

Table IV.

Relative Cost of Cutting Coal by Machine and by Hand-Labour.

Thickness of seam	3 feet.	
Cost of cutting, filling, &c., by hand		2s. 6d.
Saving of coal by machine	20 per cent.	
Tons bared per shift	160 tons.	
Labour, steam, cutters, interest and depreciation at 15 per cent.	0s. 3d.	
Cost of filling after machine, taking up floor, laying rails, &c.	1s. 3d.	
Total cost by machine		1s. 6d
Saving over hand-labour		1s. 0d.
Saving in coal		0s. 6d.
Total saving by machine		1s. 6d.

Table IV., Appendix, gives the relative cost of cutting by machine and hand labour in certain cases ; but, although trials have extended over some time, it is, perhaps, too early to speak of what will be the ultimate saving effected by the use of these machines. Great difficulties have had to be overcome, apart from the electrical and mechanical problems, in the prejudice of the men, and in the resistance which they offer to the introduction of labour-saving machinery ; and this has reached such a pitch in some cases that the miners have actually declined to work the machines, or to remove the coal which has been cut by them. These obstacles will disappear in time, but at present they form an element which has to be considered in estimating the cost of coal-cutting by electric power.

Electric-boring and Rock-drilling Machinery.

An early example of the use of electricity in mining was the employment of the electric motor for working rock-drilling plant. This part of the subject has, although apparently simple, proved to be one of the most difficult to deal with ; the reasons of this being—first, that the amount of power required is small, and, therefore, the advantage gained by electricity not so noticeable ; secondly, that very powerful and complete drills, particularly percussive drills, are in the market, and, thirdly, that the use of machine-drills is generally resorted to in cases where the necessity for at once carrying out the work is very pressing, so that the contractors are less willing to try any experimental plant.

Drilling machines may be divided into two classes : (1), rotary, and (2), percussive. A form of rotary drill was shown complete with its own electric motor, and mounted upon trolley-wheels, applicable for use for coal or ironstone boring. The motor, the framework of which is made in one with the bed, is a small ¾ H.P. enclosed mining motor, of the authors' design. The revolving drill-bar has a thread cut along its length, working through a nut which is free to revolve except in so far as it is held by an adjustable brake-band. The result of this is that if the brake be slack no feed is imparted to the drill ; if the brake be tightened so as to prevent the nut revolving, a feed of $\frac{3}{16}$in. per revolution, or any intermediate amount, may be given.

The power is taken from the motor-shaft by bevelled gear, giving a reduction in speed of 1½ to 1 ; it is then transmitted by the vertical shaft and through a worm-gear to another pair of bevels. The total reduction in speed is from 1,600 revolutions per minute to 50 revolutions on the drill spindle. This drill will bore a hole 2in. in diameter in hard coal at a speed of 12in. per minute.

It will drill in slate at the rate of about 3in. per minute, but the principal difficulty in dealing with material as hard as slate is to procure a sufficiently satisfactory fixing to the roof and sides to prevent the whole drill from shifting and getting a cross strain upon it. It is, therefore, principally recommended to be used for coal or ironstone, where rapid sinking through moderately hard material is required. The drill takes about 10 amperes of current, at a pressure of 110 volts. Some experiments made to determine the power actually developed, through all the gearing and on the drill-shaft, show that the ratio $\frac{\text{mechanical power on drill-shaft}}{\text{electrical power}}$ is about 40 per cent.

For dealing with harder rock, diamond drills, working in a similar form of machine, may be used ; but the cost of maintaining diamond drills is so heavy that in general little economy is effected by their use. Percussive rock drills, therefore, are generally used for this purpose. The use of percussive rock drills driven by electricity has, so far, been limited, one of the principal difficulties being the construction of a really suitable percussive action, driven by a rotary motion. An arrangement devised by the authors for driving an Ingersoll rock drill by means of an electric motor was shown. In order to diminish the weight of the drill it is separate from the motor, which is mounted on a trolley, the connection between the two being made by a length of about 8ft. of flexible shafting.

The drill itself is well known. It consists of a bar lifted by a crank motion, connected to the driving handle by a rachet and pawl, in such a manner that after the drill has been lifted by the connecting rods against the pressure of a spring, as soon as the dead point on the top centre is passed, the spring forces the drill forwards, over-shooting the driving handle, which gears again as soon as the blow is expended. Two blows, or nearly so, are therefore given for each turn of the handle, which is designed to make sixty revolutions per minute.

The driving-wheel is geared into a bevel pinion which is carried by an adjustable frame or quadrant and driven direct by the flexible shaft. The speed reduction is in the ratio of ten to one.

The motor, which is of the pattern previously described, and is entirely enclosed, is mounted on a trolley, and has a fibre pinion driving a gear wheel, which gives motion to the flexible shaft. The speeds are as follows :—Motor, 1,500, flexible shaft, 600, drill wheel, 60. This plant may be taken to represent the present position of electric percussive-drilling ; but the authors have been for some time engaged upon effecting the design of a new machine, doing away entirely with a separate motor, giving a direct percussive action and reducing the total weight to a considerable extent. The experiments upon this drill are not yet complete, and therefore, for the present, it will only be mentioned.

Dynamo for Transmitting Power.

Illustrations were given showing in section a class of dynamo well adapted for use in transmitting power for electric mining work, with pressure up to 1,000 or 1,500 volts. The bed is of cast-iron, and a block in the centre of it forms the connecting yoke of the magnets, which are of the "inverted" type, and stand upon it. The magnet cores are of rectangular section, and are made of wrought-iron. The pole-pieces are of cast-iron, or in some cases are forged in one with the magnet-bars. The armature, which by preference is of the "Gramme" type of winding, is composed of a number of thin sheets of charcoal-iron, insulated from one another by paper, mounted upon a phosphor-bronze spider, which is notched into the plates, and firmly keyed upon a stout steel shaft. The magnet may be shunt or compound wound, but in the case of transmitting power from a dynamo to a single motor is preferably series-wound. The commutator is composed either of phosphor-bronze or of hard-drawn copper, insulated with mica. The brush-holders are of a special type, enabling the brushes to be fed through the holder and adjusted by a feeding-screw at the back, thus doing away with the necessity of loosening any bolts or nuts. This is valuable in case of long runs extending over nights and days together, such as often occur in mining work.

Special point is made in these machines of the ample clearance given to the armature in the pole-piece gap ; three-sixteenths of an inch a side is usually adopted, thus allowing room for wear in the bearings and for the expansions which inevitably take place, and obviating the annoyance and delays caused by the armature rotating against the pole-pieces. The shaft and bearings are of large dimensions, compared with ordinary dynamos, for similar reasons, and the precautions thus taken of providing ample margins, not only in the mechanical factors, but also in the electrical design, have contributed largely to the success and freedom from accident which has marked the working of these machines in mining experience. Several of them have been running for periods extending over two or three years, in the hands of persons quite unacquainted with electrical matters, without any breakdown or repairs being necessary, and with very small wear upon the commutators.

Summary.

The instances described will be sufficient to show that :—

A. Electrical power is destined to become an important factor in mining mechanics, on account of the three following reasons :—

Digitized by Google

1. The greater facility with which it can be used with machines which require to be moved from time to time as the work advances.
2. The great economy in first cost, and reduced cost of working owing to its efficiency being higher than that of compressed air, or any other medium of power transmission.
3. The smaller cost of maintaining the cables, as compared with piping, on shifting floors in roadways, &c.

B. That the methods described are sufficient to obviate all objections to the use of electric motors in coal-mining, either by excluding inflammable gases, or by constructions which allow of their safe combustion.

C. That the experiments, trials, and practical work, extending over four years, show that—

1. Electrical pumps may be used with advantage and economy for mine draining.
2. Electrical coal-cutters can replace hand-labour, with saving in cost and increased production of coal.
3. Electrical drilling-machines are available in place of machines worked by hand or compressed air.

While doubtless on all these points opinions may to some extent differ, and the particular methods adopted may be subjected to criticism, the authors hope that the subject they have brought forward will be found of interest to the members of the Institution.

The electrical details of many of the machines described are due to Mr. H. W. Ravenshaw, Assoc. M. Inst. C.E., who has used considerable skill in adapting them to meet the conditions required. The authors also have to express their thanks to Messrs. W. T. Goolden & Co., for placing drawings and results of test at their disposal, as also to Mr. R. Hancock for his kind assistance in connection with the preparation of the drawings illustrating this Paper.

DISCUSSION.

Sir JOHN COODE, President, hoped that the question of safety with regard to the use of electricity in coal mines as compared with other methods of conveying power would occupy a prominent place in the discussion. It was a most important point, and should be fully debated.

Mr. LL. ATKINSON desired before the discussion commenced to call attention to one of the cutter-bars on the table which was not described in the Paper. In order to avoid the grinding of the steel points and the expense of renewing these steel cutters, the latter were permanent and had chilled-iron points inserted in them which were nearly as hard as steel, and when worn out could be thrown away, being inexpensive. They had not had much experience with that form, but thought that it would lead to a considerable economy in the item of grinding cutters. He had been told several times lately that although the question of sparking on the motors had been treated in the Paper, they had not dealt with what would be likely to happen should the roof fall, or should the cable be broken from some other cause. The reason was that although they had devised a mode of getting over the difficulty, it was so novel that their experience of it did not justify them in placing it before the Institution. The form of the cable,* however, was such that even should it be absolutely torn asunder by the breaking of the roof, there would be practically no sparking, and an arc was impossible That, he thought, removed the remaining objections to the use of the electric cables in fiery coal pits.

Mr. ALBION T. SNELL said that during the past four years great progress had been made in the use of electricity in mining; and the General Electric Power and Traction Company (Limited), with which he was connected, had from the first been identified with the work. He advocated the use of over-compound dynamos and series or shunt-wound motors, so as to make the system applicable for both lighting and power. He wished to draw the attention of the Institution to a new system of electric haulage for use on stiff brows in mines, by means of a cable or rope, fixed at either end, and lying parallel to the road. The energy was supplied through wires above or beside the track. The system was introduced by Messrs. Immisch and Walker, and was the property of the General Electric Power and Traction Company. The cable was passed over a sprocket-wheel or a friction-clutch geared in a suitable manner to an electric-motor on a small trolley, the whole forming a light and compact electric-locomotive, not depending for its grip on the friction between the wheels and the rails, but getting a direct pull on the fixed rope. The principle was similar to that employed for working floating bridges and barges. At the Wharncliffe Silkstone Collieries a brow about 500 yards long had been equipped in this manner, and the locomotive had been working successfully for about three months. The inclination of the road averaged 4in. to the yard, and the rolling load was approximately four tons. The trolley carried a 10-H.P. electric-motor, and weighed about 20cwt., which was unnecessarily heavy for that particular work. It ran in a headway of about 4ft. 3in., and the current was supplied by an overhead wire. The objection that had been raised with regard to sparking did not apply in this case. Amongst the many interesting points referred to in connection with the application of electricity to mining, was the risk of igniting gas. As far back as 1868, when speaking on the subject before the Midland Mining Institute,† he gave it as his opinion, that under normal circumstances the sparks at the brushes of a motor would not readily fire gas, owing to their having a low temperature by reason of the large masses of metal in contact with them. His opinion was combated by several leading mining experts, and he therefore decided to make experiments to determine the point at issue. With that view he procured a wooden box about six feet long, with an internal cross-section of about a square foot. One end was blocked up and the other had a hinged door, so as to make an easy outlet for the probable explosion. In the centre a small motor and a gas indicator were placed. Ordinary coal gas was admitted from the closed end until the gauge registered an explosive mixture. The motor was then started, and the experiment watched through a glass window in the side. From time to time the sparking was increased by changing the position of the brushes, and the mixture of gas and air was varied through all ranges. It was found that even with excessive sparking the gas did not explode until the commutator and brushes had become heated to a far greater extent than ever obtained in ordinary machines. It followed that although under normal conditions a motor would be unlikely to ignite gas, yet if by any means the brushes and commutator became heated beyond a certain point, the exact temperature of which was not ascertained, the sparks would fire an explosive mixture of gas and air. It was unsafe to place an unprotected motor in an explosive mixture: and he did not think that under the ordinary mining regulations such an absurdity would ever happen, but it by no means followed that even in fiery mines a properly arranged motor should not be installed. He, personally, was inclined to lay the utmost stress on the necessity of providing ample ventilation by well-designed fans rather than trusting to any safety device in the motor itself. Roughly speaking, there were two main lines on which motors might be protected; first, by enclosing the whole of the armature, and secondly, by covering the commutator and brushes only. His Company was building a 25 H P. motor with an inverted commutator and internal brushes, but there would be some little difficulty in adjusting the latter, which he hoped to get over by using carbon brushes. Too much stress could not be laid on the necessity for care in selecting the cable, and on the need of good honest work in erecting and jointing. In no other class of installation did badly designed or careless work so soon tell its own tale. Speaking generally, it appeared that lead-covered cables, protected by an outer serving of braided and ozokerited hemp, were the most durable for wet pits, and should always be used in the shafts. The risks to be expected from the mains were two-fold. There was the very remote chance of an explosion, in the event of a cable being broken when transmitting energy; and there was also a possible chance of a bad "short-circuit" or "earth" causing trouble by firing timber. So far as he knew, the leakage of an electrical conductor had never caused any difficulty more serious than a short delay; and although he had seen timber charged in a pit top by a short circuit, yet there was no chance of a fire, because the electrical instruments showed immediately that a leakage had occured, and the engineer in charge was at once on the alert. Indeed, the ease with which the supply of energy was governed and noted, formed one of the chief recommendations for the use of electrical power in mines. Electrical plant really entailed less trouble than steam or air-machinery, and the men only required to get accustomed to it to appreciate its many advantages.

Prof. ARNOLD LUPTON remarked that with reference to the question of safety in the use of these machines, the mines of this country might be roughly divided into fiery and non-fiery. The non-fiery were those in which gas might perhaps be found sometimes, but ordinarily speaking it was never seen, and blowers were never heard of. In these non-fiery mines there was a great opening for the use of electric machines. Those devices might be clever, but he ventured to prophesy that in the course of the next twenty-five years those machines would not be introduced into fiery mines. Why should an electric coal-cutter or any other electric machine be used? As stated by the authors, there was this strong reason, that the work could be accomplished with one-half the power, for a great deal less capital outlay, and for a much smaller working cost. He should like to ask what evidence there was that electrical transmission of power was any more economical than compressed-air transmission of power? The authors had quoted a Paper by Mr. Daniel, which was read in 1874, but since 1874 he believed there had been some improvements in the construction of air-compressing machinery. He should like to say that because in a colliery they did not have a very economical engine, it did not follow that one could not be made. At an average colliery were they not consuming three or four times as much fuel per horse-power as they all knew to be necessary? And was it likely that if they were not very careful about economy of fuel for a steam engine they would be much more so in the case of an air-compressing engine? He did not think that the instances of want of economy in individual air-compressors and motors in a colliery were any proof of what could be done by the system. It had been said, "You can only get 20 per cent." because there were some bad examples. He would suggest that there should be a competition between the electricians and the advocates of compressed air, each working a steam engine, the power of which was to be taken to a distance of 10,000 yards, and used in lifting water to a given height. In Table II. the authors had referred to the transmission of power to a distance of 2,000 yards with a cable of seven wires, No. 16 gauge. Mr. Brain, in the Forest of Dean, had used a cable of exactly the same length of 19 wires, No.16 gauge, for the transmission of the same horse-power, and he lost 20 per cent. of the power by the friction in the main. It was true that Mr. Brain used one-half the voltage that the authors proposed. If they had 10 per cent. loss of the power put into the main they would still require a cable of 19 wires, 16 gauge. The result was that the cost would be £100 more for the cable, without any insulators or fixing, than had been stated by the authors in Table II. The cost of 4in. pipes for compressed air had been given as £700. A 3in. pipe would be ample for the horse-power delivered, and if they took off £200 from the cost of the pipe, and put £100 on the cost of electric mains, the figures would be materially altered. He had been told by a great authority that a small motor, say 2 or 3 H.P., could not be worked at much more than 100 volts. He was also told that it was

Digitized by Google

impossible to take electricity any great distance in a mine at a less voltage than 500 to do the work economically. Therefore, in order to drive several small motors in the mine at a distance from the shaft, they must have a transformer, which with continuous-current electricity absorbed at least 20 per cent. of the power. How did that affect the economy of the two methods? Then there was another equally important matter. Supposing a motor or 20 motors in a mine, all driven off one set of cables charged with electricity at a constant voltage; the motor was fixed to run at a given speed, and all the gearing was so arranged. Suppose they desired to make it run at half speed; how could that be done? He had consulted a number of electricians, who said, "Put in resistance." A resistance to reduce the speed to one-half absorbed half the power, and then what became of the economy? He had nothing to say against electrical machines, and he wished them all success; but when he heard statements that were not in accordance with his own exp erience, he thoughthe was justified in asking for some further explanation.

Mr. ALBERT GROTHE said that two years ago he visited several mining camps in the Western States of America with the object of making himself acquainted with the application of electricity to mining work. In Virginia City, Nevada, the water which had spent its energy in driving a silver mill was taken through pipes down a shaft which communicated with the great Sutro Tunnel, and was made to act through ½in. nozzles, with a head of 1,630ft. upon six Pelton water-wheels of 40in. diameter, and each connected with a dynamo. The electricity thus generated at the bottom of the shaft was conveyed back to the mill on the surface, where it drove six electric motors of 60 H.P. each at a nominal expense, thus saving 360 H.P. which formerly was absolutely wasted. At Aspen, Colorado, there was at that time only a small plant consisting of several hoisting engines driven by two dynamos of 27 H.P. It worked so well that large additions had since been made, and there were now three dynamos for sixty arc-lights each, four others supplying an aggregate of 2,500 incandescent lights, and two power dynamos, one requiring about 60 and the other 120 H.P. These drove several motors at a distance of about two miles at points underground to which it would have been most inconvenient to convey power by the older methods of transmission.

Mr. EMERSON BAINBRIDGE said the immediate point before them was the comparison instituted by the authors between compressed air and electricity. They had, however, gone a little further, and had become exponents of a certain mode of cutting coal by machinery. He was now cutting about 1,000 tons per day by machinery, and therefore had some experience in that direction. Prof. Lupton had spoken of a colliery manager being naturally disinclined to apply electricity underground in places where there was any chance of danger. Absolute security was therefore wanted in regard to sparking before a mining engineer would be justified in adopting electrical machinery in a fiery mine. His firm was using compressed air, but he did not agree with Prof. Lupton as to the comparative economy of the two systems. Mr. Snell's experience at a colliery in Yorkshire was important, because it supplied a comparison between two modes of doing the same work; and even if the compressed air machinery in that case had been badly managed, and the economy mentioned by Mr. Snell were much reduced, it would still be considerable. There was often a great mistake made as to the importance of what was called the percentage of useful effect. He supposed that the authors meant the work done as compared with the I.H.P. of the driving engine. In coal-cutting the power exerted by each machine was 6 or 8 H.P., and if with compressed air 23 H.P. was required to yield this amount, whereas with electricity 12 H.P. might suffice, the difference in cost, with a well-arranged engine, would not exceed £30 or £40 a year, which was not worth considering in comparison with the risk of stoppages and accidents underground. In the case of compressed air there was an almost perfect freedom from the risk of stoppage, which was a matter of great importance in a colliery. Although the useful effect might not be half so good with compressed air as with electrical machinery, fewer repairs would be required. If a colliery manager could have the assurance of being able to carry on his electric work without an electrician, he would be much more inclined to use these machines than he was at present. Whatever might be said about the difficulties of applying electricity to coal-cutting would not apply in the same sense to pumping. As a general rule, a pump was fixed for a longer or shorter period, but a coal-cutting machine was constantly being moved about, and there was the risk of dirt and dust flying about, and damaging the machinery and the various parts of the gear which carried the electric current, especially where several hundred yards had to be traversed. In the case of pumping there could be no comparison between the cost of compressed air and electricity. In a few days he should have a pump raising 50 gallons a minute 400ft. high at a distance of 2¼ miles from the engine; and the first cost would be less than one-half that of compressed air.

Mr. THOMAS PARKER (of Wolverhampton) remarked that as the authors had referred to the plant at the Trafalgar Colliery, with regard to which exact data were to hand, some few statements respecting it might be of interest. The first installation was put down in 1883 by Messrs. Siemens. It was only 1½ H.P, but the colliery manager was so favourably impressed with it that in 1885 an order was given to Messrs. Elwell-Parker to put down 2½ H.P. plant. That machine ran until 1887, at which date an order was given for a 20 H.P. motor in addition. That was used for pumping, and there was also a small plant for ventilating. The distance was 2,000 yards, and although the motor and dynamo were manufactured five years ago, the efficiency obtained was 40 per cent. of the brake horse power in water raised, and the cost per horse-power in water raised was 0·2d. If the loss incurred in the leads was assumed to be 10 per cent., they could easily obtain at full load an efficiency of 75 per cent. of mechanical energy delivered at any point, however distant. With regard to a question asked by Prof. Lupton implying that at varying loads they were compelled to use the same amount of energy, under ordinary circumstances the electrical motor had the power of regulating the amount of energy it received by the amount of resistance which was imposed in the way of work. As one proof that compressed air was beginning to lose favour with mining engineers where they were satisfied with the safety of the application of electricity, he would state that he had just received orders from a colliery company in his neighbourhood, after careful trial on a smaller scale, to replace compressed air plant with a 60 H.P. installation for electrical transmission. With reference to the suggestion that there should be a competition to determine the merits of electricity and compressed air, he could only say that he would be glad to enter the competition at any time that might be selected. If the cables were run in iron piping, in which also the switches might be enclosed, and if that iron piping was made to carry a supply of fresh air from a safe portion of the mine into a chamber loosely covering the motor, there would be very little risk indeed if ordinary care were taken.

(To be continued.)

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *September* 26, 1891.

Institute of Electrical Engineers.—On Tuesday last was held the first autumn meeting of the American Institute of Electrical Engineers. The Paper of the evening was the discussion of the relation of the air gap and shape of the pole pieces to the performance of dynamos, by Prof. Harris J. Ryan, of Cornell University. The Paper was exceptional in character, and contained some interesting information regarding magnetic details of machines in relation to their performance. There was a brief discussion, principally by Messrs. Mailloux and Tesla. At the next meeting, October 20th, the discussion of Prof. Ryan's Paper will be carried on, and Mr. H. Ward Leonard will give a description of the method of regulation he has devised for motors, and which he employed in the exhibition of the electric hoist at the Montreal Convention of the National Electric Light Association. I am not at liberty, on account of the foreign patents, to state the exact character of the means taken to secure the desired end; but the result is excellent, although it is attained at the cost of operating dynamo and motor as a single dynamical unit, thereby rendering it inconvenient unless a considerable amount of power is used where the output required is great enough to justify the cost. Mr. Leonard's plan of regulation is ideal in its flexibility.

A New Railway Motor.—The Thomson-Houston Electric Company is about bringing out a new style of railway motor, an iron-clad with a very powerful gramme armature, intended for low-speed work. The motor is designed with special reference to the compactness of form desirable where motors are to be applied to narrow gauge roads. Its efficiency is said to be exceedingly satisfactory, and the design was made with special reference to securing a good speed curve, so as to attain a high average efficiency as well as a high maximum. Some new wrinkles in the methods of supporting the motor on the truck are promised at an early date.

Accumulator Traction.—The Waddell-Entz storage car, of which I wrote you some time since, has been undergoing a series of trials, and has operated on the whole very successfully; but I am informed by those who have been examining its performance somewhat critically that the batteries show a tendency towards irreversible action and disintegration when discharged at a high current density, so that it is a little early yet to give anything more than a qualified endorsement to the system.

Accident on Electric Railway.—A serious accident occurred recently on the St. Paul and Minneapolis electric line; a car running at high speed jumped the track, and four persons were killed besides seriously injuring others. The managers of that line unwisely attempted to go to speeds as high as 25 miles per hour with single truck cars having 6ft. wheel bases. Some of these are equipped with motors arranged to run in parallel at high speed after passing out of the thickly settled portions of the cities, and so arranged as to run in series at a comparatively low speed when well inside the city limits. A short wheel-base and an 18ft. car, at such speeds as were attempted, resulted in a very serious amount of oscillation, so great indeed that it is a wonder that such an accident has not happened before. The result will probably be that double truck cars will be used in future, thereby obviating all danger of a repetition of a casualty of so serious a kind.

TRADE NOTES AND NOTICES.

TENDERS WANTED.—Tenders are invited by the Postmaster-General for the supply of red fir telegraph poles, to be delivered in London, King's Lynn, or Sutton Bridge ; and at Northumberland Dock (River Tyne), West Hartlepool, Hull, or Grimsby. Tenders are also invited for creosoting the above-mentioned poles with either 10lb. or 12lb. of creosote to the cubic foot, as may be decided. Tenders may be submitted for either (A) the supply of the poles ; (B) both the supply and creosoting ; or (C) the creosoting only ; but, if B be tendered for, tenders for A and C should also be submitted. Further information will be found in our advertisement columns ; and forms of tender, containing all particulars, may be obtained on application to Mr. Charles E. Stuart, Controller of Stores, Telegraph-street, London, E.C., by whom tenders will be received until noon on Friday, October 30, 1891.

——— The London General Omnibus Company (Limited) invite proposals for the supply of sixty electric hand lamps. Proposals are to be sent to the Managing Director, 6, Finsbury-square, E.C. See advertisement columns.

SOFIA.—In a recent issue we mentioned that the tender of Messrs. Ganz and Co. had been accepted for the lighting of Sofia by electricity. The lowest tenders were as follows :—Overhead wiring : Ganz and Co., £76,400 ; Seimens and Halske, £95,500 ; Compagnie Continentale Edison, £126,800. Underground mains : Ganz and Co., £96,900 ; Crompton and Co., £123,000 ; Siemens and Halske, £124,000 ; Schuckert and Co., £135,000.

PARTNERSHIP. — Mr. Morgan Williams, formerly installation engineer to the Electrical Power Storage Company and the Electric Construction Corporation, has now entered into partnership with Mr. Frank King, and the firm are practising as consulting electrical engineers, under the title of Messrs. Morgan Williams and King, at 39, Victoria-street, Westminster, S.W.

DISSOLUTIONS OF PARTNERSHIP.—Messrs. Bennett, Hides, and Colley, trading as the Midland Electric and Telephone Company, Haxworth-chambers, Fig Tree-lane, Sheffield, electricians.—Messrs. Coveney Brothers, 67, King-street, Ramsgate, manufacturing electricians.

LONDON ELECTRIC WIRE COMPANY.—This Company have made arrangements by which all high-conductivity copper supplied by them will in future have a minimum electrical conductivity of 100 per cent. of that of pure copper, according to Matthieson's standard. Having of late years greatly increased and improved their machinery, the Company are now in an exceptional position for supplying large quantities of covered wires of any gauge at short notice.

MESSRS. J. H. HOLMES AND CO.—An electric light installation has just been put in operation by this firm at the Tarbrax Works of the Caledonian Oil Company.

HOSPITAL LIGHTING.—The St. George's Hospital Committee have decided to avail themselves of the electric current from the supply mains for electric lighting the operating theatre, &c. ; also for cautery purposes. The work has been entrusted to Messrs. Drake and Gorham, who have designed complete arrangements to meet all the special requirements.

THE MINING AND GENERAL ELECTRIC LAMP COMPANY (LIMITED). —This Company are issuing particulars of their various specialities, including their electric safety lamps and storage batteries. The Company are sole manufacturers of "Lithanode," and accumulators under the patents of Fitzgerald, Frankland, and others, and are manufacturers of general accumulator accessories.

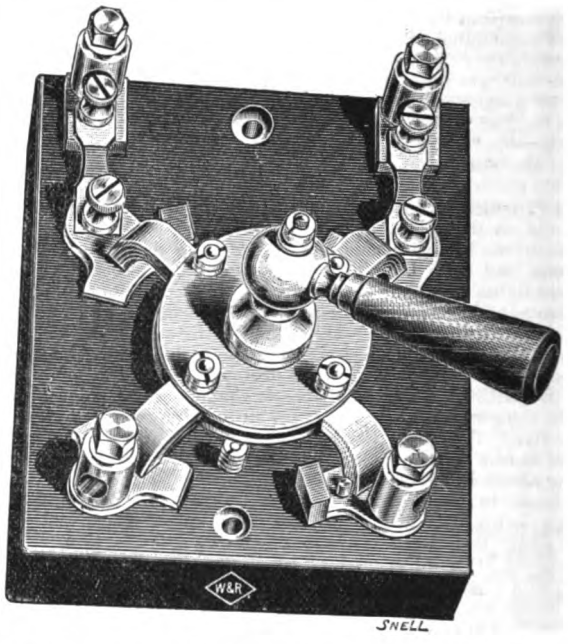
THE NEW YORK INSULATED WIRE COMPANY.—We have received from this Company a neatly-printed *brochure*, giving fully illustrated particulars of their distributing main-line cut-outs, junction boxes, angle boxes, conduits, &c.

INSTITUTE OF MEDICAL ELECTRICITY (LIMITED).—It was resolved at a meeting on September 15th, and the resolution was confirmed at a further meeting on October 1st, that the Institute be voluntarily wound up ; and that Mr. John W. Biggs, 12, Delahay-street, Westminster, be liquidator. Claims are to be sent in to the liquidator by October 31st. We much regret the enforced stoppage of this useful institution, which failed to receive support from the medical profession. It may be the Institute will be resuscitated in a modified form later.

MESSRS. JOHNSON AND PHILLIPS.—This firm informs us that they are extremely busy in their manufacturing departments, and that, in particular, they have heavy orders on hand for their arc lamps.

ELECTRICAL ENGINEERING CORPORATION, LIMITED (IN LIQUIDATION).—Replying to a letter recently addressed to him, Mr. F. W. Pixley, the receiver and manager of this concern, says : "I am now realising the assets of this Corporation, which, however, I regret to say will hardly be sufficient to pay the debenture holders, and there will therefore in all probability be no dividend for ordinary creditors." This is cheering news for the numerous creditors of the defunct Corporation.

A DOUBLE POLE SWITCH.—The practice of placing switches in both paths of an electric lighting circuit, especially at the entrance to buildings which are supplied with electric current from central-station supply mains, is recommended by some authorities, and is condemned by others on account of the proximity of the base metal conductors. When switches are thus arranged the current may be shut off from all contact with the house wires, except when the lamps are actually burning, thus lessening the risk of leakage, and the possibility of damage to the insulation. Messrs. Woodhouse and Rawson United (Limited) have lately introduced types of double pole switches which combine on one base and with one movement the action of two separate ordinary switches. Our illustration shows the form given to those intended for ordinary electromotive forces. It is "quick-break," the handle is fitted loosely, and



powerful springs come into play and break both circuits simultaneously. Great care is taken to insulate the two circuits completely from one another.

MESSRS. WOODHOUSE AND RAWSON UNITED (LIMITED).—We have received a copy of List B, just issued by this firm. The book relates to measuring instruments, &c. ; is admirably printed, and contains a mass of useful information.

NEW COMPANIES, STATUTORY RETURNS, &c.

ABERCARNE ENGINEERING AND FOUNDRY COMPANY (LIMITED). This Company has been registered with a capital of £15,000, in £5 shares, to acquire the undertaking of an ironfounder and manufacturer, now carried on by Jesse Bailey, at Abercarne, near Newport, Monmouthshire, in accordance with an agreement made between Jesse Bailey of the one part and John Moxon of the other part, and to carry on in all its branches the business of steel and iron founders, mechanical engineers, &c.

RICHARD S. HUGHES (LIMITED).—This Company was registered on October 3, 1891, with a capital of £15,000, in £10 shares (for private subscription only), by Thomsons, Brooks, and Danby, solicitors, 63, Cornhill, E.C. The objects are to acquire the goodwill of, and take over as a going concern, the business carried on by R. S. Hughes at 95, 96, and 97, Hatton-garden and Robin Hood-yard, E.C., to adopt an agreement for the purpose, and to carry on the business of gas and electrical engineers and fitters, manufacturers of gasaliers, chandeliers, electroliers, and of gas and electric lighting fittings and appliances, lamp-makers, &c. The number of Directors is not to be more than four, the first being Richard S. Hughes and Fleetwood Stileman for twelve years after the registration of the Company. So long as Mr. Hughes holds one-third of the original capital of the Company he may appoint other Directors, but so that the number does not exceed four. Remuneration £250 per annum for each of the above or two years, but that of F. Stileman will be increased to £300 after hat time. Secretary and office : D. J. Sadler, 96, Hatton-garden.

BYNG TELEPHONE COMPANY (LIMITED).—The following notice from J. P. Spencer, of 32, Moseley-street, Newcastle-on-Tyne, the liquidator of the above Company, was filed on October 2, 1891 :—"To the Registrar of Joint Stock Companies. I beg to inform you that a general meeting of the above-named Company was held on September 17th, for the purpose of having an account laid before it, showing the manner in which the winding up of the said Company had been conducted, and its property disposed of, and of hearing any explanation that might be given by the

Digitized by Google

liquidator. I have further to inform you that the notice calling the meeting was duly published in the *London Gazette* of August 14, 1891, and that a circular notice thereof was also sent to each member, together with a copy of the liquidator's report and a copy of the statement of accounts." The above Company was registered on February 25, 1886, with a capital of £5,000 in £10 shares.

"ECLIPSE" ELECTRIC LIGHTING SYNDICATE (LIMITED).—The offices of this Company have been removed from 18, Telegraph-street, E.C., to 2, Pancras-lane, Queen-street, London, E.C. (Filed on October 3rd, 1891.)

ELECTRIC WELDING COMPANY (LIMITED).—The registered office of this Company has been removed from 3, Tokenhouse-buildings to 2, Tokenhouse-buildings, E.C.

LAING, WHARTON, AND DOWN CONSTRUCTION SYNDICATE (LIMITED). The following special resolution was passed July 27, 1891, confirmed August 12th, and a notice filed August 22nd:—"That the capital of the Company be increased to £100,000, of which not more than £30,000 may be issued at the discretion of the Directors in shares to be called preference shares, and to carry a fixed preferential dividend, at the rate of £5 per cent. per annum." The annual return, made up to August 10, 1891, was filed on September 8th. The nominal capital is £40,000, in £100 shares, of which 399 have been taken up, the full amount called and paid on 266, and the remainder considered as fully paid. Office: 82A, New Bond-street.

LIVERPOOL AND DISTRICT PULSION TELEPHONE COMPANY (LIMITED). The statutory return of this Company, made up to July 8, 1891, was filed on the 14th following. The Company, which was registered on March 5, 1891, has a capital of £6,100, divided into 6,000 ordinary and 100 founders' shares of £1 each. 4,080 of the ordinary and the founders' shares have been taken up, and upon 1,080 of the ordinary shares 5s. per share has been called, and £257. 10s. paid, leaving £12. 10s. unpaid. The remaining shares (*i.e.*, the founders' and 3,000 of the ordinary shares) are considered as fully paid. The Company holds a licence from the Primary Syndicate (Limited), for the exclusive use, within 20 miles from the Town Hall of Liverpool, of Patent No. 8,457 of 1888, in respect of an invention for "improvements in mechanical telephones," and in full satisfaction for such licence 3,000 ordinary and 100 founders' shares in this Company were allotted to the Primary Syndicate or its nominees. Office: C, Queen Insurance-buildings, Liverpool.

MAITLAND AND COMPANY, LIMITED (Commission Agents, Contractors for Railways, Telegraphs, Telephones, Electric Light, Heat, and Power Works, &c., in China).—The annual return of this Company, made up to October 1, 1891, was filed on the following day. The Company, which was registered on May 3, 1890, has a nominal capital of £10,000, in £100 shares. All the shares have been taken up, and £5 per share has been called and paid. Messrs. Thorne and Co. (Limited), of 66, Old Broad-street, E.C., hold 93 of the shares. Office: 66, Old Broad-street, E.C.

NATIONAL TELEPHONE COMPANY (LIMITED).—The annual return of this Company, made up to June 30, 1891, was filed on September 29th. The nominal capital is £4,000,000, divided into 30,000 preference shares of £10 each, and 740,000 ordinary shares of £5 each; 30,000 preference and 447,234 of the ordinary shares have been taken up and the full amount called. All the calls have been paid, amounting to £2,536,170.

W. T. HENLEY'S TELEGRAPH WORKS COMPANY (LIMITED).—The annual return of this Company, made up to September 1, 1891, was filed on the 21st following. The Company, which was registered on February 21, 1880, has a capital of £70,000, in £10 shares, 6,697 of these have been taken up, the full amount called, and £66,700 paid, leaving £270 unpaid. Office: 27, Martin's-lane, E.C.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY (LIMITED).—The accounts of this Company, subject to audit, show a profit sufficient to enable the Directors to recommend a final dividend of 1s. per share, making, with previous distributions, a total dividend of 6 per cent. for the year ended June 30, 1891, and also the payment of a bonus of 4s. per share, both free of income-tax, which together will amount to £32,500, leaving a balance of £88,210. 16s. 9d., of which amount £60,000 has been placed to the reserve fund, increasing that fund to £474,878. 7s., and £28,210. 16s. 9d. carried forward. The very exceptional increase in revenue mainly arises from the disturbed state of affairs in South America. For the purpose of paying the above dividend and bonus on the 22nd inst. the register of transfers will be closed from the 12th to the 21st inst., both days inclusive. The traffic receipts for the week ended October 2nd were £5,226.

CITY AND SOUTH LONDON RAILWAY COMPANY.—The traffic receipts of this Company for the week ended October 4th amounted to £748; aggregate receipts for half-year to date, £9,663.

CITY OF LONDON ELECTRIC LIGHTING COMPANY.—Colonel Ben Hay Martindale, C.B., has been elected a Director of this Company. Application has been made to the Stock Exchange Committee to appoint a special settling day in, and to grant a quotation to, the ordinary shares.

CITY OF LONDON ELECTRIC LIGHTING (PIONEER) COMPANY (LIMITED).—Notice is given, that an extraordinary general meeting of this Company will be held at Winchester House, Old Broad-street, E.C., at 2.30 p.m., on Tuesday, the 20th inst., when the subjoined resolution, which was passed at the extraordinary general meeting of the Company held on the 30th ult., will be submitted for confirmation as a special resolution:—"That the Company be wound up voluntarily." Should the resolution be confirmed, a further resolution will be proposed at the same meeting for the appointment of the Hon. Alan Charteris and Mr. Joseph Cecil Bull to be liquidators for the purposes of such winding up and for fixing their remuneration.

CUBA SUBMARINE TELEGRAPH COMPANY.—The estimated traffic receipts of this Company for the month of September were £3,000, as compared with £2,997 in the corresponding month of last year.

DIRECT SPANISH TELEGRAPH COMPANY.—The traffic receipts of this Company for the month of September were £2,004, as compared with £2,526 in the corresponding period of last year, a decrease of £522.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this Company for the month of September, 1891, amounted to £56,589, and to £55,346 in the corresponding period of 1890, an increase of £1,243.

EASTERN EXTENSION TELEGRAPH COMPANY.—The receipts of this Company for September amounted to £40,586, as against £43,938 in the corresponding period of last year, showing a decrease of £3,352.

ELECTRIC CONSTRUCTION CORPORATION.—Mr. W. W. Duncan, in his October circular, after referring to the fact that the price of the ordinary shares of the Brush Electrical Engineering Company has risen to a premium of about 15 per cent., and calling the attention of investors to the value of the Electric Construction Corporation shares as an investment, makes the following remarks on the financial position of this Company:—"The Electric Construction Corporation has for its Chairman Sir Henry Mance, who is one of the most experienced electricians in the country, and has for its manager Mr. Thomas Parker, who as a practical electrician is second to no one. Let us, however, judge the position of the Corporation by actual practical results. The accounts for the first year's working were made up to September 30, 1890, with the following results:—A net profit of £56,640, which enabled the Directors to write off the preliminary expenses (£4,350), and to pay a dividend of 6 per cent. upon the shares for the year, after carrying £15,000 to reserve. I understand that the profits of the year just closed will show considerably better results, although I would not like to anticipate a higher dividend than 6 per cent., as I believe it is the policy of the Directors to build up a large reserve fund. The report will be issued and the dividend paid in the course of next month; but, meantime, the shares can be bought cum dividend at about 40 per cent. discount. The only reason I can assign for the remarkable cheapness of these shares is that some of the larger shareholders were, owing to the recent financial crisis, obliged to realise at a time when there were very few buyers about. The Company's works are fully employed, and it has some very important and valuable contracts on hand, among which is the application of electric traction to the Liverpool Overhead Railway and the South Staffordshire Tramway Company. This Corporation and its affiliated Company, the Electric Traction Company, are ahead of all other construction companies in the immense field which is opening up for electric traction, and some of the most important provincial tramways, notably the Glasgow Tramway, are in close negotiation for the application to their systems. Instead of these shares being at a discount, in my opinion, with the undoubted future before the Corporation in the manufacture of both electric lighting and electric traction appliances, they ought to be at a considerable premium. I maintain that the field for profitable enterprise covered by this Corporation is greater far than it ever was in the case of telegraphy, and that there is every ground, therefore, for believing that it will meet with at least equal success."

EUROPEAN SIMS-EDISON ELECTRICAL TORPEDO COMPANY (LIMITED). The prospectus of this Company was issued early this week. The Company is formed with a capital of £201,000, divided into 10,000 ordinary shares of £20 each (first entitled to all profits up to 10 per cent. per annum, and half the surplus profits) and 1,000 founders' shares of £1 each (subscribed for by the vendors, and entitled to the balance half of the surplus profits). Included in the directorate are Mr. John L. Martin, one of the Directors of the International Okonite Company; M. Albert Ellissen, a Director of the Compagnie Continentale Edison, Paris; Everett Frazer, President, and W. Scott Sims, General Manager of the Sims-Edison Electric Torpedo Company of New York. The chief engineer is Mr. W. Scott Sims; consulting electrical engineer, Mr. T. A. Edison. The offices of the Company are at No. 9, Fenchurch-avenue, London, E.C.; 3, Rue Vignon, Paris; and the secretary (*pro tem.*) is Mr. Henry Shaw. The Company is formed (so the prospectus states) to work the inventions relating to the Sims-Edison Electrical Torpedo for the whole of Europe, India, and the British Colonies. The following are among the advantages claimed for this torpedo:—1. An effective range of two miles, at a rate of speed of over 20 knots. 2. Instant control from a distance by electricity as to starting, stopping, steering, and exploding. 3. Invulnerability to the shot or shell of the enemy, all but the float being under water. 4. Absolute reliability in operation. 5. The power to dive under or cut through obstructions placed in its path. 6. Capacity to carry a charge of 500lb. of the highest explosive, sufficient to disable, if not destroy, the largest warship, even if it exploded 30ft. distant, which is about the limit of netting defence. The Government of the United States of America, after an exhaustive series of official tests, have adopted this torpedo and purchased several, and more are now being constructed under contract for that Government. The Société des Forges et Chantiers de la Mediterranée has contracted for their manufacture for France, Russia, Austria, Belgium, Spain, Greece, and certain other Continental countries on terms which the Directors believe to be very favourable for this Company. Messrs. Sir W. G. Armstrong, Mitchell and Co. (Limited), have expressed their willingness to contract on similar terms for the United Kingdom, the Colonies, and Italy; and negotiations are pending with the Vulcan Works of Stettin, Germany, for the Empire of Germany. The Directors feel a

Digitized by Google

difficulty in stating publicly the estimated profits on these torpedoes, but even on a moderate amount of business anticipate highly satisfactory dividends to the shareholders. The electrical mechanism employed in the Sims-Edison torpedo, by which it can be propelled at high speed with great force through the water and steered from the shore, is also applicable to lifeboat service. We must refer our readers to the full prospectus for further particulars. The subscription lists opened on Monday and closed on Wednesday last.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic returns of this Company in September, 1891, were £24.000; January 1st to September 30th, £213,400; corresponding period, 1890, £206,800; corresponding period, 1889, £203,200.

INTERNATIONAL OKONITE COMPANY (LIMITED)—The first annual general meeting of this Company has been postponed from Friday, October 9th (to-day), and will be now held on Wednesday, October 14th prox., at noon, at the Cannon-street Hotel, City of London.

NATIONAL TELEPHONE COMPANY (LIMITED).—The Directors have made a new issue of 4½ per cent. debentures to provide capital for further extensions and improvements of the system. The issue was offered to the present shareholders at £105 for each £100, and it has been largely over applied for.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The traffic receipts of this Company for the month ended September 30th were £3,650.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended October 2nd, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £4,100.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The traffic receipts of this Company for the half-month to September 30th were £1,598, as compared with £2,438 in the corresponding period of last year.

WINFIELDS (LIMITED).—At a meeting of the shareholders of this Company held on the 2nd inst., the Chairman, in moving the annual report, stated that all the profits of the year had been required in the business, and that he was much disappointed with the result of the year's trading. During the first six months of the past year trade had been fairly good, but the latter half of the year had been bad. The Directors were modernising the plant and means of production.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 700.—Vol. XXVII. FRIDAY, OCTOBER 16, 1891. Price Fourpence.

NOTES.

The Annual Report of the Post Office for 1890-91 just issued, and signed by the late Postmaster-General, gives, as usual, some interesting figures relating to the Telegraph Service. Business, it appears, continues to increase, but not at the same rate as formerly; whilst the average value of each transaction has a slight tendency to diminish. This latter fact may be due to an increase in the number of short business messages; or it may be to increased expertness of private senders in the practice of brevity. Any way the result is the same, the increase in receipts for the year being less than it has been since 1886-87. Mr. Raikes ascribes the falling off in the normal increase of messages to the increasing use of the telephone, not only in the metropolis but throughout the provinces. It is, perhaps, as well that this admission should be publicly made just now, though it comes rather late. The Post Office on the one hand and the Telephone Companies on the other, each for reasons of their own, have maintained until now a conspiracy of silence on this delicate point. One would be curious to know what proportion the Telephone Companies' royalties bear to the estimated loss of public revenue traceable to this licensed competition with the State Telegraphs.

More pointed allusion is made to a still greater loss of revenue through what may be justly termed the shameless abuse of the free railway message privileges. It is not the first time Mr. Raikes has referred to it with evident chagrin. This year the ugly fact is displayed with conspicuous particularity, a short table showing on page 11 the number of messages of various kinds for the past two years and the money derived from them. Opposite the item, Railway Telegrams, we have, for 1890-91, 1,535,067; for 1889-90, 1,291,788; increase, 243,279; Receipts, Nil. The plain English of this is that the burden of free telegrams, which the railway companies contrived to impose at the time of the transfer, and which at that period was quite insignificant, has assumed the enormous proportions above stated, and is now increasing at the rate of a quarter of a million messages a year. Mr. Raikes estimates the value of these franked telegrams at no less than £76,500 per annum—a moderate estimate we fancy, as there is no restriction as to the quantity of words these missives may contain. The number of free railway messages during the first year of the concession was only 116,000. Its increase since that period can be described only in the terms we have employed above.

The daily papers have been occupied of late with the provincial orations of our leading politicians. We read, or do not read, as the case may be, the verbatim reports of these speeches within a few hours of their delivery, and give hardly a thought to the careful organisation and hard work that they entail. The papers send down their reporters, and while these are still at work the copy begins to be handed in in Fleet-street. This is taken so much as a matter of course that they forget to put "by telegraph;" and the space being reserved (the eminence of each member of Parliament being estimated at so many columns), there would be a great outcry if the Post Office were to fail in transmitting these messages. But for the alacrity of the Post Office officials in South Wales, no reports of Mr. Chamberlain's recent speech would have been forthcoming on Wednesday morning; and as his remarks were probably intended to reach a wider audience than that which was actually before him, he might have been tempted to curb his eloquence had he known that the storm had interrupted all telegraphic communication between South Wales and London. But the Post Office was equal to the occasion; and the lines to Chester, Liverpool, and Preston were connected and put through to London, and the speech was sent by that route with Wheatstone automatic instruments.

The explanation of a phenomenon, the existence of which is doubtful; the description of a method of investigation, which has not yet been tried; and a negative result of a series of experiments; have a purely scientific interest which "the practical man" will often fail to appreciate. The explanation will be thrown away if the phenomenon turns out to be imaginary; the method may prove to be illusory; and two negative results need not necessarily produce a positive one. We therefore wait until Prof. Ewing satisfies us as to the first two of these points, and in the meantime note the communication of Messrs. Evershed and Vignoles which bears on the same subject. On the appearance in these columns of an article by Mr. Kennelly (*The Electrician*, Vol. XXV.) on "Permeability of Iron at Right Angles to the Direction of Magnetisation," Messrs. Evershed and Vignoles contributed an account of some experiments on cross-magnetisation, in which they showed that a slight transverse field "joggled out" the residual magnetism. With the view of ascertaining whether the alleged reduction of hysteresis in a loaded transformer was due to a slight cross-magnetisation produced by magnetic leakage, they have applied a transverse

Digitized by Google

magnetisation to a small transformer in the core of which a clinical thermometer was embedded.

The result as interpreted by the authors is a negative one. We are inclined to think that it may bear a somewhat different explanation, but they promise to continue the account of their investigation. The method is worth noticing. The rate of rise of temperature and the correction can be measured with much greater accuracy than might be supposed, as is proved by the closeness with which the observations lie on the lines. One of the objections urged, last winter, to an experiment in which the heating of a transformer was measured by a thermometer, was that the temperature never became constant, by which the critics meant that they never had the patience to wait. But the present method, which occupies minutes instead of hours, and where the transit of the mercury across the divisions was read in seconds, not only makes less demand on time and patience, but enables a steady current to be maintained throughout the experiment without difficulty.

The acquisition of the telephones by the State proceeds apace on the Continent, the protracted negotiations for the purchase of the exchanges worked by the Telephone Company of Austria in some eight towns of the Empire having at last terminated. The first proposals of the Austrian Government were, we believe, of a somewhat confiscatory character; but owing, it is stated, to the intervention of the British Ambassador (the Company is mainly a product of English capital), an amount bearing some relation to the capital invested and the business done will now be paid. At the end of next year the Telephone Company of Austria will cease to exist, and its 6,000 or 7,000 subscribers will then enjoy the benefits of State management. Interurban telephony, which has attained considerable vogue of late in Austria, has always, it may be remarked in passing, been a Government enterprise, as well as several small exchanges with a total of about 1,500 subscribers.

Our New York letter this week gives a brief summary of the official report relating to the recent electrical executions at Sing Sing prison. Contrary to what was asserted at the time it now appears certain that in no case was death instantaneous, several shocks having to be administered before the ghastly jobs were finished. It is said that consciousness ceased on the first application of the current; but as respiration began to be resumed in at least one case before the second shock, this humane assertion cannot be confidently accepted.

Contradictory and erroneous accounts of the Gülcher thermopile have been circulated in various journals. We paid little attention to the invention at first, since it is handicapped by so serious difficulties; but having received several inquiries about it, we applied for information from Herr Gülcher, who has been good enough to give us some figures. These are not very encouraging, but as we are promised some further information we will postpone their publication at present.

Royal Microscopical Society.—A meeting of this Society will be held on Wednesday next at 8 p.m., when several Papers are down for reading.

Telephone Charges.—According to a correspondent of the *Scotsman* in Paisley, an exchange connection is offered for £5 per annum; and where two people use the same wire, each with their own instrument, the rate of £3 per annum each is charged.

Queenstown.—At a recent meeting of the Town Commissioners, the Clerk was instructed to write to Messrs. J. E. H. Gordon and Co., supplying them with particulars as to the area, population, and water supply, and asking them what they would light the town for.

Toynbee Hall.—A course of ten lectures will be given by Mr. A. H. Fison on Electricity, on Monday evenings, at 8 p.m., commencing October 5th. The first four lectures will deal with the principles of the science, and the remaining six will be devoted to applications. The fee for the course is one shilling.

Mica Deposits in Queensland.—A discovery has been made of mica in large quantities at a point about 25 miles west of Muldiva. The plates are of fairly good quality, are improving as the development proceeds, and are free from impurities. Four leases have been applied for, comprising an area of 100 acres.

Institution of Mechanical Engineers.—Two general meetings of the above will be held on the 28th and 29th of October, at 7.30 p.m., when a paper will be read on "Some Details of Construction of Modern Lancashire Boilers," by S. Boswell; and a report to the Alloys Research Committee will be presented by Prof. Roberts-Austen.

The Rhondda and Swansea Bay Railway.—The Directors of this railway have obtained a report from Messrs. Morgan, Williams, and King, of Victoria-street, S.W., on the question of the electric lighting of a two-mile tunnel, and also of their passenger trains. We understand it is proposed to utilise water-power for generating the current.

Lauffen-Frankfort Transmission.—We heard from our Frankfort correspondent yesterday that the transmission plant is working smoothly at 17,000 volts. A workman named Rau was killed on the 12th inst. in the transformer house at Lauffen, having entered it against the rules. He was altering a lamp. The engineer observed fluctuations in his instruments and went straight to the transformer-house, where he found the man dead.

Transmission of Power in Wurtemberg.—The plant for the transmission of 80 H.P. by electricity has been laid down at Messrs. Kutter and Co.'s paper mill, at Wolfegg. The fall from which the power is derived lies about half a mile from the mill. The wires are carried on telegraph poles to the mill, the efficiency of the transmission being 80 per cent. This work, as well as that of lighting the works, has been carried out by Messrs. Reisser, of Stuttgart.

Theatre Lighting in Portugal.—The Government has declined to continue to pay for the electric lighting of the Lisbon Opera House, which amounts to over £6,000 a year, or to contribute towards any other system of lighting. The Government never was under an obligation to pay for the lighting as it has done hitherto, and it is stated that the electric method is being found too costly, while the laying down of gas pipes would amount to a still greater sum.

An American Engineering Problem.—A short time since it became necessary to move a large building across the track of the Concord Electric Street Railway. Of course objection was made to cutting the wires, but after some consultation with the movers, Superintendent George W. Pierce concluded to try to lower the wire sufficient to pass the building over it. Although this line is constructed in the most substantial manner, it was found that releasing four or five span wires would let the wire down sufficiently. It was then planked over, and the building passed over without interruption of service.

Project for Transmission of Power in Austria.—We learn from the *Elektrotechnischer Anzeiger* that Messrs. Franz and Co, of Marburg, intend to make use of a 180 foot waterfall,

Digitized by Google

situated at St. Lorenzen, 18 miles distant, for the purpose of running their works. The power available at the generating station will be about 600 H.P., and it is expected to utilise about 450 H.P. of this at the works, the total cost of the plant being estimated at £22,500.

Dover.—The Electric Light.—A recent meeting of the Town Council was held for the purpose of considering the tender of the Brush Electrical Engineering Company for the supply of the electric light to the borough. Since the last meeting a modified tender had been received, which provided a lesser number of lamps at a greater distance apart at a cost of £650, the first tender submitted being for £1,245. It was decided to provisionally accept the company's modified tender.

The Recent Storm.—The General Post Office gave notice on Tuesday last of considerable delay in telegraphing to all offices south and west of Exeter, Bristol, South Wales, and Ireland. Communication with the Channel Islands by the English route was totally interrupted. Several of the cables to America were also idle, owing to broken land lines. On making enquiries we learn that the breakages were all due to trees falling across the lines, no failure of posts having been reported up to yesterday morning.

Fire at the Bournemouth Telephone Exchange.—A fire occurred at the central office of the Bournemouth Telephone Office on Tuesday; and telephonic communication in Bournemouth, and with Southampton, Poole, and other places is suspended, and likely to be so for some days. The telephone officials state positively that the fire was caused by an electric light current, through contact with the top of an iron roof standard to which the electric light wires were fixed. The fire was quickly extinguished.

New Electrical Scheme in Switzerland.—An important plant is about to be laid down at the bridge between Hundwil and Herisau. A tunnel three miles long, with a fall of ·5 in 100, is to convey water from the junction of the rivers Silter and Urnach, which will furnish power to the extent of 1,200 H.P. Some of this is to be applied to working a tramway between St. Gallen, Speicher, and Trogen; and it is expected that 800 H.P. will be available for distribution for industrial purposes in the neighbourhood.

Crystal Palace, Sydenham, District.—The foundation stone of the supply station for this district will be laid on Saturday next. Messrs. J. E. H. Gordon and Co. propose to use dynamotors for transforming down the continuous high-pressure supply, in connection with storage batteries. In the first instance about 500 H.P. of electrical energy will be transmitted from the generating station to the Crystal Palace, for the purposes of the Electrical Exhibition which opens on January 1, 1892, and no time will be lost in laying the mains for supply of the consumers in the district.

Edinburgh Corporation and the Overhead Electrical System. The Lord Provost's Committee of the Edinburgh Town Council had before them a letter from Mr. R. Addison Smith, on the subject of the erection of a temporary overhead electrical system in Leith Walk, with the view of showing the Corporation and the Tramway Company that tramcars can be worked on steep grades by electricity, and also with the view of obtaining data as to the cost of driving. A report by the Burgh Engineer on the subject was read, and the committee resolved to recommend the Town Council to decline to give their sanction to the proposal.

Obituary.—We regret to record the death of Mr. C. H. Orwin, son of the late James Orwin, M.D., which occurred on September 26th, at Barbadoes, while returning home invalided. Mr. Orwin, who was born in 1853, served for five years with the Telegraph Construction and Maintenance Company, and in 1875 joined the West India and Panama Telegraph Company as electrician. In this capacity he took part in a great many cable repairs in the West Indies. When the "Grappler" was built for the West India Company he was appointed electrician on board, in which position he remained until his death. Mr. Orwin leaves a wife and family.

Portsmouth.—At a meeting of the Electric Lighting Committee of the Portsmouth Town Council, held at the Town Hall, it was decided that the appointment of Mr. J. N. Shoolbred, C.E., as consulting engineer for the installation, be deferred, in order that further opinion may be obtained, more particularly as to the financial aspect of the scheme and the revenue to be derived from the supply, which is to consist of 5,000 16 c.p. incandescent lamps and 100 arc lights. The committee unanimously resolved to invite Prof. Garnett, Principal of Durham College of Technical Education, to give his opinion on the matter, and until this is received no further action will be taken.

Personal.—On Saturday evening last Mr. G. F. L. Preston, late district engineer, and Mr. R. A. Dalzell, local manager of the National Telephone Company, at Sunderland, were presented with testimonials on their appointments to other districts. Some 60 members of the staff were present, and the proceedings were opened by Mr. Clay, who presented each gentleman with a handsome keyless gold watch on behalf of the subscribers. Messrs. Dalzell and Preston having replied, some vocal and instrumental music brought the proceedings to a close.—We learn from Mr. C. E. L. Brown, late of the Maschinen Fabrik, Oerlikon, that he is practising as a consulting engineer at Baden (Switzerland), under the style of Brown, Boveri and Co.

Birmingham Town Hall.—The electric lighting of this Hall has been carried out for the City Council under the superintendence of the firm of Henry Lea and Thornbery. The supply is obtained from the public mains of the Birmingham Electric Supply Company. The main body of the Hall is lighted by 18 pendants, carrying in all 200 32 c.p. obscured lamps without shades. There are in addition 23 16 c.p. lamps under the galleries, and 160 16 c.p. lamps in the corridors, &c. The roof also is lighted by 11 32 c.p. lamps. Double-pole main and local fuses are used throughout, having not more than six lamps on each local fuse. Throughout the recent musical festival the coolness and freshness of the building were remarkable both morning and evening.

Walsall.—At the meeting of the Town Council, on Monday, the General Purposes Committee reported that they had appointed Mr. F. Brown, of the Walsall Electrical Company, to advise as to the terms and conditions upon which the South Staffordshire Tramways Company shall be allowed to erect their overhead wires and work their tramways within the borough by means of electricity, and to superintend the carrying out of the works so as to ensure proper precautions for the safety of the public; and they recommend that the company be allowed to use steam twelve months longer on their lines within the borough, with a view to enable them to equip their lines for electric traction before the expiration of that period. The report and recommendation were adopted.

Electric Annealing of Steel Wire.—The electric current has been utilised since 1889 at the small arms factory at Saint-Etienne for annealing the steel wire of which the hammers springs of the rifle, 1886 pattern, are made. These springs are manufactured of steel wire, 7 millimetres thick, cut in lengths of 3·20 metres; the wire is rolled spirally, and a current of 23 amperes is passed through it. Heating is rapidly effected; when it is judged sufficient, the circuit is closed, and the hammer-spring is dropped into a water-tank. One man can anneal 20 springs in three minutes, equivalent to about 2,400 per day. Electric annealing being clean in operation, and cheap, will no doubt soon be applied in numerous cases analogous to the one indicated.

An Alumino-titanium Alloy.—The Pittsburg Reduction Company, of Pittsburg, Pa., is, says the *Engineering and Mining Journal* of New York, manufacturing a new aluminium alloy which promises to be of considerable industrial importance. It is an alloy of aluminium and titanium, discovered and patented by Prof. J. W. Langley, which possesses a remarkable degree of hardness—not so much in the cast form as when the metal is rolled or otherwise worked. Tools can be made of this alloy with a cutting edge which will hold nearly as well as steel. At the same time the metal has a resilience and spring which will make it of very considerable use for many purposes. The specific gravity of the new alloy is not much greater than that of pure aluminium. The amount of titanium used is very small. Indeed, when the proportion of this element exceeds 10 per cent., the alloy is too brittle for ordinary uses.

Kelvinside Electricity Company.—A conference was lately held between a deputation from the Kelvinside Electricity Company and the Glasgow Corporation Committee on Electric Lighting. The deputation made the request that the Corporation, in order to maintain the control of the streets in their own hands, should lay down the electric mains required for the supply of electricity within the Company's statutory area, which is to be added to the city on November 1st next; and they stated that the Company would be prepared to pay a fair return on the cost of such mains in respect of the use thereof. Some conversation took place on the subject, and the Electric Lighting Committee assured the deputation that their request would be carefully considered. The deputation consisted of Messrs. J. B. Fleming (chairman), Finlay, and Paterson, with Mr. J. M. M. Munro, their engineer, and Mr. Alexander, the Company's secretary.

Cost of Street Lighting.—At a meeting of the Grays Local Board last week it was reported that in order to ascertain the conditions under which similar neighbouring towns were lighted, the Clerk had communicated with their authorities, and from the replies it was found that (with the exception of Southend) the lamps are lighted from sunset to sunrise on the following terms:—1st. Gravesend, £2. 5s. 6d. per lamp, the Corporation lighting, extinguishing, and cleaning; 2nd. Northfleet, £3. 3s. 6d. per lamp, the Gas Company lighting, extinguishing, and cleaning; 3rd. Romford, a portion of the lamps are lighted for ten months all night (except seven nights at each full moon, for which £3. 6s. per lamp is paid, the Company lighting, extinguishing, cleaning, and repairing. The other portions are alight all night all the year round at £4 per lamp; 4th. Southend, £2. 0s. 6d. per lamp; the lamps being extinguished at 11 p.m. from November to June, and at 11:30 from July to October.

City and Guilds Central Institution.—Of the candidates, some 100 in number, who presented themselves for the recent Matriculation Examination at the City and Guilds Central Institution, 64 passed, and 14 did sufficiently well to be admitted as unmatriculated students. In addition to the students who have come forward from last session, and these 78, all now attending courses in each of the four main departments of the College, some 14 special students have entered for advanced courses, and 59 for the courses on Carpentry given to elementary teachers. The departments of Mechanical and Electrical Engineering have now their full number of students. At this entrance examination the Clothworkers' Scholarship, of £60 a year and free education for two years, was gained by J. R. Dick, B.Sc., Edinburgh University; the Siemens Memorial Scholarship, of £50 a year for three years, by F. Maeers, St. Dunstan's College, Catford; the Mitchell Scholarship, of £30 a year and free education for two years, by E. L. Joselin, from the Finsbury Technical College; and the three Institute's Scholarships, giving free education for three years, were awarded to S. Mendel, Charterhouse School, R. J. C. Woods (educated abroad), and W. H. Everett, Queen's College, Belfast. At the close of the last session, the John Samuel Scholarship, of £30 and free education, granted to the best second year's student and tenable for his third year, was gained by F. H. Hummel, and the Siemens Medal for the student of greatest proficiency in the department of Electrical Engineering, by G. C. Turner.

Gutta-Percha in Singapore.—The *Kew Bulletin* for the current month reproduces from the *Comptes Rendus* an interesting article on the rediscovery of the gutta-percha tree in Singapore. Its existence there was first made known to the civilised world by Dr. Montgomerie in 1842, and the first specimens reaching Europe under that name arrived in London in April, 1843. Wheatstone conceived the idea of employing the substance in submarine telegraphy, and in 1849 a cable sheathed part of its length with gutta-percha was laid in the English Channel. It is becoming scarcer and dearer every year, and attempts have been made to replace it by some other substance in cables. Submarine telegraphy requires the finest gums, and the only ones which are of use as insulators are those produced by trees of the genus Isonandra (gutta-percha having been originally described as Isonandra Gutta), whose natural habitat is exclusively in the Malayan region. The destruction of the Malay forests proceeds rapidly owing to native waste; the gums are growing scarcer, and submarine telegraphy "is on the eve of finding itself destitute of those plants which are indispensable to it in the present state of science." The gutta-percha tree has been described as extinct in Singapore since 1857, but M. Sérullas in the ravines of an ancient forest in the island found the tree living and reproducing itself in 1887 at a place where all gutta collecting had ceased for 30 years. "The extinction of the tree was supposed to be complete. Nevertheless, hardly three years ago there still existed in the remnants of the ancient forest of the island adult trees of this species, represented chiefly by offshoots." As to the derivation of the word M. Sérullas remarks that "gutta" in Malay is only used in the general sense of gum or glue. The word "percha" does not mean Sumatra, as has been generally supposed. Sumatra is called by the Malays "perxa," which means the inhabited terrestrial world. Percha means "rag," and exactly characterises the appearance of the gums, which before treatment with warm water resemble rags half reduced to compressed paper-pulp. The *Bulletin* also contains an interesting section describing a new process for recovering the gutta-percha which is left in the bark of the trees after collection by the ordinary wasteful native methods. Some official correspondence on the subject has been published through the Colonial Office; and in a letter from the India-rubber, Gutta-percha and Telegraph Works Company, enclosing a report from Mr. T. T. P. Bruce Warren, it is stated that this sample of bark contained too much resin to make it of commercial value, the resin makes it brittle, and extraction by solvents would not be remunerative.

The Chicago Exhibition and the Chambers of Commerce.—We have no space to give the reasons why various towns think that it is worth while to exhibit at Chicago, but we make an exception in the case of the powerful arguments used at Bristol. The following opinions have been expressed elsewhere:—*Bradford.*—The question of Bradford participating in this Exhibition came up at the September Council meeting of the Bradford Chamber of Commerce on a letter from the Society of Arts. Sir Henry Mitchell said there was a pretty general feeling in the Bradford district that exhibitions of the kind named were becoming too frequent. *Bristol.*—The president reported at a meeting of the Council of the Bristol Chamber of Commerce on September 23rd that he had replied to Sir H. Trueman Wood, respecting participating in the Chicago Exhibition, to the effect that, as the birthplace of Sebastian Cabot, and as the point of departure of some of the earliest New England settlers, Bristol was very largely associated with the new world, and in view of the old association the Chamber had already appointed a sub-committee to consider what steps should be taken to bring the aim and scope of the Exhibition under the notice of local manufacturers. *Cardiff.*—The Chairman of the Council of the Cardiff Chamber of Commerce said he did not know what steps the Chamber could take in this matter beyond making the contents of the letter public. This was not an exhibiting district. It was then agreed to allow the letter to lie on the table. *Macclesfield.*—On consideration of the letter from the Society of Arts, Mr. J. O. Nicholson said that after America had put a duty of 60 per cent. on silk goods imported into their country, he would not spend a penny in sending out articles to be exhibited there. *Oldham.*—The letter was read at the meeting of the Oldham Chamber of Commerce, but no action was taken. *France.*—The Minister of Commerce recently sent a circular letter to the French Chambers of Commerce asking them to furnish him with a list of firms desirous of taking part in the Chicago Exhibition. The replies which have come to hand show that there is very little enthusiasm for the Chicago Exhibition, manufacturers being held back by the McKinley Tariff. The Chambers of Commerce of Bordeaux, Lille, and Roubaix inform the Minister that no intending exhibitor has yet communicated with them. The Chambers of Commerce of Lyons, Saint Etienne, and Roanne have each received one application. Nearly all the other Chambers of Commerce merely note the absence of any applicant.

ELECTROMAGNETIC THEORY.—XVII.

BY OLIVER HEAVISIDE.

(*Continued from page 574.*)

§ 90. It may have been observed that the equations employed by me in the preceding differ from those in use in all mathematical treatises on the subject in a certain respect (amongst others), inasmuch as the constant 4π, which is usually so obtrusively prominent, has been conspicuous by its absence. This constant 4π was formerly supposed to be an essential part of all electric and magnetic theories. One of the earliest results to which a student of the mathematics of electricity was introduced in pre-Maxwellian days was Coulomb's law of the relation between the density of the electric layer on a conductor and the intensity of electric force just outside it, say

$$E = 4\pi\sigma; \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

and, since this was proved by mathematics, it seemed that the 4π was an essential ratio between two physical quantities, viz., electricity and the force it exerted on other electricity. Never a hint was given that this 4π was purely conventional; it was not, indeed, even recognised to be conventional, and is not at the present day in some quarters. Then, again, at the beginning of magnetism, was Gauss's celebrated theorem proving mathematically that the total flux of magnetic force outward through a closed surface equalled precisely 4π times the total amount of magnetism enclosed within the surface; and, for all that might appear to the contrary, this remarkable result flowed out necessarily from the properties of the potential function and its derivatives, and of the three direction cosines of the normal to an element of the surface. It was funny—very funny. However the 4π managed to find its way in was the puzzle in these and similar results; for instance, in the well-known

$$\mu = 1 + 4\pi\kappa, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where μ is the permeability and κ another physical property, the susceptibility to magnetisation of a substance. The dark mystery was carefully covered up by the mathematics. It was as hard to understand as the monarch found it to explain the presence of the apple in the dumpling—how did the goodwife manage to get it in? Nor was the matter rendered plainer by Maxwell's great treatise. Maxwell thought his theory of electric displacement explained the meaning of the 4π (in the corresponding electric theorem), as if it were a matter of physics, instead, as is the fact, of irrationally chosen units.

As the present chapter has been mainly devoted to a general outline of electromagnetic theory expressed in formulæ involving rational units, it will be fitting, in bringing it to a conclusion, to explain here the relation these rational units bear to the ordinary irrational units.

§ 91. The origin of the 4π absurdity lay in the wisdom of our ancestors,—literally. The inverse square law being recognised, say that two charges q_1 and q_2 repelled one another with a force varying inversely as the square of the distance between them; thus,

$$F = aq_1q_2/r^2, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

where a is a constant; what was more natural than to make the expression of the law as simple as possible by giving the constant a the value unity, if, indeed, it were thought of at all? Our ancestors could not see into the future,—that is to say, beyond their noses,—and perceive that this system would work out absurdly. They were sufficiently wise in their generation, and were not to blame.

But, after learning that certain physical quantities bear to one another invariable relations, we should, in forming a systematic representation of the same, endeavour to avoid the introduction of arbitrary and unnecessary constants. This valuable principle was recognised to a small extent by our ancestors, as above; it was emphasised by Maxwell and Jenkin in their little treatise on units in one of the Reports of the B. A. Committee on Electrical Standards (1863, Appendix C; p. 59 of Spon's Reprint). Thus, referring to the magnetic law of inverse squares, we have the following:—

"The strength of the pole is necessarily defined as proportional to the force it is capable of exerting on any other pole. Hence the force f exerted between two poles of the strengths m and m_1, must be proportional to the product mm_1. The force f is also found to be inversely proportional to the square of the distance, D, separating the poles, and to depend on no other quantity; hence, we have, *unless an absurd and useless coefficient be introduced*,

$$f = mm_1/D^2." \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

Observe the words which I have italicised. When it is considered what Maxwell had then done in the way of framing a broad theory of electromagnetism, it is marvellous that he should have written in that way. By mere force of habit one might, indeed, not consider there to be anything anomalous about the 4π in Coulomb's and Gauss's theorems. But did not Maxwell's electrostatic energy $K\mathfrak{E}^2/8\pi$ and his magnetic energy $\mu\mathfrak{H}^2/8\pi$ per unit volume loudly proclaim that there was something radically wrong in the system to lead to such a mode of expression, which fault should be attended to and set right *ab initio*, especially in framing a permanent system of practical units, which was what Maxwell and his colleagues were about?

It would seem that the proclamation fell upon deaf ears, for not only were the units irrationally constructed, but in his Treatise, which followed some years later, we find the following statement (p. 155, second edition). After an account of his theory of electric displacement, we are told that "the theory completely accounts for the theorem of Art. 77, that the total induction through a closed surface is equal to the total quantity of electricity within the surface multiplied by 4π. For what we have called the induction through the surface is simply the electric displacement multiplied by 4π, and the total displacement outward is necessarily equal to the total charge within the surface." That is, his theory of electric displacement accounts for the 4π. So it seems to do; and yet the 4π has no essential connection with his theory, or with any one else's. Though by no means evident until it is pointed out, it is entirely a question of the proper choice of units, and is independent of all theories of electricity. It depends upon something much more fundamental.

§ 92. When looked into carefully, the question is simply this: What is the natural measure of the strength of a source? Suppose, for instance, we have a source of heat in a medium which does not absorb heat, how should we measure the intensity of the source? Plainly by the amount of heat emitted per second, passing out through any surface enclosing the source. If the flux of heat be isotropically regular, its density will vary inversely as the square of the distance from a point source, giving

$$C = S/4\pi r^2, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

if C be the heat flux (per unit area) at distance r from the source of strength S. If we knock out the 4π we shall obviously have an unnatural measure of the strength of the source.

Similarly, if we send water along a pipe and let it flow from its end, which may therefore be regarded as a source, we should naturally measure its strength in a similar manner, viz., by the current in the pipe, or by the *total* outflow.

Now in an electric field, or in a magnetic field, or in the field of any vector magnitude, we have everywhere mathematically analogous cases. We find, for instance, that electrostatic force is distributed like velocity in an incompressible liquid, except at certain places, where it is, by analogy, generated, or has its source. If, then, we observe that the flux of force through a closed surface is not zero, there must be sources within the region enclosed, and the natural measure of the total strength of the sources is the total flux of force itself. I have put this in terms of electric force rather than of electric displacement, merely to exemplify that the matter has no particular connexion with electric displacement. In the former case it is a source of "electric force" that is considered; in the latter, it would be of displacement; and the principle concerned in a rational reckoning of the strength of a source is the same in either case. It is a part of the fitness of things, and holds good in the abstract theory of the space-variation of vector magnitudes, apart from all physical application.

Digitized by Google

Using, temporarily, the language of lines of force, or of tubes of force (which, however, as here, sometimes works out rather nonsensically), we may say that a *unit* pole sends out *one* line of force, or one tube, when rationally estimated.

Next there is the proper measure of the strength of circuital fluxes to be considered; electric current, for instance. The universal property here is that the circuitation of the magnetic force is proportional to the current through the circuit; and the natural measure of the strength of the current is the circuitation itself, without, as usual, dividing by 4π. Now this division by 4π arises out of the irrational reckoning of the strength of point sources. We may therefore expect that when the point sources are measured rationally, the 4π will disappear from the reckoning of electric current, making the circuitation of magnetic force the proper reckoning. This is so, as may be easily seen by substituting for a linear electric current an equivalent magnetic shell, and so bringing in point sources distributed over its two faces.

Thus, in rational units, if we have a point source q of displacement, and a point source m of induction, we have

$$D = q/4\pi r^2, \qquad B = m/4\pi r^2, \quad . \quad . \quad . \quad (6)$$

to express the displacement and induction at distance r, when the fluxes emanate isotropically; and

$$E = (q/c)/4\pi r^2, \qquad H = (m/\mu)/4\pi r^2, \quad . \quad (7)$$

if q/c and m/μ are the measures of the sources of electric and magnetic force respectively. In the magnetic case m may represent the strength of a pole, on the understanding that (since the induction is really circuital) we ignore the flux coming to the pole (as along a filamentary magnet), and consider only the diverging induction. Also,

$$H = C/2\pi r \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

expresses the intensity of magnetic force at distance r from a long solitary straight current of strength C.

§ 93. Considering merely the formulæ belonging to point sources with uniform divergence, we see that the effect of changing from irrational to rational units is to introduce 4π. If this were all, we might overlook the fundamental irrationality and use irrational units for practical convenience. But, as a matter of fact, it works out quite differently. For the unnatural suppression of the 4π in the formulæ of central force, where it has a right to be, drives it into the blood, there to multiply itself, and afterwards break out all over the body of electromagnetic theory. The few formulæ where 4π should be are principally scholastic formulæ and little used; the many formulæ where it is forced out are, on the contrary, useful formulæ of actual practice, and of the practice of theory. A practical theorist would knock them out merely from the trouble they give, let alone the desire to see things in their right places. Furthermore, it should be remarked that the irrationality of the formulæ is a great impediment in the way of a clear understanding of electromagnetic theory. The interpretation of equation (2) above, for instance, or of the similar well-known equation

$$\mathfrak{B} = \mathfrak{H} + 4\pi\mathfrak{I},$$

presents some difficulty even to a student of ability, unless he be given beforehand a hint or two to assist him. For if κ is a rational physical quantity, then μ cannot be; or if μ is right, then κ must be wrong. Or $\mathfrak{B}$, $\mathfrak{H}$, and $\mathfrak{I}$ must be incongruous. The 4π is also particularly inconvenient in descriptive matter relating to tubes of force or flux, and in everything connected with them.

This difficulty in the way of understanding the inner meaning of theory is still further increased by the 4π not entering into the magnetic formulæ in the same way as into the electric. Thus, it is $\mathfrak{D}$ and $\mathfrak{B}/4\pi$ which are analogues. Again, in many of the irrational formulæ the irrationality *appears* to disappear. For instance, in $\frac{1}{2}\Psi\rho$, in $\frac{1}{2}\mathfrak{A}\mathfrak{C}$, in $\frac{1}{2}\mathfrak{E}\mathfrak{D}$, in $\mathfrak{E}\mathfrak{C}$, and in some others. This is because both the factors are irrational, and the two irrationalities cancel. It looks as if $\mathfrak{D}$ were the flux belonging to $\mathfrak{E}$, but it is not. In reality, we have, if $x = (4\pi)^{\frac{1}{2}}$,

$$\mathfrak{E} = x\mathbf{E}, \qquad c\mathfrak{E} = x\mathbf{D}, \qquad \mathfrak{D} = x^{-1}\mathbf{D};$$

therefore,

$$\mathbf{E}\mathbf{D} = \mathfrak{E}\mathfrak{D},$$

whilst c is the same in both irrational and rational units.

§ 94. The question now is, what is to be done? Are we modern pigmies, who by looking over the shoulders of the giants can see somewhat further than they did, to go on perpetrating and perpetuating their errors for ever and ever, and even legalising them? If they are to be enforced, it is to be hoped that it will not be made a penal offence not to use the legal and imperial units.

The "brain-wasting perversity" of the British nation in submitting year after year to be ruled by such a heterogeneous and incongruous collection of units as the yard, foot, inch, mile, knot, pound, ounce, pint, quart, gallon, acre, pole, horse-power, etc., etc., has been repeatedly lamented by would-be reformers, who would introduce the common-sense decimal system; and amongst them have been prominent electricians who hoped to insert the thin end of the wedge by means of the decimal subdivision of the electrical units, and their connection with the metre and gramme, and thus lead to the abolition of the present British system of weights and measures with its absurd and useless arbitrary connecting constants. But what a satire it is upon their labours that they should have fallen into the very pit they were professedly avoiding! The perverse British nation—practically the British engineers—have surely a right to expect that the electricians will first set their own house in order.

The ohm and the volt, etc., are now legalised, so that, as I am informed, it is too late to alter them. This is a *non seq.*, however, for the yard and the gallon are legalised; and if it is not too late to alter *them*, it cannot be too late to put the new-fangled ohm and its companions right. It is *never* too late to mend. No new physical laboratory determinations will be needed. The value of π has been calculated to hundreds of places of decimals; so that rational ohms, volts, etc., can be now fixed with the same degree of accuracy as the irrational ones, by any calculator.

When I first brought up this matter in *The Electrician* in 1882-3, explaining the origin of the 4π absurdity and its cure, I did not go further than to use rational units in explaining the theory of potentials, scalar and vector, and similar matters; then returning to irrational units in order to preserve harmony with the formulæ in Maxwell's treatise, and I did not think a change was practicable, on account of the B. A. Committee's work, and the general ignorance and want of interest in the subject. But much has happened since then. The spread of electrical knowledge has been immense, concurrent with the development of electrical industries, to say nothing of theoretical and experimental developments. I therefore now think the change is perfectly practicable. At any rate, some one must set the example, if the change is to occur. I have, therefore, in the preceding, wholly avoided the irrational units *ab initio*; and shall continue to use rational units in the remainder of this work.

So far as theoretical papers and treatises are concerned, there is no difficulty. Every treatise on Electricity should be done in rational formulæ, their connexion with the irrational (so long as they exist) being explained separately (in a chapter at the end of the book, for instance), along with the method of converting into volts, amperes, etc., the present practical units. At present you have to first settle whether to use the electrostatic or the electromagnetic units, and then introduce the appropriate powers of 10. If rational formulæ are used, then, in addition, you must first insert the constant 4π in certain places, so long as the irrational units last.

When, however, the real advantages of the rational system become widely recognized and thoroughly assimilated, then will come a demand for the rationalisation of the practical units. Even at present the poor practician is complaining that he cannot even pass from magnetomotive force to ampere turns without a "stupid" 4π coefficient getting in the way. That the practical electrical units should be reformed as a preliminary to the general reform of the British units requires no argument to maintain. That this reform is coming I have not the least doubt. Even the perversity of the British engineer has its limits.

(To be continued.)

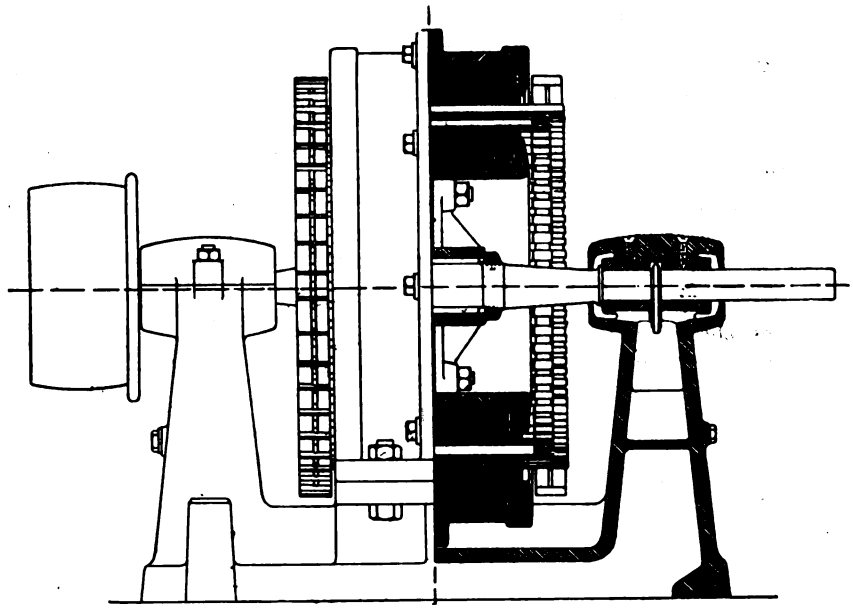
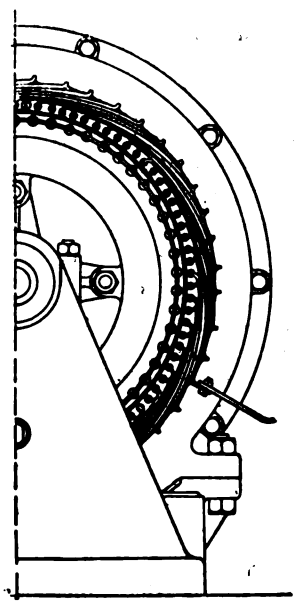
C. E. L. BROWN'S 20 H.P. THREE-PHASE ALTERNATE-CURRENT MOTOR.

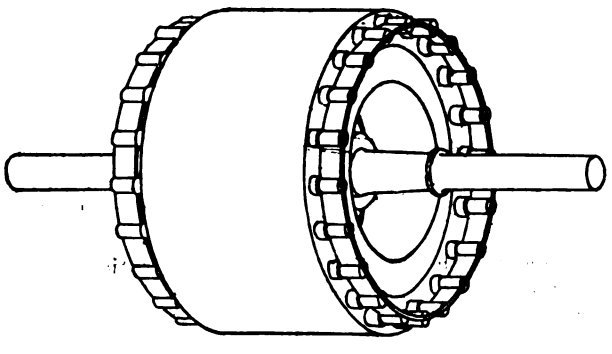
In the middle of last year Mr. Brown gave his attention to the use of multiphase currents, since the absence of sliding contacts in multiphase machinery is sometimes of considerable convenience, and may in the future be of great importance in the industrial use of electric motors. The Allgemeine Electricitäts Gesellschaft in Berlin were working in this direction, and the Oerlikon Company eventually joined with them to develop this system. In August, 1890, the first multiphase motor on a commercial scale was built to Mr. Brown's design. This machine developed 2 H.P., and has a perforated or "hole armature;" that is to say, an armature in which solid bars of copper are completely imbedded in holes in the iron core, the connections being made in Gramme fashion. In the same month Mr. Brown applied this perforated armature in connection with drum-winding to the 300 H.P. generator and motor designed for the electric transmission of power between Bülach and Oerlikon, which, though it is not generally known, suggested the Frankfort-Lauffen experiment; one of these machines, being, in fact, employed at Lauffen. The perforated armature in this application offers, among other advantages, the possibility of reducing the magnetising current to a minimum.



Elevation, half-sectional of Brown's Alternate-current Motor.



Half Elevation.



Armature of Brown's Alternate-current Motor.

From the illustrations it will be seen that the part which may be called the armature is stationary, and that the general arrangement is similar to the 300 H.P. generator. The armature being of a smaller size, it is provided with more than three wires per pole.

The three armature circuits are connected as in a Thomson-Houston armature, and the winding is so arranged that four rotating poles are produced (Fig. 3). With 40 cycles the motor makes about 1,200 revolutions per minute. The motor takes 30 volts normally; a reduction to 50, or an increase to over 100, will not make any practical difference in the speed. Of course, in the first case, the heating of the armature wire is greater, and in the second the heating of the iron is increased. The magnetic field rotates, and is produced by the armature reaction, thus avoiding all sliding contacts. The field-magnet is composed of a laminated ring with holes, in which are placed insulated copper bars. The free ends on both sides are connected by copper rings. It is not easy to imagine a more simple construction. Before giving results of the trials, some general data of the motor may be of interest. The armature has 90 conductors of about 40 sq. mm. section. The weight

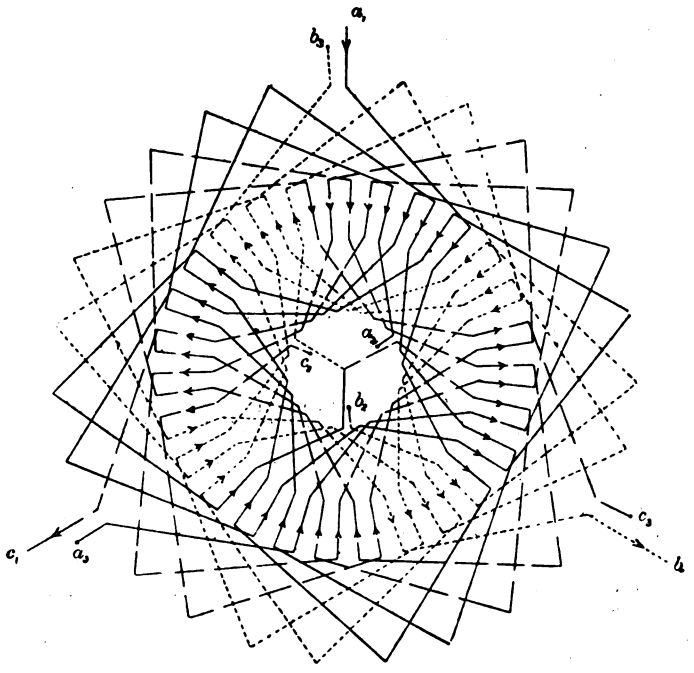


FIG. 3.

of copper is 20kg., the iron about 100kg. The breadth of the armature is 200mm., the outer diameter about 500. The rotating magnet carries 54 copper bars, with a section of 100 sq. mm. The weight of the copper is 15kg., that of the iron is 70. Recent trials in Oerlikon with this motor showed that it can easily supply 20 H.P. No part of the motor showed with a continuous run a higher temperature than 20°C. to 25°C. above the temperature of the test room. It may be of interest to mention

Digitized by Google

that the rotating part shows practically no heating. The difference of speed between no load and full load is only about 3 per cent. The torque of the motor at starting is considerable. It easily ran a separately excited dynamo, which was working on a resistance absorbing 20 H.P. Over 200kg. torque could be obtained on the 20cm. pulley. The motor can carry also a considerable overload, and runs without the least noise. The starting of the motor is similar to that of a continuous current motor controlled by a resistance in series with the armature circuit. Regarding the commercial efficiency no accurate tests have been carried out. The losses in armature copper amount to about 4 per cent. in the magnet copper and iron, inclusive of friction, to 4 per cent. From this there would be an efficiency of 92 per cent. A commercial efficiency of 90 per cent. may be relied upon. That the losses are very small is further clearly shown by the very moderate heating, in spite of the small size of the motor and the absence of ventilation. A further advantage is that the commercial efficiency remains high, even if it works on a light load. The weight of the motor is 420kg., say a trifle over 20kg. per horse-power. For locomotive purposes it might without difficulty be reduced to 300kg., the result of which would be only 15kg. per horse-power. This result must be looked at as a very good one, especially considering the low current density with which the motor is worked. The bearings are automatically oiled, and contain large oil reservoirs, so that this motor should run without any attention for months.

IMPRESSIONS OF FRANKFORT EXHIBITION.

BY H. W. RAVENSHAW.

The German practice in dynamo building being so entirely different from ours, the following impressions may be of interest to those who have not been to the Frankfort Exhibition.

Taking continuous-current machines first, the immense size of the commutators and great number of sections are most striking, there being several commutators of at least three to four feet in diameter and having about 400 sections, the brush surface being about six inches long. These appear to be well designed and fitted up, but must be enormously expensive both in first cost and renewals. A far more simple arrangement is the use of the armature bars themselves as commutator sections, the 600,000 watt machine by Siemens and Halske being a magnificent example of this type of machine. The same firm also shows some alternating and continuous-current transformers with the secondary similarly built. The insulation between the sections is fibre. There was not the sign of a spark on any of these commutators, although being Exhibition dynamos it is not likely they were loaded. Siemens and Halske also show a number of over-type, continuous-current, wire-wound, drum-armature machines with wrought-iron commutators.

The commutators are open-ended and have air insulation between the sections, and appear to run very well. The armature ends are covered with black macintosh, which is tied round at the waist without any regard to true running, giving the machines when running a most slovenly look. In almost all the commutators in the Exhibition the wires from the armature are fixed by means of screws.

As regards general design, the saying that "whatever end up a dynamo is made, it can be made efficient even if it is inside out," is most remarkably exemplified, there being huge armatures with very small magnets inside, running close to large box-shaped magnets, the only evidence of whose armature is a commutator sticking out of a hole in the side. In fact, a Thomson-Houston machine strikes one as being quite neat and primitive by the side of some of the wonderful multipolars with a huge net-work of brush-holders sprawling over them.

It is curious to note that the bar-drum armature which is getting almost universal in England is entirely absent at Frankfort, the writer being unable to find one in the whole Exhibition.

The neatest machine on view is certainly one by Shuckert coupled to an engine by Kuhn, a disc armature with multipole side magnets, and a large commutator. It is beautifully finished and a grand job.* Close by is a gas engine coupled to a dynamo of the Manchester type, giving 7,500 watts at 200 revolutions, an immense plant for the output.

In alternating dynamos the use of iron in the armatures appears to be universal. Siemens and Halske and Helios Co. both have very large slow-speed machines of the Lontin type, the noise from which is tremendous, a loud trumpeting, evidently due to too great density in the armatures. But this could easily be obviated. A density of more than 10,000 per square cm. is sure to produce a humming noise in either dynamo or transformer.

Shuckert shows a multiphase alternator driving a similar motor, dynamos and motor separately excited, apparently starting together synchronously. This set is driving a rotary pump, which gives the motor a good chance to start without load. The Lauffen-Frankfort transmission plant is, of course, the most interesting exhibit, but the writer did not see the generating plant.

The Frankfort end however, is very interesting, the wires appear to be run in rather a primitive fashion, more particularly in the Exhibition grounds, where great numbers of bare wires are run, crossing each other in all directions, in very close proximity.

The motor strikes one as being of reasonable size and of compact design; the four brushes and collectors, however, are disappointing; the most fascinating feature of the rotary field transmission being the possibility of a motor with a rotary part entirely boxed in, and the entire absence of collectors or brushes. There is a very considerable amount of vibration of the revolving part, occurring about 20 times a minute; it would be interesting so know whether this is due to want of balance, or whether it represents the difference of speed of rotation between the rotary fields, and the revolutions of the machine.

The machine appears to be very strongly constructed, but the vibration is quite sufficient to cause considerable damage in time. The motor starts very smoothly with a splendidly rich hum, which however dies away as it gets up its speed. The machine is driving a rotary pump, the water from which does not appear till some time after the machine has attained its full speed.

The transformers are very large and leave a great deal to the imagination, as they simply look like big oil tanks. They are carefully locked up in a fireproof room. Some very fine engines are shown, those by Kuhn being capital examples of the marine type, the running exceedingly smooth, and the finish far superior to the average English engine. As to workmanship and material, it is not possible to judge by a casual inspection. A number of small open engines are shown, running at an excessively high speed. The running is smooth, but they must require very careful attention to keep in good order.

THE FRANKFORT EXHIBITION.—XIII.

(FROM OUR SPECIAL CORRESPONDENT.)

The firm of Siemens and Halske are well to the front with dynamos and motors with rotating magnetic fields. The small model motor, of which an illustration is given, together with diagrams of the method of winding, is a promising step in the direction of obtaining a rotary current motor in which the speed can be kept constant with varying load.

The motor differs from the usual three-phase motor in the fact that the "rotary" current is communicated both to the ring magnet and also to the armature. On the laminated iron core of the magnet ring are wound the three coils whose terminals are at *a*, *b*, *c*, Figs. 1, 2, 3. The other terminals of these coils are connected each with one of three brushes, their points of contact with the armature commutator being at equal intervals from one another. The armature is wound in the ordinary Gramme ring way, and the brushes are movable either to the left or right on the commutator, but always kept at the same distance apart by the vulcanite disc, on to which their supports are fastened. The currents to drive the motor are

* *See* full-page illustration, *The Electrician*, October 9th, p. 633.—ED. *E.*

Digitized by Google

generated by a three-phaser, which is also provided with a commutator to allow of its being driven by continuous current; the three alternating currents of 120deg. phase difference being taken off three rings set on the axis beyond the commutator.

The currents thus given to the magnet wires, and through them to the armature, as shown in Figs. 1, 2, 3, create two rotating magnetic fields, one in the magnet ring, and the other

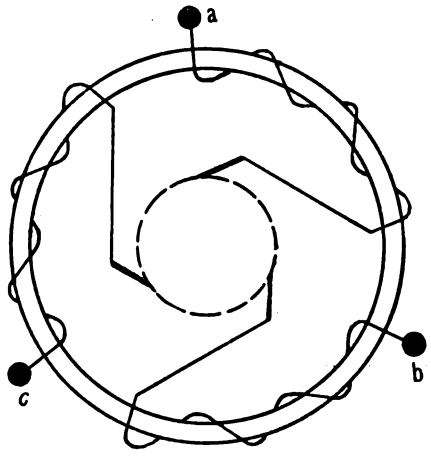

Fig. 1.—Magnetic Axes coincident. Motor stands.

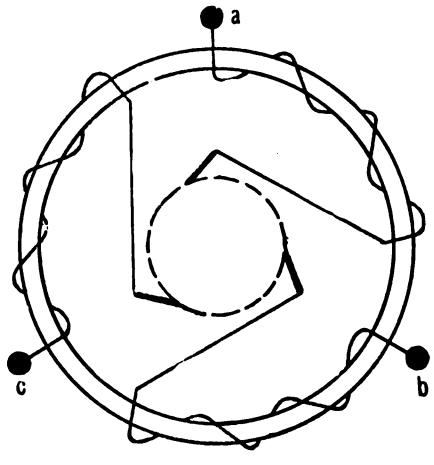

Fig. 2.—Left running. Brushes turned to left.

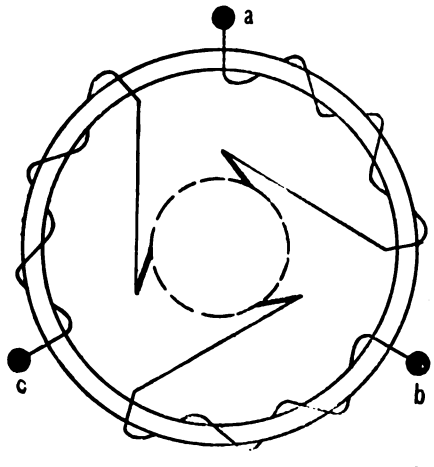

Fig. 3.—Right running. Brushes turned to right.

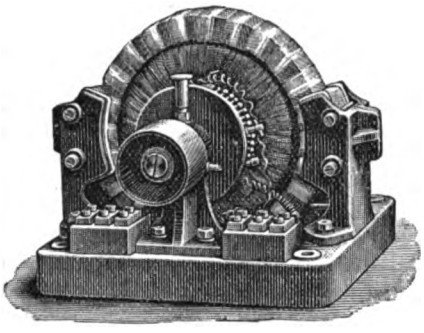
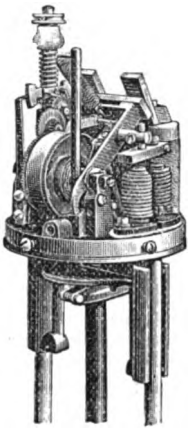
in the armature, the axes of the fields rotating with the same angular velocity. In Fig. 1, where each brush falls directly under the outer terminal of the coil with whose other terminal it is directly connected, the magnetic axes will be coincident in direction; and in Figs. 2 and 3, where the brushes are displaced to the left and right respectively, there will be certain angles between the axes.

In the first case, the repulsion between the poles of like name in armature and ring cannot result in turning the armature round, because it is, as it were, at a dead point, the poles of like name rotating one exactly over the other at the same rate.

If, however, as in Figs. 2, 3, the brushes are moved round in either direction, the magnetic axis of the armature field is moved backward or forward on that of the other field; and now the repulsion between the poles of the same name is able to force the armature round in the direction in which the brushes have been moved, the speed depending on the angle between the magnetic axes of the two fields, and, therefore, on the position of the brushes.



Siemens and Halske Three-phase Motor.

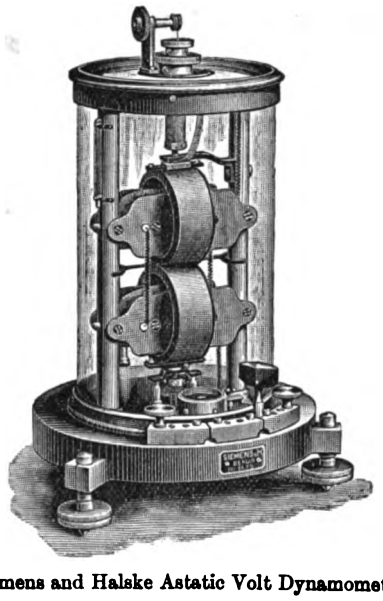


Siemens and Halske "Band" Arc Lamp.

The motor is only a small one, put together for experimental purposes.

The chief advantage of the system is the possibility of keeping the speed constant, or varying it from zero to the highest point in either direction by simply moving the brushes, an adaptability which would render it a useful motor if the rotary current ever came to be applied to tram driving, &c.

On the same stand as the above motor is another small rotary current motor without brushes made by the firm. It is for 1 horse-power, and of the same system as that already described in *The Electrician*. There are twelve coils wound in the Dobrowolsky method on the magnet ring, the winding method having, however, been designed independently. The armature which rotates inside the magnet ring is of solid



Siemens and Halske Astatic Volt Dynamometer.

iron with copper bolts running through it, and connecting the two flat copper discs which form the outer faces. The motor very quietly gets up to its highest speed (without load), and can by means of a switch be almost instantly stopped and reversed. The system has been described at such length in these columns that it is unnecessary to enter upon it here.

While dealing with Messrs. Siemens' exhibit we illustrate herewith the dynamometer and "band" arc lamp, of which a description will be found in our issue of last week.

Cheques and Money Orders should be made payable to* "THE ELECTRICIAN" *Printing and Publishing Company, Limited, and be crossed* "*Coutts and Co.*" *All Editorial letters to be addressed to the Editor.*

All letters intended for insertion in "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails.*

"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from Publishing Offices as above.*

New Volumes of "THE ELECTRICIAN" *commence in May and November. Back Numbers and Volumes of* "THE ELECTRICIAN" *are frequently wanted, and offers will be made by the Publisher therefor.*

SUBSCRIPTION RATES.

The rates for Subscriptions to "THE ELECTRICIAN" are as follows:—

	3 months.	6 months.	12 months.
	s. d.	s. d.	s. d.
For the United Kingdom	5 0	10 0	19 6
For Foreign Parts and Colonies:—			
Within Postal Union	6 6	12 6	24 0
For Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	14 6	28 0

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

Advertisement Rates, &c., forwarded on application as above.

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday. Renewals of expiring advertisement orders and alterations to standing advertisements should be in Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday.*

SMALL PREPAID ADVERTISEMENTS *accepted up to 4 p.m. Thursday.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, 1891, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with well-written Biographical Notices of leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1891 should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Prospectuses free.

ELECTRICAL BOOKS AND PUBLICATIONS

All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad*

"THE ELECTRICIAN" *Series at present consists of—*

THE ALTERNATE CURRENT TRANSFORMER IN THEORY AND PRACTICE. By Dr. J. A. FLEMING. Vol. I. Price 7s. 6d., post free.

THE ART OF ELECTROLYTIC SEPARATION OF METALS (Theoretical and Practical). By Dr. GEORGE GORE. Price 10s. 6d., post free.

PRACTICAL NOTES FOR ELECTRICAL STUDENTS. By A. E. KENNELLY and H. D. WILKINSON. Vol. I. Price 6s. 6d., post free.

THE STEAM ENGINE INDICATOR AND INDICATOR DIAGRAMS. Edited by W. W. BEAUMONT. Price 3s. 6d., post free.

ELECTRO-CHEMISTRY. By Dr. GEORGE GORE. Price 2s., post free.

Several Further Volumes in Active Preparation.

NOW READY, IN TWO VOLUMES.

"THE ELECTRICIAN" PRIMERS.

Fully Illustrated.

Price: Stout paper covers, 2s., post free, 2s. 2d. each; strong cloth, 2s. 6d., post free, 2s 9d. each. Single Primers, 3d., post free, 3½d. Abroad postage extra.

CONTENTS OF THE CURRENT NUMBER

"THE ELECTRICIAN" PRIMERS, in 2 volumes, bound in cloth (2/6, post free 2/9, each), or in paper covers (2/-, post free 2/2, each), are NOW READY.

Full particulars and Prospectus on application to the Publisher.

MULTIPHASE CURRENTS.

Fashion is essentially fantastic and inexplicable. "A volume on this subject," wrote the elder D'ISRAELI, "might be made very curious and entertaining, for our ancestors were not less vacillating and perhaps more capriciously grotesque . . . than the present generation." The latest fashion in electrical engineering is the Drehstrom. How are we to translate this expression? "Rotary current" is an ill-fitting name; for while we concede the time-honoured convention that an electric current has a direction, and for convenience of expression we say that it moves in such a direction, we are outstepping all licence of phrase when we talk of it as rotating. Nor do we mean to imply anything of the kind. The word "multiphase" has been suggested. True this is a hybrid, like bicycle, and we gave a trial some months ago to the more classically modelled "polyphase"; but if at least correctly compounded, it is too pedantic. With commendable boldness the fashionable dynamo and motor used for the Frankfort-Lauffen demonstration have been called "three-phasers," a hybrid expression indeed, but of some robustness. Three-phaser be it then till we are inflicted with more; but the word does not lend itself kindly to the derivatives, "three-phasing" and "three-phasedly."

With none of the candour of modern advertising, but with real sense of shortcoming, the purveyors of electric current of the alternating brand confessed some three years ago that it "won't run motors"; but everybody had an alternating motor in the dark, though the details could not of course be published "owing to incompletion of foreign patents." Then came the Tesla motor, very crude at first and very mysterious. It was thought, at all events, that something might be made

Digitized by Google

of it. The efficiency was doubtful, and the torque on starting was a mere nothing; there were great variations in the strength of the magnetic field during each period, which gave rise to wasteful Foucault currents. Then, amid wonderfully tangled diagrams and strange formulæ, the Drehstrom was born, and we taught our tongue to form the name of DOLIVO VON DOBROWOLSKY. The man who, by adding another wick to an oil lamp, gave us the Duplex, made a very important invention; but when somebody else tried to add a third, it was held that he was only introducing unnecessary complications, and was offering no real advantage; but we are not going to compare three-phase currents with three-wick'd lamps. Under the comprehensive but not altogether pertinent title of "The Frankfort Exhibition" Mr. SWINBURNE has been writing several articles in *Industries* on this latest electrical fashion. There seems to be something very comprehensive about the Frankfort Exhibition; we notice that under the same title our contemporary *Nature* is describing the Deptford station. But to return to the last number of *Industries*, we find that the writer fails to see that the triple-current is any real advance upon the double-current machine. We really hope that he is right. There are many electrical engineers who will not be bothered with alternating currents of any description; they fortify themselves behind the excuse that this new-fangled system will not lend itself to storage or to transmission of power. The latter of these arguments has been knocked away by Mr. MORDEY, and long may they enjoy such security as is afforded by the other. Meanwhile, it is our duty to watch the new developments, to understand them if we can, and to keep our readers posted as to what is being done with them. We often long to hand the whole department of the alternate-current system to the charge of an assistant, and if the present complications increase he would probably want a multi-phase sub-editor to assist him.

Electrical engineering went on very well in the old days with continuous currents, when the Wheatstone bridge told us truly how many amperes would pass with a given number of volts, and we could wind magnets and use iron wire resistances with no misgivings or suspicion. Motors would mote without hesitation, aye, and rack their very keys with impetuous torque under the first rush of current. Nor were the Brush and Thomson-Houston folk afraid of high volts if generators for transmission to a distance were wanted. But an idea is prevalent that alternate currents lend themselves willingly to high pressure, the real facts being that on the one hand the armature coils of the dynamos are more easily kept apart, and that when the high-pressure current arrives at the end of the mains it can easily be transformed down to comfortable voltage. When Sir WILLIAM SIEMENS and Sir WILLIAM THOMSON spoke years ago of transmitting power from Niagara continuous currents were thought of, and with continuous currents the work might have been done.

But, taking the later development of the simple alternating current, what can it do, and what can it not do? Mr. MORDEY'S experiments afford the reply; and now that the scientific world is ringing with the Frankfort-Lauffen transmission we regret that these remain but experiments, conducted quietly with scarce a dozen witnesses, and no demonstration whatever. As though to meet a defect in his motors, the English inventor suggested that the continuous-current exciter coupled to the main shaft would run it up to speed from a battery, and when synchronism was attained the load could be put on. The glory of the three-phaser is that it will start. Some manipulation of resistances, it is true, is needed to check the rush of current at first, but it turns without necessarily synchronising with the generator. This facility of starting has easily been developed in the imagination of enthusiasts into a power of starting under full load; and the description in another column of the latest multiphaser by Mr. BROWN, one of the leading authorities on the subject, contemplates the use of such a motor for an application in which initial torque is of the utmost importance, viz., electric traction. The assumption by such an authority that a multiphaser will be suitable for this purpose is tantamount to a positive assertion, but it is to be noted that in all the descriptions which have hitherto appeared of the Frankfort experiment it has been assumed that the load, viz., that of pumping water, was taken up at once. Mr. RAVENSHAW informs us, however, in his brief article, which will be found elsewhere, that the water is not delivered until some time after starting, so the Frankfort demonstration cannot be said to show a starting under full load.

The writer to *Industries* says, in summing up, "We have given so much space to the discussion of the multiple current because so much has been said about it, and so much is expected from it. We have reluctantly come to the conclusion that it has no great future before it, and that it is not really the solution of the problem: and as this opinion seems to be opposed to that of nearly the whole electrical engineering world, we felt obliged to give reasons to support it." We think that the applause of enthusiasts has been mistaken for "the opinion of nearly the whole electrical engineering world." We admit all that the Lauffen-Frankfort transmission does, and are prepared to hear of more that can be done on this very interesting system. That the insulators were unable to stand the pressure of 30,000 volts need not be regarded as a failure. The chief points are the absence of sliding contacts and the stepping up and down of the volts, which is preferably done by alternate currents simply because it is easier to insulate a transformer than a dynamotor or ordinary motor. But the fear of the former is natural in Germany, where such prodigious commutators are to be found—commutators which do not spark it is true, for the non-sparking position is not a mere line, but a foot or so of the amazing circumference. The heavy "watt-less" currents, the difficulties of measuring, the complications and expense of the wiring, are serious objections to the wide development of multiphasers. If anybody wishes to transmit power for industrial purposes on the scale on which it is done at Frankfort, he has only to give an order for a reproduction of the admirable plant which is running so well. Cases in which such transmission will be remunerative are not likely to be very numerous, for it must be remembered that it does not lend itself to such bold schemes of general distribution as that recently propounded by Mr. MASSEY. A little more simplicity is desirable, and meanwhile we are inclined to look upon the whirling of the three-phase armature at Frankfort, in more senses than one, as a *tour de force*.

REVIEWS.

"Steam Boiler Construction." By WALTER S. HUTTON, Author of "The Works' Manager's Handbook," "The Practical Engineers' Handbook," &c. (London: Crosby, Lockwood, and Son.)

To electrical engineers engaged in the heavier branches of the industry the importance of a thorough knowledge and study of the various types of steam boilers, as well as a proper understanding of the management and working thereof, cannot be over estimated. For in a very marked degree does the efficient and economical supply of electrical power, when generated by steam, depend upon the manipulation and use of the boiler.

In the first place, the electrical engineer must be able to select from the various types of boilers placed before him by

Digitized by Google

the mechanical engineer that boiler which is best suited to the purpose in view. This in itself may be said to be no easy matter, when it is remembered how many different points there are to be considered, each of its own importance and demanding due consideration. He is next called upon to be able to scheme and superintend the fixing and setting of the boiler, its flues, and chimney of suitable dimensions; the latter, again, is a matter of very considerable moment, as on it depends to a large extent the efficiency of the draught, which must be suited to the nature of the fuel to be used; while the arrangement of pipes for feeding the boiler and carrying away blow-off water, those for conveying steam to the engines, with all the accessories, such as pumps, injectors, valves, and cocks, necessary for the proper control of the station and which must be arranged in duplicate so that failure of one portion may not affect the continuous supply of steam, are such as to call forth quite an unlimited amount of ingenuity. Following the installation of the boiler is its proper management and use, which, perhaps, is most important of all, for on this not only depend largely the economical result as to the efficiency of the evaporation per lb. of coal, the fewness of repairs and the length of the life of the boiler, but upon it hangs the continuous supply of steam power which is necessary to maintain the continuity of the supply of current.

The steam boiler, then, is worthy of the greatest study and consideration of electrical engineers, and in the book before us we find a great deal of information of the kind required with the above object.

This work, which we should have thought more fitly entitled "Boiler Construction and Management," inasmuch as the latter absorbs quite half of the book, is divided into six sections, which we shall treat *seriatim*.

The first section commences with the subjects heat, radiation, and conduction, and contains useful tables of various properties of different substances; the various sorts of fuel are described, including liquid fuels. From this the author proceeds to explain the various methods of firing; but we do not agree with him that the so-called spread-firing system is necessarily the most efficient. Mr. L. E. Fletcher, in his exhaustive and well-known tests at Wigan, found that the coking system gave the best and most economical results. From mechanical stokers the author passes to the temperature and efficiency of the furnace, the composition of the gaseous products and smoke, and the effect of soot in depreciating the utility of the heating surface. We observe that in speaking of the temperature of the flue gases the author says that in well-arranged boilers the average temperature is 570°F.; we think, however, that this is somewhat high, as the weight of gases delivered by the chimney is only about 4 per cent. less at 350°F., a greater efficiency should be obtained by using the lower temperature and working at a lower rapidity.

In Section II. chimneys are first treated; as this subject does not receive the amount of attention in handbooks on engineering which it deserves, this part of the work is useful and interesting. With regard to the formulæ given for calculating the size of chimneys we should have preferred to have the constant C, which varies from ·1 to ·065, given in terms of the amount of fuel consumed, rather than in the number of boilers, which is somewhat vague. In speaking of the velocity of gases in the flues the friction against the sides of the flues does not appear to have been considered. It is customary to take this factor as being equivalent to a reduction in the size of the flue of two inches all round the perimeter, while Peclet found it varied as the hydraulic mean depth. From this we pass on to natural and forced draught; here some useful formulæ and data are given as to the comparative efficiency of the two systems. The composition of various sorts of feed water, and the effect of heat thereon, and the action of the water inside the boiler follow, while this section is closed by particulars of the evaporative results of different kinds of boilers, as well as the relative evaporative power per square foot of grate area. We observe that it is stated that an externally fired boiler will only evaporate 5lb. of water per lb. of fuel per hour; we fear that this statement will not be readily accepted in America, where, we understand, a large number of this class of boiler are now being manufactured and used. Table 38, as it stands, does not appear to us of much use, as it is obvious that with a temperature in the chimney of 1174°F., and other high temperatures, uneconomical results are obtained; but if the amount of evaporation per square foot of heating surface were added to this table it would be useful in showing the relation between economy and rapidity of evaporation per square foot of heating surface.

In Section III. are enumerated the requirements of a good boiler, which is well worthy of close reading. Then follow several pages on the heating surface of boilers, and the thermal conductivities of different metals. The evaporative power of the different sections of a boiler is well explained and illustrated by several tests, among which we note an average evaporation of 18lb. water per square foot of total heating surface per hour from 56° F., while with a so-called water evaporator 140lb. were evaporated per square foot of heating surface per hour. As the average working evaporation of stationary land boilers is 3lb. to 4lb. per square foot, it will be seen how much this quantity may be exceeded under favourable conditions. In passing, we may point out an error in the calculation of the average evaporation of the boiler referred to in page 125; this should be 12·4lbs. of water per square foot, and not 49·6, as stated. After devoting some space to smoke tubes, including various formulæ for the calculation of the strength and size thereof, the author returns again to the subject of heating surface. Water surface and the relative amounts of water and steam space are next treated of; and this part of the work, we think, is especially interesting to electrical engineers. A table is given showing the relative amount of water per square foot of heating surface contained in different types of boilers, from which a rough comparison of the amount of coal required to raise steam may quickly be made. Whilst speaking of this table we may remark that the quantities of water given for the Lancashire and Galloway boilers, viz., ·54 and ·47 cubic foot per square foot of heating surface respectively, seem somewhat low. We calculate for a Lancashire boiler 7ft. 6in. diameter, with 3ft. flues, ·9 cubic foot of water per square foot of heating surface, while the boiler sent by Messrs. Galloway to the Philadelphia Exhibition had ·6 cubic feet per square foot of heat surface. The quantity given for the water-tube boilers, such as Babcock's, viz., ·15 cubic foot, is about correct. The Lancashire boiler, then, contains six times the quantity of water to be heated up to evaporating temperature that is contained in a water-tube locomotive type of boiler, certainly a very strong argument in favour of the latter type of boilers when it is remembered that the coal used in steam raising in central stations must be averaged over but a few working hours. Details of grates and fire bars are next touched upon. We do not attach importance to the ratios between grate area and evaporative power of a boiler, as the former depends to so large an extent upon the nature of the fuel and conditions of draught. As it is always easy to reduce the area by firebricks laid on the bars, or otherwise, we prefer to have a large grate provided, unless the exact conditions are known beforehand. The author again returns to heating surface, afterwards treating the strains, stresses, and strengths of the shells and tubes of boilers.

Section IV. continues the subject commenced in the last section, and many interesting tests of the strength of various materials are given. The art of riveting is well explained, while boiler construction generally is treated in this section.

Section V. is chiefly descriptive of various types of boilers, and contains a number of illustrations, some of which are specially well drawn. We notice a number of different types of water-tube boilers. A table is given showing the comparative weights of various types of boilers.

Section VI. treats of boiler mountings, their size and strength; there are also rules and tables given as to steam pipes. We note that the author gives 5,100ft. per minute as the maximum rate of flow of steam in steam pipes permissible in practice, whereas Seaton gives 8,000. For central stations, owing to the length and multiplication of steam pipes, this question is one of considerable importance; by using large pipes we reduce the loss by friction, on the other hand we increase the loss by radiation, and *vice versâ*. Probably the best size lies somewhere between the two quantities above mentioned, but more reliable data on this subject is much needed. The author

Digitized by Google

might have given more attention to methods for overcoming the difficulties of expansion in steam pipes, as in the use of high-pressure steam and long lengths of large pipes this matter is one of considerable difficulty, and has given rise to serious accidents in the past. Some useful hints are given as to prevention of scaling; and it should be noted that though there are many claimants to secret specific compounds effecting certain cures in all cases of scaling, there is no one compound which is applicable in all cases. The water must be treated according to the nature of the impurities contained therein, and that which is good for one may be bad for another sort of water. With an average water, a Lancashire boiler, evaporating 5,000lb. of water per hour, each gallon of water containing 28 grains of impurities, would have deposited per week of 54 hours about 1cwt. of solid matter; the greater part of this would be blown off in ordinary working. In a table giving the loss of fuel for different states of incrustation, we note that a scale of $\frac{1}{32}$in. thick causes a loss of 4 per cent., while $\frac{1}{4}$in. causes 38 per cent., and $\frac{3}{4}$in. 90 per cent. The tests given showing the saving obtained by use of an economiser, viz., 30 per cent., is perhaps misleading, as the heat of the chimney gases without the economiser was 645°F., showing that the boiler was either overworked, or that there was some defect in the heating surface, preventing the due transmission of heat from the flue gases. The information as to the inspection and testing of boilers is useful, and the notes on the heating surface necessary for the heating of various buildings by steam pipes is also of use. A number of actual cases of boiler explosions, with the causes thereof, are explained and illustrated; and the book closes with a paragraph on the life of steam boilers, in which we note that the author estimates the average life of a locomotive type of boiler at 10 years, and of a Lancashire boiler at 25 years.

The descriptions and formulæ are as a rule clear, and should be easy for all to understand, while the plates and illustrations are well done. At the same time, the book would be improved by some alteration in the arrangement of the subject matter. For example, the evaporative power of boilers is treated in Sections II., III., and VI., and in different parts of some of the sections, which necessitates turning to some half dozen parts of the book to learn all there is said on this one subject.

We commend this book to all interested in the practical use of boilers, as it contains a large amount of useful information carefully compiled.

MAGNETISM IN IRON AND OTHER METALS.*—LIII.

BY PROF. J. A. EWING, F.R.S.

(*Continued from page 603.*)

§ 183. **The Molecular Theory and the Effects of Temperature.**—To see the bearing of the molecular theory on experimental results regarding the effects of temperature on magnetic quality, we have to revert to Figs. 79, 80, and 81, § 111, which show Hopkinson's determination of the permeability of iron at various temperatures, for a small, a moderate, and a fairly strong magnetic force respectively. In the first of these figures (Fig. 79) the magnetic force is only 0·3, and consequently the susceptibility at ordinary temperature has the comparative small value which we expect to find in the first stage of the magnetising process. As the temperature is raised the susceptibility increases, at first but slightly, until a temperature of about 600°C. is passed. Then the rise in susceptibility becomes very rapid. It quickly increases more than ten-fold, showing that the effect of this heating is to *bring on the second stage of the magnetising process.* Finally, at a temperature of 775°C. or so there is an extraordinarily sudden fall of susceptibility, so sudden and complete that when the temperature reaches 785°C. practically all magnetic quality is lost.

Under a moderate force (of 4 C.-G.-S. units, *see* Fig. 80) there is none of the sudden rise of susceptiblity during heating which occurred when the force was weak. This is because, under the stronger magnetic force, the second stage in the magnetising process had already been entered before the piece was heated. Further, the loss of susceptibility at high temperature occurs much more gradually. Still more is this the case when the field is comparatively intense (Fig. 81).

The first effect of heating is to hasten the transition from the first to the second stage of the magnetising process, that is to say, to make this transition occur at lower value of the magnetic force. This is probably due to two causes. Heating expands the structure, and that weakens the ties between the molecules by increasing the distances between their centres. We may conjecture that it also sets up oscillations which contribute to make the ties more easily broken. When the field is weak, so that the second stage has not been reached while the metal is cold, heating is consequently favourable to magnetisation, and with an appropriate relationship of temperature to field the metal is in a critical state, in which a small rise of temperature produces an immense augmentation of susceptibility by making groups of molecules which were stable at the lower temperature become unstable at the higher.

This effect of heating cannot occur if the field is strong enough to have upset most of the molecules while the piece was still cold. Hence the curve of Fig. 80 has no sharp apex like that of Fig. 79.

The case of a fairly strong field is more simple. Heating has two antagonistic influences. On one hand, the alignment of the molecular magnets is still being facilitated by the weakening of their mutual forces. On the other hand, the oscillations which they acquire have virtually the effect of reducing the moment of each molecule. Throughout a wide range of temperature the two influences nearly counterbalance one another; the curve in Fig. 80 and Fig. 81 is nearly level for a great part of its course; but as the temperature becomes rather high the prejudicial effect becomes stronger,.and the curve bends down.

At this stage the molecules seem to acquire oscillation very rapidly, and a plausible conjecture to account for the complete loss of magnetic quality which ensues when the temperature rises a little higher, whether the field be weak or strong, is that the oscillation then becomes so violent as to develope into *rotation.*

The establishment of this rotation would account for the energy which we know to be absorbed during heating, while the iron passes from the magnetic to the non-magnetic state; and the rapid subsidence of this rotation into oscillations of comparatively narrow range, during cooling, would in the same way account for the energy which the iron then gives out as it recovers its power of being magnetised (§ 109).

§ 184. **Time-Lag in Magnetisation.**—The phenomena of magnetic viscosity, described in §§ 88 and 89, have some light thrown on them by the molecular theory. We saw that when a weak magnetic force is applied to soft iron, or is raised a step, the resulting change in the magnetism is not completed instantly. There is a protracted creeping up of the magnetism, which goes on long after the magnetic force has become constant. We saw that the softness of the iron and the thickness of the specimen had a great influence on the extent of the time-lagging. A piece of hard iron, or a very thin piece of soft iron, showed little or no lag; a thick piece of soft iron showed much, especially when the experiment was made at an early part of the second stage (stage B, Fig. 136) of the magnetising process.

§ 185. **Effects of Permanent Mechanical Strain.**—It was shown in § 66 that when a piece of iron is hardened by being strained sufficiently to take permanent set, the curve of I and H assumes a rounded form which allows the condition of the metal to be readily recognised. The successive stages of the magnetising process become much blended. No part of the curve has nearly so steep a gradient as we find in dealing with annealed iron. The susceptibility is less throughout, and saturation is approached with greater difficulty. There is much less retentiveness; on the other hand, there is much more coercive force. We may refer back, in illustration of these differences, to Fig. 34, § 66, where the curves for a cyclic pro-

* All rights reserved.

Digitized by Google

cess of reversal are drawn side by side for the same piece of iron in the annealed and hardened states.

These differences, regarded in connection with the molecular theory, seem to indicate that mechanical set resolves a structure which is relatively homogeneous and continuous into one which may be described as a patchwork of more or less distinct molecular groups. Hardening the metal by set makes only a slight change in the density, and it appears probable that it brings some of the molecules closer together, while the intervals between others are widened, with the result that groups are formed in which the intermolecular forces between members of any one group are stronger than the forces which are exerted across the wider gaps between members of different neighbouring groups. The "gaps" tend to shear over the curve of I and H, to round the outlines of the curve, and to reduce the residual magnetism. The closeness of the members within each group increases the coercive force. Thus, without any necessary change in the density of the metal, this modification of the structure would bring about the alteration in magnetic quality which is observed. Another consideration lends some support to this view. In hard metal there is exceedingly little, if any, "time-lag" in magnetisation. The explanation of "time-lag" suggested in the last paragraph seems to require that the structure (of annealed iron) be continuous throughout platoons of many molecules As soon as the platoons are split up into little groups the action described there cannot be expected to take place.

In connection with this it may be remarked that any interruption of the continuity of the molecular structure tends in some measure to shear over the diagram of I and H, and, in particular, to reduce residual magnetism, by making the conditions of constraint of molecules at and near the boundary differ from those of molecules far from the boundary. It seems probable that this consideration gives a clue to the "magnetic resistance" of joints, described above in §§ 162-165. Let the separated parts of a cut bar be ever so well fitted together, the molecules at the boundary, and for some little distance from it, are not subject to the same conditions of constraint as subsist in the uncut bar.

(To be continued.)

THE MEASUREMENT OF HYSTERESIS AND EDDY CURRENTS IN TRANSFORMERS.

BY SYDNEY EVERSHED AND ERNEST B. VIGNOLES.

The publication by Prof. Ewing, in *The Electrician* of October 9th, of the method of measuring loss by hysteresis and eddy currents in alternately magnetised iron, suggests to us that it may be of interest to record some results obtained, early in the present year, by a similar method to the one described. We say, "hysteresis and eddy currents," for it is clear that the latter source of waste cannot be neglected, even when the core consists of a bundle of iron wires.

The measurements were undertaken primarily with the view of trying whether an explanation of the effect which Mr. Mordey's experiments appeared to indicate—viz., decrease of the power wasted by hysteresis and eddy currents in the iron at full load—could be found in the fact that transverse magnetisation is applied to certain parts of the core when current is flowing in the secondary, which is not present when the secondary circuit is open. The transverse magnetisation is due to the construction of the transformer, in which the primary and secondary coils are wound side by side, thus producing local distortion in the main induction path.

From results previously obtained we had reason to suspect that such cross-magnetisation might result in a decrease of hysteresis; and although the disturbance in an ordinary transformer is extremely small and confined to a small portion of the core, it was conceivable that the effect might spread to the remainder of the core; just as in a super-saturated solution of some salt a small local disturbance instantly crystallises the whole mass.

The question we set ourselves to investigate, therefore, was: Does a transverse alternating magnetising force in a piece of iron affect the loss by hysteresis and eddy currents produced by an alternating longitudinal induction?

We determined to measure the loss by means of the rate of the rise of temperature in a model transformer, using a delicate clinical thermometer for the purpose. When the proper corrections are applied, the rate of rise of temperature is a measure of the rate of production of heat, and consequently of the waste of power in eddy currents and hysteresis.

A thermometer seems less likely to lead to errors than the use of a thermo-electric junction and galvanometer, from the circuit of which it would be difficult to eliminate induced currents. Of course, even the most sensitive thermometer lags behind the temperature, but as we are only concerned with the *rate* of production of heat a very small time lag cannot affect the results; and, as a matter of fact, we found the lag almost inappreciable.

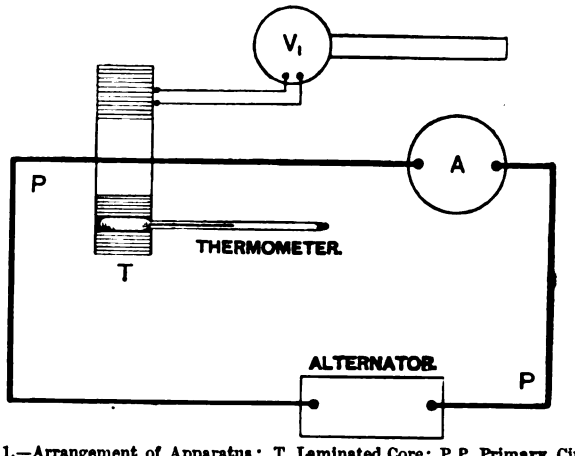

FIG. 1.—Arrangement of Apparatus: T, Laminated Core; P P, Primary Circuit; A, Ammeter; V_1, Cardew Voltmeter connected to Secondary Circuit on Core measuring Induction in Core.

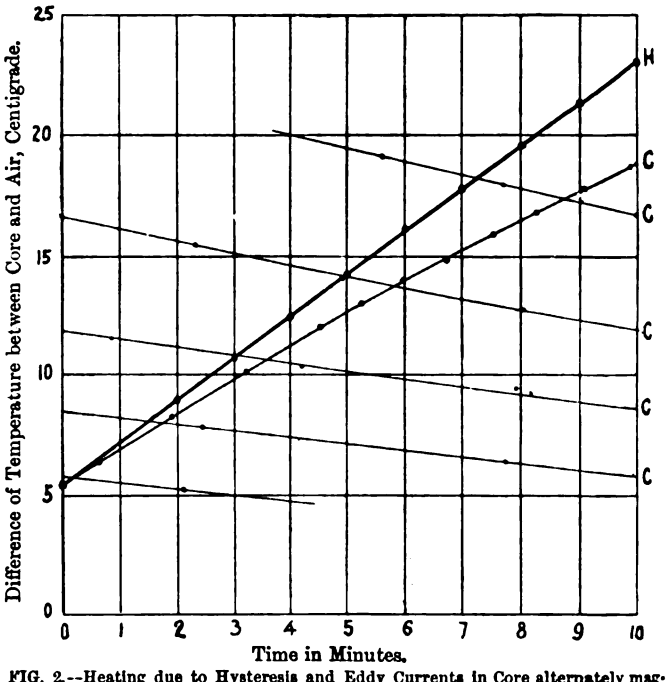

FIG. 2.—Heating due to Hysteresis and Eddy Currents in Core alternately magnetised longitudinally: O, Observed rise; H, Rise corrected for cooling; C C C, Cooling curve. Mean production of heat = 1·77° C. per minute.

We built a transformer of charcoal iron tape, each turn insulated from the last (the lamination being at right angles to the plane of the transformer), and bent so as to form a chamber in the interior of the core, into which the thermometer bulb tightly fitted. The transformer was wound evenly with a secondary coil of 105 turns of No. 24 wire, while the primary consisted of a single stout conductor, on which the transformer was threaded.

The induction in the core was measured by a Cardew voltmeter on the secondary circuit, allowance being made for the loss of volts due to the secondary winding. The primary current has only to be kept constant, and need not be accurately known, except so far as is necessary to reproduce its effective value in a direct current. The standard ammeter of Messrs. Goolden and Co.'s calibrating room was used for the purpose. The arrangement of the apparatus is shown in Fig. 1.

In the first experiment we determined the rise of temperature in the core while the speed of the alternator, the primary current, and the secondary volts were kept constant. Having allowed a rise of 15°C. or 16°C., the alternating current is quickly replaced by its equivalent direct current, and a cooling curve is taken, from which the rate of cooling at any particular

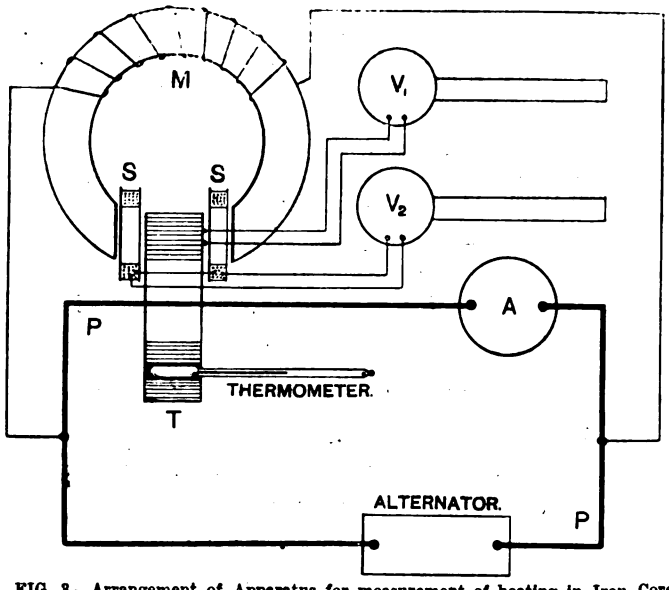

FIG. 3.—Arrangement of Apparatus for measurement of heating in Iron Core under alternating longitudinal and cross magnetising forces: T, Laminated Core; P P, Primary Circuit; A, Ammeter; V_1, Cardew Voltmeter measuring longitudinal induction in Core; V_2, Cardew Voltmeter attached to Coils S S measuring cross induction.

temperature may be determined. It is clear that the only cause of difference between heating with the alternate and the direct current is the waste of energy in the core, provided the temperature of the surrounding air remains constant, or that any small variation is allowed for. It will be noticed that we neglected the heating effect of the voltmeter current, the resistance of the secondary being very small; it may obviously be corrected by maintaining the equivalent direct volts in the secondary circuit during the cooling.

The method of correction for cooling is as follows:—Taking any temperature as a starting point, note the rise in any small time "t." From the cooling curve get the rate of cooling at the mean temperature during this interval; and add to the observed rise the loss by cooling in the time "t," thus obtaining a point P on the curve denoting the rate of production of heat.

Taking this point as a new datum, the repetition of the process gives the next point; and so on. The slope of the resulting curve is the rate of production of heat. The uncorrected heating and cooling curves are so nearly straight that no error is introduced by taking the successive points at comparatively long intervals.

The rate of heating being uniform, the curve should be a straight line; and it is a remarkable and gratifying proof of the soundness of the method that the curves given in Figs. 2 and 4, are, within the limits of observational error, absolutely straight lines. The following are the results obtained:—

Experiment I.—*Observations: March 5, 1891.*

No transverse magnetising force.

Frequency = 104 ∽ Primary current = 125 amperes. Secondary volts = 27·5 Maximum induction density = 8,900 gausses.

				28	26 3	22	...

For the second experiment, a laminated magnet was arranged as shown in Fig. 3, so as to magnetise transversely a portion of the transformer core; the amount of transverse induction being measured by a coil embracing it and connected to a Cardew voltmeter. The magnet was excited by an alternate current, arranged in parallel with the primary circuit. This arrangement was adopted in order that the phase of the current in the magnet might be independent of that of the primary circuit; and by winding a suitable number of turns on the former the cross magnetising force is at its maximum when the primary current is about zero.

Experiment II.—*Observations: March 5, 1891.*

Transverse induction = 2,300 thoms. Frequency = 104 ∿ Primary current = 125 amperes. Secondary volts = 27·5. Maximum induction density = 8,900 gausses.

14	14 23	36	15·2	27	59 15	24	18·3

It will be noticed from the curves (Figs. 2 and 4) that the rate of heating is nearly 8 per cent. greater in Experiment II. than in Experiment I. This proved that whatever the results obtained by Prof. Ayrton and Mr. Mordey might be due to, cross-magnetising force was not the cause.

Leaving this question for the time, we next compared the calculated loss by hysteresis and eddy currents with that obtained experimentally by the method described above; and the results of this investigation will form the subject of another article.

[A "thom" = 1 line of force, a "gauss" = 1 line per sq. cm.—Ed. *E.*]

THE ELECTRIC LIGHTING OF DUBLIN.

At the annual conference of the Incorporated Association of Municipal and County Engineers, an interesting communication was given of the plant and arrangements for lighting the city of Dublin, by Mr. Spencer Harty, the city engineer. In accordance with powers obtained the Corporation of Dublin have now in course of construction a central electric lighting station to supply the first area covered by their licence. The streets through which the mains for public and private lighting will now be carried are as under :—Westmoreland-street, Sackville-street, Mary-street, Grafton-street, College-green, College-street, D'Olier-street, Henry-street, Dame-street, Parliament-street, Capel-street (part of), provision being made for future extension of the area as required. The public lighting will be by means of Brockie-Pell single carbon arc lamps in series, taking a current of 10 amperes and 50 volts, and arranged to burn 16 hours without re-trimming. They will be fixed on iron lamp-posts 21ft. high to centre of lamp, of ornamental design, and fitted with weather hoods and opalescent globes : in the base of each post will be fitted a special short-circuiting switch, to enable any lamp to be completely isolated from the circuit when necessary, and alternate lamps will be on different circuits to avoid the total extinction of light in case of temporary interruption to any one line of conductor. The current will be generated by Brush dynamos and will be kept constant by an automatic regulator. The supply for the private lighting will be on the "high-tension alternating-current transformer system," the pressure in the street mains being at 2,000 volts, and reduced by transformers in the consumers' houses to 50 or 100 volts as desired. The transformers are guaranteed to reproduce in the secondary circuit 95 per cent. of the energy absorbed in the primary circuit at full load, and not less than 75 per cent. at half load, and will run continuously without overheating. The generating plant is being erected upon land belonging to the Corporation, situated at the back of the Bank of Ireland, and will cover an area of about 12,000 square feet, with room for future extension. The frontage in Fleet-street is of red brick with granite string courses, and comprises a three-story building in which the various offices, stores, switch and test rooms will be placed, and a machinery hall 100ft. long, 50ft. wide, and 40ft. high, the latter being ventilated by swing windows in the sides and skylights in the roof. At the back of these buildings the boiler house, coal stores and water tanks are placed, and at one end a brick chimney 120ft. high from the ground level is being erected. The foundations for the walls of main buildings are of cement concrete, and are carried 12ft. below the ground level, the foundations for the engines, dynamos, and chimney being carried some 2ft. lower, to the solid rock. The engines selected for driving the private lighting plant are being built by Victor Coates and Co., of Belfast, and consist of three pairs of coupled compound non-condensing horizontal engines, guaranteed to realise 280 h.p. on the fly-wheel of each pair, with steam pressure of 140lb., and running at 85 revolutions per minute, the diameter of the high-pressure piston being 17in., the low-pressure 34in., and the length of stroke 36in. The public lighting plant will be driven by three vertical compound engines, each capable of realising 60 brake horse-power at a speed of 220 revolutions per minute with steam at 140lb., the high-pressure cylinder being 9in. diameter, the low-pressure 15in. diameter, and the stroke 10in.; the cylinders will be fitted with automatic and hand expansion gear, adjustable while the engine is running, and the governor will be of a specially sensitive high-speed type. The output of the plant installed is equal to 120 arc lamps of 50 volts each, and 5,000 incandescent lamps of 60 volts each, being in use at one time, with one complete spare plant in reserve in each case. The switch-room, situated on the ground floor of the office building, is separated from the engine-room by a glazed partition, and will contain three complete sets of Lowrie-Hall automatic regulating apparatus to maintain a constant electromotive force at the terminals of the alternators ; this is effected by placing a shunt of varying resistance across the field of the exciter.

The test-room, which is placed adjoining the switch-room, is fitted with a very complete set of instruments for testing the condition of the various circuits and machines, and recalibrating the numerous ammeters and voltmeters in use in the station ; the adjustment of meters and testing transformers will also be carried out here. The Thompson reflecting galvanometer is mounted on a concrete pillar, carried some 12ft. below the ground line to minimise vibration. The Wheatstone bridge and testing battery will be permanently connected on an isolated testing table in a convenient form. The boilers will be fed by three Worthington steam pumps, each one capable of supplying sufficient water to two of the boilers when fully loaded, and arranged so that any boiler can supply any pump with steam entirely independent of the main steam pipes. The Corporation will bring their surface lines, free of expense, to any consumer's premises, situated within 30ft. of any of their mains, any extra charge being made for any greater distance, and in all cases the consumer's installation must be passed by the Corporation Inspector before connection will be completed, and be in accordance with the rules laid down by them to secure efficiency and safety. The charge to the consumer will be either by special contract or by meter as may be desired, the minimum charge per quarter being £2 for any quantity up to 60 units ; for any quantity over 60 units and under 100 units per quarter, 8d. per unit ; for any quantity over 100 units per quarter, 6d. per unit. Hire of meter per quarter, 6s. Hire of transformer, primary safety fusible cut-outs :—For 25 16 candle-power lamps per quarter, 5s. ; for 50 do. per quarter, 10s, ; for 100 do. per quarter, £1 ; for 150 do. per quarter, £1. 10s. ; for 200 do. per quarter, £2. The meters will, of course, be fixed on the low-tension mains, their accuracy being guaranteed by the Board of Trade Inspectors, and the current will be available for twenty-three hours per diem. The entire cost of the works as at present designed will be about £31,000, and will be maintained by, and kept under the control of, the Corporation.

ELECTRIC MINING-MACHINERY, WITH SPECIAL REFERENCE TO THE APPLICATION OF ELECTRICITY TO COAL-CUTTING, PUMPING, AND ROCK-DRILLING.*

BY LLEWELYN B. ATKINSON AND CLAUDE W. ATKINSON, ASSOC. MM. INST. C.E.

(Continued from page 647.)

DISCUSSION *(continued).*

Mr. FRANK BRAIN said that with reference to the plant his firm had put down at the Trafalgar Colliery in the Forest of Dean, he might mention that they had increased it three times and had had no trouble with it. With the first installation they carefully boxed up the cables, anticipating that a fall of the roof might damage them. When they put in the second and third installation they did nothing of the kind, as it was found that there was no necessity for it with a fairly insulated cable, to which proper attention was given. It was a non-gaseous mine, and the trouble from the falling of the roof, &c., was very small. He had closely followed the discussion with reference to the means taken to prevent the explosion of gas. As a practical man he looked upon the machine as well fitted for putting into the hands of the miner. There were many mines where it could be used without danger from fire-damp, and he thought it was one of the most practical in the market. It was so strongly made, and so closely boxed up, that it appeared almost impossible to injure it. It was much better, as the authors had shown, to protect an armature going at a high speed, in a machine which was intended for use in a dark mine. That he regarded as a distinct advance, apart from the question of gas. The authors stated that the construction of the machine was such that they could ensure its running in explosive gas for two hours with perfect safety. If so, that was all that colliery managers required, and so far from suggesting that a non-explosive compound should be introduced, he would say, "Stick to your text and prove it, and we shall be satisfied." The matter of efficiency had exercised his mind. At the meeting of the South Wales Institute, the President, Mr. Colquhoun, who had a great deal to do with colliery plant, summed up ; he said he had had nothing to do with electric motors, but he must confess that, so far as his experience went, the efficieney of compressed air machinery had never exceeded 25 per cent. Mr. Brain had recently spoken on the subject to an eminent engineer, who was describing a large compressed air plant with all the latest improvements which he was putting down ; and on asking him what efficiency he expected, he said that he hoped to get 40 per cent. A short time since, a large colliery owner whom Mr. Brain knew asked his manager to furnish him with indicator diagrams of the compressed air plant at all his collieries, and the efficiency was found to be 17 per cent. In the case of some modern machinery belonging to one of his friends (who had nothing to do with electricity), the average result obtained from the diagrams was 18 per cent. That was pretty strong evidence as to the present day efficiency of compressed air plant.

Prof. GEORGE FORBES differed from the authors as to the danger of using the machinery which they suggested in fiery mines. He believed that in 1878 the largest employers of coal-cutting machinery in the country were the firm of Merry and Cunninghame. They were then using compressed air to drive it and were getting an efficiency of about 25 per cent. He was asked to look into the question of applying the electrical transmission of energy to the purpose. He accordingly worked out a plan, and was only deterred by a consultation with Mr. John Cunninghame, the manager of the Company, who with himself came to the conclusion that the danger of sparking was so serious that it was utterly impossible to employ electrical motors for coal-cutting machinery. And he still said, after carefully reading the authors' Paper, that even with the precautions therein mentioned, it would be dangerous to introduce the machinery described into a fiery mine. Various theoretical reasons had been given why it was perfectly safe. First, it was said that in the ordinary way of using an electric

* Abstract of discussion on the Paper read before the Institution of Civil Engineers.

Digitized by Google

motor the temperature of the spark was so low that it would not fire an explosive mixture. The authors further said that, even if an explosion could be so caused, they had enclosed the commutator in a casing by which such a result was rendered impossible. They maintained that there never could be any serious accumulation of marsh-gas in the casing, because the spark of the commutator would be continually burning it up; in other words, that the sparking was really a safeguard against an explosion. He thought they had utterly failed to recognise the fact that if the machine were left for a considerable time the gases would accumulate inside the casings, which would be a very serious matter when the machine was started again. It was said in the Paper: "These precautions, which have been carried out successfully in practice, are, in the authors' opinion, amply sufficient to meet all objections on the point of safety in connection with the application of electric motors to mining work." He wanted to know what those words meant. Had the machine been tried in an explosive mine, where there was known to be an explosive mixture of gases at the place where it was used, or (what was much more important) had it been worked in a chamber filled purposely with an explosive mixture of fire-damp and air? He then described the Tesla motor, and he thought they were certainly the type of machine that would naturally be employed in places where there was danger from fire-damp.

Mr. JOHN TAYLOR referred to some gold mines in California, the property of a company of which his firm had the management. They had been abandoned for some years, in consequence of the impossibility of working them to a profit by steam-power, the ores being of low grade. A Pelton wheel, 87 inches in diameter, and capable of developing 125 H.P. with 400 miners' inches of water under a pressure of 110 feet, drove a Brush generator of 100 H.P. The current was transmitted to the mines by a No. 3 insulated copper wire less than a quarter of an inch in diameter. The length of wire to complete the circuit was 4 miles and 1 furlong. At the mines there was a Brush motor working up to 60 H.P. actual. It drove a ten-stamp battery, and three Huntington mills besides, equal in all to a forty-stamp battery, and there was also a large rock-breaker. In addition, all the mills and buildings were lighted by incandescent lamps by the current taken direct from the transmitting wire. The power required for running the machinery as at present used was from 41 to 43 electric H.P. The electricians present would be able to give their opinion as to whether there could be anything questionable in the results given by these instruments. He had received particulars taken on the 12th of January. At the power-generator there was registered 29 amperes at 1,250 volts, equal to 48½ electrical H.P. The current at the mills at the same time was 28 amperes and the pressure 1,100 volts, equal to 41¼ electrical H.P.; so that practically they were receiving at the mills from 83 to 85 per cent. of the horse-power generated as actual working energy, at a distance of over two miles. They were confidently told by the electricians who put up the machinery, that a wire two sizes larger would give from 2 to 5 H.P. additional; they might therefore talk about 90 per cent. of the horse-power at a distance of more than two miles. Two miners had been instructed, and they attended solely to the machinery where the Pelton wheel and the dynamo were working. Up at the mill there was no supervision whatever of the motor beyond one of the men going in to see that the oil cups did not run empty. The machinery, Mr. Pearson stated, was entirely under control, and in all his experience he had never had to do with a motive power which could compare with it for economy, cleanliness, steadiness, and the ease with which it could be handled.

Dr. LE NEVE FOSTER and Mr. WARREN ROBERTS made some remarks on rock-drills.

Mr. HOLROYD SMITH said the figures which had been given from America with reference to the transmission of electrical energy meant that 15 per cent. was lost in the wires themselves; and for a distance of only two miles such a loss, without some further justification than the saving in copper, was not to be commended. He assumed that the authors when speaking of their percentage of efficiency, and comparing it with that of pneumatic machines, were referring to the power exerted by the steam engine and the power given out in actual work where it was received. On a question of transmission the authors had stated that there was little difficulty in obtaining 50 per cent. of the power expended in the engine. He wished to ask whether that meant indicated horse-power or the power given out by the engine. His own experience had not been such as to enable him to say with certainty that he could expect an engine to lose less than 15 per cent. in itself before it began to give anything to outside work. [Mr. ATKINSON said that the horse-power referred to in the Tables was brake horse-power.] The brake horse-power given out, and the actual work done, were to his mind the points from which they ought to start and at which they ought to end in any calculations of that kind. He thought there was no electrician present who would not much prefer an alternating-current motor if it could be economically constructed, and could be made reliable not only in working, but in the very important point of starting.

Mr. R. E. B. CROMPTON called attention to a diagram of the first electrical coal-cutting machine about three years before the date mentioned by the authors. It consisted of an oscillating arm furnished with cutters, and mounted on a vertical spindle, so as to oscillate through a stroke of from 5in. to 8in., and worked by a pair of electro-magnets. The next point to which he wished to draw attention was the moderation of the language used by the authors when comparing the efficiency of electrical transmission with that of compressed-air transmission. He agreed with several speakers that nothing was to be gained by overstating the case, but he thought that those who were conversant with the use of electricity would agree with him that the authors had, if anything, erred on the side of moderation. He was surprised to hear them say that their percentages were taken on the brake horse-power. He thought that they had taken them on the indicator diagram, and even then he was prepared to substantiate them. He was quite certain, therefore, that they had allowed an ample margin, and that electrical engineers ought to be able to carry out, and more than carry out, all that had been said with regard to the transmission of power up to the distances named. Professor Lupton had thrown down a challenge to electrical engineers which he believed had been taken up by one or two gentlemen present. But it had already been taken up in a much more practical form, namely, by the supercession of air-transmission plant all over the country. This was being done to a large extent in South Wales, and he believed that in a few years the transmission of power by compressed-air would be nearly obsolete. Reference had been made to the cost of repairs for electrical-transmission plant as compared with compressed air plant. The one complaint that the owners of the latter had made to his firm was the great expense of the up-keep. It was costly in two ways—first, on account of its being so inefficient: that portion which answered to the generating plant—the steam-engine and boilers and the air-compressing pumps—was from two and a half to three times as big as was necessary for the electrical plant, and the expenses of the up-keep were proportionately increased. Then there was also the interest on the money invested, and not only was the prime cost greater, but more space was taken up by the machinery. He had carefully gone through the figures presented by the authors, as to the comparison of the first cost of air transmission plant with electric-transmission plant, and he unhesitatingly stated that they were correct and moderate. They had left out one important item that ought to have been put in, namely, the cost of the boiler-power necessary, which, in the case of air-transmission plant, was nearly three times as much as was required for electrical transmission. He had heard with considerable interest the remarks of Prof. Forbes as to the extraordinary dangers which he foresaw in the use of electrical machinery in fiery mines. Prof. Forbes had apparently overlooked one important matter. It was true that, however carefully they might guard against the danger of the communication of the sparks inside the casing to the explosive gases, there was some risk. He admitted it, but it would always be so wherever machinery was introduced into mines. They could not work any kind of coal-cutting machinery without the possibility of the steel points coming into contact with some material harder than the coal, and so causing sparks. Explosions might be produced in that way. He thought, however, that the risks from such a cause were greater than they would be from sparks communicated from the commutator in carefully-devised casings such as the authors had recommended.

Mr. ARTHUR SOPWITH felt certain that a much lighter machine, although at a great sacrifice of power, would gain so much in portability and convenience, that in the long run it would do as much work as a big one. The principle of what was known in America as the Electro-Magnetic Reciprocating Machine appeared to him to be certainly applicable to drills. In it, a bar was drawn into a coil by the action of a current, and brought back again either by springs or by its own weight when the circuit was broken. The great point was the question of the make and break; but if a generator was constructed by which rising and falling currents were created in a closed circuit, the work was done without any possibility of sparking. He thought there should be no difficulty in designing a coal-cutter upon the same principle. It might be said that it would not be easy to construct a machine which would do anything like the same amount of work; but then it would have all the advantages of simplicity, and the absence of movable parts subject to wear and tear. In his case he had used, although not for conveying power, a quantity of old iron and old wire-rope instead of coper, the resistance being only one-twenty-fifth ohm per 1,000 yards, and the cost, including insulation, the same as that of a copper cable of nineteen-sixteenths of good insulation. The relative economic value of iron to copper was as 5 to 1, so that at all events there was room for allowing five times the amount of current at the same expense He mentioned it because it had impressed itself upon his mind, especially as he had tried an experiment with laying wire-ropes side by side on the floor of a coal-mine, and found that, practically, there was no leakage at all, the coal-dust being a perfect insulator. Certainly great economy might be effected by the use of such conductors for conveying the current to centres of distribution in a mine.

Mr. SYDNEY F. WALKER agreed with the authors up to a certain point. As to the important question of sparking, he had repeatedly expressed his opinion, before mining institutes, that the sparking at the commutator was not dangerous, and would not fire gas, and he still adhered to that view, for the following reasons:—First, he had discharged ordinary coal-gas over an old series commutator 10 years ago, and could not get the slightest sign of ignition. Then it should be borne in mind that in order to produce ignition the spark must pass through the gas, and he would ask whether a revolving armature did not create something like a vacuum in the neighbourhood of the commutator, which would keep the gas out. He had another and a much stronger argument which had come to him only recently. Petroleum gas, he understood, was much more inflammable than ordinary coal gas. The chief engineer of a petroleum steamer had told him that he had a dynamo working in their pump-room which was always full of petroleum vapour, into which it was dangerous to go with a naked light; but there had not been the slightest sign of ignition. At the same time, Mr. Walker realised, with the authors, that if there was any feeling among the mine owners that the danger existed, that feeling must be respected and provided for. He did not think that their cover was of the slightest value, for they could not bottle up a spark; the proper course was to get rid of it. There were two points where the spark might be—one at the switch, and the other at the commutator. It appeared to him that there was no reason why the switch need be in gas at all. It could be put in the engine-house, or at any convenient point, with an ordinary electric bell signal between it and the motor station. With regard to the motor itself, his view was that where the gas had to be provided for, and there must be no sparks, there were three ways out of the difficulty. If the alternate-current motor proved itself a success, that was evidently the machine of the future for all work of that kind. The second way was the one which Mr. Sopwith had mentioned

Digitized by Google

and which he thought could be arranged very simply, and worked by an alternate dynamo from the engine-house or by reversing gear in the engine-house near the dynamo. The third way was to reduce the spark at the commutators below the firing point. He thought it was clearly proved by experiments that had been made, some by himself and some by Mr. Mordey and others, that it was not a spark *per se* that ignited the gas, but a spark of a certain energy ; there must be a current of about 10 amperes, and, at any rate, a pressure of 2 volts. If, therefore, they could construct a motor so as never to have a spark with a pressure of 2 volts at the brush, including self-induction and everything, it would be harmless. That was simply a question of construction and of size. Like Mr. Sopwith, he strongly advised that the tension in a mine should be kept low. He was aware that, at the present moment, both pumping and hauling were being done with 300 and 500 volts, and no serious harm had resulted. As to the gearing, the whole thing appeared to him to lead to low voltage, which would enable them to go at a slow speed. Everyone knew that the gearing was one of the difficult points that electrical engineers had to deal with ; and for that reason, and also on account of the danger of shocks, he strongly advised that the motor should be made as large as possible and with a low voltage. Though the copper in the cable would be larger, the interest on the money spent on it would be more than made up by the decreased cost of maintenance.

Mr. REGINALD BOLTON gave a few diagrams with reference to the question of percussive rock drills in order to illustrate the particular duties required of them.

Prof. HENRY ROBINSON had carried out works for compressed air at Birmingham on a somewhat large scale, and some experiments were made last year with a view of ascertaining as nearly as possible the efficiency of the system. There were 34 motors worked by compressed air at 45lb. above atmospheric pressure, and it was found that the average efficiency of them was 42·66. When he said the average efficiency, he wished it to be understood that the fittings of some of the motors were very imperfect, so that the results were lower on that account. It was only right to say that in some cases the air, besides being used expansively, was heated before utilisation, which was, of course, an important feature. In many instances, however, waste heat was employed, so that it did not cost the manufacturer anything. But taking the bad with the good, the average efficiency was 42·66. Within a short time after those observations were made the most defective motors were altered, and the working parts modified so as to give better results ; and, as far as he had been able to ascertain, the average efficiency had been raised to 45 per cent. In another case a 40-horse engine, worked by compressed air, was experimented on very carefully, and the air was heated to 280deg., and the efficiency in that case was found to be 73 per cent. Those figures might be taken as accurate, and he thought they should be recorded. When he heard of the average efficiency of compressed air being as low as 20 to 25 per cent., he felt that those who were not familiar with the subject might receive an erroneous impression. For example, in the Birmingham works at the central station installation, in one corner of the site there was a small 200 H.P. engine, which was used during the laying of the mains for testing, and in another part there were three triple-expansion high-speed engines of 1,000 H.P. each. If diagrams were taken from the old type, no doubt they would show a very low efficiency, but it would not be right to take the average efficiency of the old, badly constructed 200 H.P. engine, and the good modern engines, as a fair representation of what compressed air would do. It was, therefore, desirable to avoid coming to the conclusion arrived at by the authors, and he thought that the tables they had given were rather hard upon compressed air. He had examined collieries under different conditions, and was quite certain that he would never advise the introduction of a motor on a system which would increase the risks in fiery seams.

In answer to Mr. Ll. B. Atkinson, Prof. ROBINSON said the 73 per cent. meant the total efficiency from the engine to the motor, including the waste in the motor.

(To be continued.)

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *October* 8, 1891.

Official Report on Electrical Executions. — The official report of the details of the electrical executions at Sing Sing prison on July 7th last has just been given to the public. It is signed by Drs. C. F. MacDonald, and S. B. Ward, the official physicians in charge of the executions. These authentic details differ in some respects from the reports published at the time. The principal fact to be noted is that in no case were the vital functions immediately suspended, although there was not the slightest doubt that each of the victims was instantly and permanently rendered unconscious. Dr. MacDonald expresses the opinion that the law fulfils its purpose of producing immediate and painless death. There were several distinct shocks applied in each case, lasting from 10 to nearly 30 seconds each. The first contact in each case varied from 10 to 27 seconds, and produced instantaneous and complete unconsciousness with cessation of respiration, but did not destroy the action of the heart. In one case respiration began to be re-established, but was instantly checked on again applying the current. The voltage was from 1,458 to 1,485, most of the time at the latter figure. There was but one elaborate post-mortem examination, and that disclosed nothing of special importance. A strong effort will be made to secure the repeal of either the law itself or that portion of it which forbids the publication of the particulars of the executions. It may be that the cases brought by the district attorney against the editors of several of the New York morning papers will be brought into play to test the constitutionality of this provision of the law.

Statistics of Street Railroads—Some interesting statistics on the subject of electric street railroads have been recently published in one of the journals here. The total number of miles of street railway in the United States and Canada is 11,029, of which 5,442 is horse railroad, 3,009 electric road, 1,918 miles of steam street railroad, and 660 miles of cable road. The horse roads operate 25,424 cars, the electric roads 6,732, the cable roads 3,317, and the steam roads only 1,044, making a total of 36,517 cars. There are 412 electric roads, and the result of the remarkable growth in their number has been, that the number of horses employed on street railway lines has, since November, 1890, decreased by nearly 30,000. Four hundred and twelve is probably rather a high estimate for the electric roads actually in operation, as some of those enumerated are under construction, and others have not yet completed—in some cases have not begun—the change from horses to electricity. Still one can safely say that there are very nearly 400 electric roads in present operation in this country. The number of cars given is in all probability very nearly correct.

The American Street Railway Association.—The meeting of this Association at Pittsburgh, beginning October 21st, will be of great interest to the electrical fraternity at large, inasmuch as the list of Papers to be read deals exclusively with electrical subjects, except for a single discussion of the relations between corporations and the public, which would be equally appropriate in a meeting of the Electric Light Association. Some exceedingly practical Papers will be read, and the meeting promises to be a most interesting one.

BRUSSELS NOTES.

(FROM OUR OWN CORRESPONDENT.)

BRUSSELS, *October* 12, 1891.

The following is an extract from the report recently submitted to the Brussels Communal Council so far as it relates to electricity :—

The proposals to grant a concession for the distribution of electricity in this town has been examined by the Commission, but before taking action it was deemed prudent to obtain more exact information as to the probable cost of a system of electric distribution by the municipal authority a contractor being responsible for working the same, at first. Accordingly a fresh estimate has been prepared, and tenders are invited for the work, which should be sent in not later than October 31st.

During the past few months the cables supplying the lighting current to the Theatre de la Monnaie, the Town Hall, and La Grande Place have been thoroughly overhauled, and some important repairs have been effected, especially at the joints. Inside the theatre it has been found necessary to rebuild the electric organ and to remove nearly all the circuits from the stage, in order to make provision for a metallic curtain.

The "20 kilos" accumulators continue to do very good work ; the usual rate of discharge is $\frac{3}{4}$ ampere per kilo of plate, and it is only on rare occasions that the maximum of $1\frac{1}{2}$ amperes is reached. Under these conditions the cost of upkeep is very small.

The telescopic electric lighting poles in La Grande Place still attract much attention and but little favour. The matter is at present in abeyance, and will be dealt with later on.

There are 18 offices devoted to telephonic and telegraphic work in this town, and these offices are connected by 30 wires. The Compagnie du Telephone Bell have for the use of its subscribers 1,325 lines, and, in addition, there are 12 private wires.

Fire alarms are fitted to 44 of the principal buildings of the town. There are also 410 electric clocks.

At the beginning of August 16,500 metres of the old iron wire had been replaced by lines of phosphor bronze.

CORRESPONDENCE.

TEMPERATURE CO-EFFICIENTS FOR CORRECTING THE RESISTANCE OF WILLOUGHBY SMITH'S GUTTA-PERCHA TO 75° FAHRENHEIT.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: To nearly all text books connected with the electrical tests applied to submarine cables are appended tables of co-efficients for correcting the dielectric resistance from any temperature at which the test may be taken to 75° Fahrenheit, the standard temperature for such tests. It is to the table given in Kempe's "Handbook of Electrical Testing" for correcting the resistance of Willoughby Smith's gutta-percha that the following remarks refer, as the core upon which the observations were made was composed of that material.

On a previous occasion it had been noticed that when testing cable at a low temperature on applying the co-efficient from the above-mentioned table that the resistance at 75° Fahrenheit fell also as the temperature fell. While on a voyage recently from Singapore to New Zealand and back an attempt was made to arrive at a set of co-efficients which should be more nearly correct than those at present in use apparently are. The core of the cable which was experimented upon was composed of 107lbs. copper and 140lbs. Willoughby Smith's gutta-percha, and was 30 miles in length.

Tables No. 1 and 2 give the results of two sets of tests on this piece of cable; No. 1 while going south and decreasing the temperature, and No. 2 returning north and increasing the temperature.

Table No. 3 is a comparison of the co-efficients usually employed and an approximate set based on Table No. 2. I have worked on this latter, as on the whole I think the tests were taken under better conditions of weather, steadiness of ship, &c. It will be seen that results at same temperature vary a little in the two tables; but the difficulty of reading a thermometer to a quarter of a degree, and the galvanometer scale to, say, half a division will, I think, account for this, more especially as the majority of the tests were taken at sea, under conditions of ship rolling or pitching, occasional trouble from dampness in testing room, &c.

I merely put forward as approximate the last column in Table 3, to show the great difference between the present co-efficients and the results I obtained. It may be mentioned that for temperatures above 75 deg. by applying the usual corrections the result gradually increases with the temperature.

If some of your readers who have the leisure and appliances were to investigate this matter, by means of a series of tests under favourable circumstances, I imagine a reliable set of co-efficients differing considerably from the present ones would be the result.

I shall be interested to see if any one has already gone into this matter, and, if so, what was the result of their observations.

Trusting you will find room for this letter in your paper,

I am, &c.,

A. C. M. WEAVER,
Eastern Extension Telegraph Co.'s
Cable Ship "Recorder."

Singapore, Sept. 8, 1891.

Table No. 1.

Temperature Fahrenheit.	Megohms per kilowatt at observed temperature.	Megohms per kilowatt corrected to 75° Fahrenheit by usual co-efficient.	REMARKS.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

NOW READY.—"THE ELECTRICIAN" PRIMERS (38 in all. Vol. I., 20; Vol. II., 18), in two volumes. Price per volume 2s. paper covers, 2s. 6d. cloth; post free, 2s. 2d. and 2s. 9d. respectively. Single copies, 3d.; post free, 3½d. Prospectus on application to the Publisher.

TENDERS RECEIVED.—The following tenders were received by the London County Council for providing electric light at the Newington Weights and Measures office:—Messrs. Crompton and Co. (Limited), £182. 17s. 10d.; Brush Electrical Engineering Co. (Limited), £150; Messrs. Drake and Gorham (accepted), £143.

SALES BY AUCTION.—Messrs. Wheatley Kirk, Price, and Goulty announce in our advertising columns that they will sell by auction, on Thursday, October 29, 1891, the entire contents of the premises 323D, Kennington-road, London, S.E., including a 10 H.P. and a 4 H.P. horizontal steam engines and vertical multitubular boilers, several lathes and other machine tools, pulleys, shafting, belting, &c.

——— Messrs. Wheatley Kirk, Price, and Goulty also announce an important sale, at 39, Queen-street, London, E.C., early in November, of a large variety of new electrical apparatus, including also the entire stock of the West-End Electric Supplies Company, comprising about 50 miles of cable, leads and wires, several thousands of fancy shades, 50 arc lamps, 150 volt and ammeters, 10,000 switches of every variety, 10,000 fuse-boxes and fuses, 10,000 ceiling roses, several thousands of lamp-holders, 1,000 incandescent lamps, several thousands of plain and fancy brackets, electroliers, shades and fittings, Leclanché cells, bells, insulators, carbons, &c., several dynamos, engines, switch-boards, 100 accumulators, electroliers, &c. Full particulars and catalogues may be obtained shortly from the auctioneers, 52, Queen Victoria-street, London, E.C., and Albert-square, Manchester.

MESSRS. NICHOLSON AND JENNINGS.—This firm, trading at 13, Victoria-street, and 132, Horseferry-road, Westminster, London, S.W.; Royal Exchange-buildings, Queen-street, Newcastle-on-Tyne; and Blyth, as electrical engineers and contractors, have made an assignment of their property (filed October 8th) for the benefit of their creditors. Messrs. Edmund I. Bax, 32, Victoria-street, Westminster, S.W., and William C. Mann, 112, Belvedere-road, Lambeth, S.E., are the trustees. The secured liabilities

Digitized by Google

amount to £300, and the unsecured to £4,992. 8s. 9d.; while the net assets are £5,705. 18s. 6d. The following is a list of the principal creditors:—

Belfast Electrical Appliance Company ...	£21	0	0
Cowpen Local Board, Blyth	12	0	0
Saunderson and Co., Blyth	52	0	0

Reid, A., and Sons, Newcastle-on-Tyne..	31	0	0
Lea and Sons, Shrewsbury	11	0	0

SILVERTOWN CABLES.—We have received a very full price list of these electric light cables and wires. A large number of classes are offered, and against each of these a brief specification of the insulating materials is given, together with the insulation resistance. As much of the success of electric light cables and wires is dependent on the uniformity of manufacture and quantity and quality of material used, to ensure these conditions the makers have made it a practice to thoroughly test all cables and wires supplied, and have decided in future to issue with every length of not less than 110 yards of vulcanised india-rubber insulated cable or wire of their standard classes, a label giving the minimum insulation resistance (after twenty-four hours' immersion in water) of such cable or wire, per mile, at 60°F. This test is carried out with a battery of 450 volts, and is calculated to break down any faults in the cables should they exist. Lead-covered cables are supplied, and we observe that the insulating materials are the same in these as in the corresponding classes, no advantage being taken of the lead covering to make use of inferior or non-waterproof insulation.

BUSINESS CHANGES.—Messrs. Cuénod, Sautter and Co., the well-known electrical engineers of Milan, have dissolved partnership, and the business has been transferred to the Société d'Appareillage Électrique. This Company, with a view to the development of their business, has been reconstituted under the title of Compagnia dell' Industria Elettrica Ginevra, with works at Geneva and a branch at Milan. Signori H. Cuénod and René Thury remain with the new Company at Geneva as technical director and electrical engineer, and Signor J. Cuénod takes charge of the Milan branch.

WALSALL ELECTRICAL COMPANY.—We have received an intimation that the partnership previously existing between Mr. Frederick Brown and Mr. Howard W. Bishop, trading as the Walsall Electrical Company, has been dissolved. All moneys due to the firm will be received, and all outstanding accounts will be paid, by Mr. Frederick Brown, who is now carrying on the business under the old style and title.

MESSRS. MORGAN WILLIAMS AND KING.—This firm are superintending an electric light installation at the Mansion, Doublebois, Cornwall, for which Mr. F. M. Newton, of Taunton, is the contractor. Messrs. Williams and King are also superintending the erection of a complete electric light installation at the new parish church, Hove, Brighton.

GÜLCHER (NEW) ELECTRIC LIGHT AND POWER COMPANY (LIMITED).—We are informed that during the last six months the Gülcher Company have made considerable business progress. Mr. De Castro, Chairman and Managing Director, who has visited New Zealand, has succeeded in largely extending the business of the Company in that colony. The Wellington-street lighting installation, which has been working satisfactorily for three years, is now to be extended to include the supply of about 3,000 lamps to private consumers. Bills have passed through the New Zealand Parliament for the lighting of Christchurch, and other important towns will shortly follow. General installation work undertaken by the Company in New Zealand is also largely increasing. An important order for a central station, with plant for a first instalment of about 2,600 incandescent and 60 arc lamps, has been secured, and will very shortly be in operation for lighting part of the city of Genoa, Italy, where a branch establishment of the Gülcher Company has been opened. In London, also, the Company are busy with installations, including the lighting of the People's Palace at Mile End-road, and a large contract was recently secured for the lighting of "Modern Venice" at Olympia, West Kensington. The Company have lately opened a show-room and offices at 139, Queen Victoria-street, E.C., and we congratulate the Directors upon the general progress shown. The successful installations at the recent Spanish, French, and German Exhibitions at Earl's Court, coupled with energetic management, have doubtless assisted in bringing about this gratifying change in the fortunes of the Gülcher Company.

THE PELTON WATER WHEEL.—Messrs. Fraser and Chalmers (Limited) have been appointed the general representatives for London and the English trade generally; but we understand the arrangement with them contains a clause in favour of Messrs. Woodhouse and Rawson United (Limited), who will handle the wheels and motors for electrical work. Mr. A. P. Brayton, President of the Company, who was recently in London, complains of the fact that the Company's patents are being infringed in this country, and informs us that he is taking steps to protect same. The Company contemplate a considerable business in Great Britain and on the Continent for their wheels and motors.

ZÜRICH INCANDESCENCE LAMP COMPANY.—We have received neatly printed particulars of the various sizes of lamps made by this Company, accompanying which are some useful tables and a coloured plan of the Frankfort Exhibition.

JENSEN BELLS.—We are informed that Messrs. Hans Peter Frederick Jensen and Jens Jensen, who have hitherto been branch managers of the business carried on at No. 2, Gray's Inn-road, W.C., under the style of "The Jensen Electric Bell and Signal Co.," are no longer connected with Woodhouse and Rawson United, Limited, and that they are not authorised to transact business on their behalf. In the course of the present month the business will probably be removed to the Cadby Hall Works, Kensington, and sales will be made from the head office, 88, Queen Victoria-street, E.C. Of the date of this change notice will be given.

THE MAQUAY ELECTRIC LIGHT COMPANY.—We are informed that this Company have received a number of considerable orders for their system of electric lighting by small primary batteries; a description of the battery was given in a recent issue of *The Electrician*. The Company have received an order from the Government to make a battery for driving launches for 10 hours; and amongst other considerable orders which they have received is one for £260 from a firm of bicycle makers for small electric lamps for bicycles.

THE FOWLER-WARING CABLES COMPANY.—The District Messenger Service and News Co. (Limited) have just concluded a contract with the Fowler-Waring Cables Co., for the supply of 100 miles of wire for their messenger service. The whole to be delivered by the early part of the forthcoming year.

MESSRS. BARCLAY AND SON.—The electric light installation at the London mansion of Mr. L. de. Rothschild in Hamilton-place, Park-lane, has been entrusted to Messrs. Barclay and Son, of Regent's-street. The plans have been prepared and the work is being carried out under the superintendence of Mr. John Archbutt, the engineer to the firm. There are to be 600 lights—400 in the mansion and 200 in the garden and conservatories. The main cables for the house and garden are being supplied by the Fowler-Waring Cables Co. (Limited), and the whole of the fittings are being specially designed and manufactured by Messrs. Barclay.

ELECTRIC INSTALLATION AND MAINTENANCE COMPANY.—The system of direct current transformers is that to be adopted in the Sydenham and Crystal Palace district. Mr. Frank King (of the firm of Messrs. Morgan Williams and King) has been appointed Consulting Engineer to the Electric Installation and Maintenance Company (Limited), who are the holders of the Provisional Order, Messrs. J. E. H. Gordon and Co. (Limited) being the contractors.

MESSRS. JOHN TULLIS AND SON.—We have received from this firm a copy of their "Guide to Belt Driving," of which four editions have been issued. There is a deal of useful information on the subject of belt driving in the 58 large pages of closely printed matter, and there are a number of illustrations. The book is published by Messrs. Tullis and Co. in German, French, Spanish, and Portuguese, copies of which can be obtained on application.

ALLIANCE ENGINEERING WORKS, WEST DRAYTON.—These works were put up for sale at the Auction Mart, on Wednesday, by Messrs. Hobson, Richards and Co., but there were no bidders.

COPPER.—Messrs. Thomas Bolton and Sons inform us that in future all their H. C. copper will be guaranteed to have an electrical conductivity of not less than 100 per cent. of that of pure copper, according to Matthiessen's standard.

MICA.—A discovery of mica in the Ixopo divison of Natal has, it is stated, attracted some attention in the colony.

COMPANIES' MEETINGS & REPORTS.

City of London Electric Lighting Company (Limited).

The first ordinary general meeting of this Company (being the statutory meeting required to be held within four months after the registration of the Company) was held yesterday at Winchester House, Old Broad-street, under the presidency of Sir David Salomons, Bart.

The SECRETARY (Mr. J. Cecil Bull) having read the notice calling the meeting,

The CHAIRMAN said: At this meeting, which is the statutory meeting as required by law, no business whatever has to be done, and, strictly speaking, if your time were of great value, I might sit down and proceed to the resolution referring to the alteration in the Articles of Association. I presume, however, that you would like to hear something about what we have been doing. In the first place, to go back shortly over the history of this Company, Provisional Orders were granted and afterwards confirmed by Parliament, for the Eastern, Western, and Central Districts to be lighted by two companies—one, the Brush Company, which was to take over the Central and Western Districts, and the other the Laing, Wharton, and Down Company, who were to take over the Eastern District. The Brush Company have also the Southwark district, a very small one, but of great importance to us, as our station is situate in that district, and we have to traverse it and by the bridge get into the City. In regard to the Western District, nothing has been done at present in consequence of the Order having been granted considerably later than the others. The Central and Eastern Districts are those upon which we have begun to proceed with work. The orders would have fallen in, and the whole of the labour of obtaining them would have been lost but for the formation of the Pioneer Company, which began the work, and the concessions which had been granted have consequently been thus kept alive. The Brush Company and the Laing, Wharton, and Down Company have not large capitals available for the lighting of a place like the City of London; and it was, therefore, necessary to find financial means to carry out the work. The Pioneer Company, with a small capital, was first started, and time was thus allowed for the formation of a larger Company, which is now the City of London Electric Lighting Company. The Pioneer Company sold, under certain conditions, the whole of their rights, having taken the whole of the risk at the outset, to this Company, and hence the position in which we stand to-day. Now, of course, a certain feeling exists on the part of customers for the electric light—I know it from my own experience in the West End. The moment a company was declared to be formed for supplying a certain district, an application was sent in by me for the light; and I hoped that on the following day the wires would be put into communication with my house; and no doubt the same feeling is held in the City, judging by the orders that come in. It was only on August 21st, however, that we obtained the sanction required for the transfer of the whole of the powers of the Pioneer Company to ourselves from the Board of Trade, and we also had to have the assent of some of those to whom we are contracting—the Commissioners of Sewers of the City, for instance. Therefore it was only from August 21st last that we really got to business. It is our intention to keep everything in the open—not to do anything underhand—and to do everything in the best possible manner, so that every economy and efficiency may be practised, while nothing is hurried, so as to avoid our having to do anything a second time. All those who have made applications to us for the light must, therefore, have a little mercy with us, and give us time to carry out the work properly, rather than be sufferers through working us too hurriedly. As those who have read the prospectus are aware, the final equipment will be 400,000 eight-candle glow lamps for private lighting. We are supposing that 80 per cent. only will be in use at any one time, and practice has shown that that is a reasonable view. The underground work is extremely difficult in the City. Every hole and corner below the ground is occupied with iron pipes of some form or other, water mains, hydraulic, and gas pipes, pipes for the telephone, for Post Office wires, and a variety of other matters, which one would little dream of until digging up the streets. The difficulty and expense in the City will therefore, be considerably heavier in consequence of the ground being so much occupied, than would be the case in West-End streets or in country places, where there are not these difficulties. I point this out now because comparisons will, no doubt, be made later on, and the expenses may be considered excessive. I hope they will work out smaller, but should they appear larger than that incurred in other districts in putting down conductors and conduits, it will simply be through these difficulties that I have mentioned, as there are not subways throughout the City. The system to be employed by us is a very safe one. There are to be no transformers in the houses that are lighted. There are to be sub-stations, to which, say, 8,000 or 10,000 lamps will be appropriated; and from these points to the head station there will be a high-pressure current, delivering at about 200 volts. This is dangerous to life, but it has been tried on a large scale in London and elsewhere, and has always been successful. It is not an unreasonable pressure like some of the other companies have been trying. The delivery from some of the stations will be at a lower pressure—a little over 100 volts, or a little more than that, so as to allow for loss. There need, therefore, be no fear about any customer having a shock or being killed, for there will not be the least danger in the world. I think this statement will give confidence to a great many customers who otherwise might feel nervous when they hear about the high-tension currents that are sometimes spoken of. The arc lighting will be on the continuous system, part of the district being lighted by the Brush system and part by the Thomson-Houston system. Both of them are very good, and I do not suppose from the gentlemen employed in carrying out the work, that there will be any failure of any kind excepting at the start, perhaps, when little difficulties nearly always occur. In Queen Victoria-street there are now 26 arc lamps at work, but as the lamp-posts have not yet been passed by the City Engineer, we cannot proceed with that work until it is absolutely settled. As soon as the matter is approved, the final posts will be erected. Still, 26 lamps are running for the time being. We have already had as many as 200 applications—just upon that number, a few under or over—for private use; and assuming from the size of houses in the City—which are not like ordinary private houses, but consist of offices—assuming 200 lights to every building, about 40,000 lamps have thus already been applied for. These applicants have not stated their numbers yet, but very shortly a proper form will be issued to them to be filled up, stating exactly what the requirements of the applicants are, so that we may know how to supply them properly. It may interest you to know the

Digitized by Google

class of persons from whom these applications have been received. They include the Post Office, the Mansion House, the Guildhall, banks, offices, and such like; so that, at any rate, large public concerns seem already to put some faith in us, and I trust that this will be continued, and that we shall be able to maintain their confidence. If all goes well it is expected that by the end of this year private lighting on a small scale will be started, but it is dangerous to promise anything by any date. I think it was promised—though not by this Company—first by August and then by November, and now I have just said that it will be started by the end of this year. If it is not quite ready by the end of the year, I hope that very soon afterwards it will be ready. As you are aware, when the Company was brought out, times were not promising in any way. There had been great trouble in the City, and we hardly expected to get anything like the support we received, which was for slightly over three-fourths of our whole demands. Money is not wanted for the moment, but it will be as the work proceeds, and we shall then issue the remaining one-fourth. The Board have under consideration whether they shall not offer the remaining capital first to the shareholders at a small premium. In the prospectus you will notice that a certain sum was reserved on the part of the Pioneer Company to pay the expenses of issuing this Company. In consequence of the whole of the capital not having been allotted, and in consequence of other economies, there will be an extra sum of £6,000 placed to our credit. To-day we have done very good work at our Board meeting, which has come to the climax after a considerable amount of examination, which is necessary in connection with the expenditure of large sums. The final order has gone forth for the wiring of all the chief districts in the City, and by the end of next year it is to be hoped that not only will all these districts be completed, but also the greater part, if not all, of the public lighting, which will bring us in a considerable revenue. I think I have now given you all the chief circumstances that have occurred in connection with the Company up to to-day. The work is progressing, and it is simply a question of patience and waiting. The only other point that I need mention is in respect to a question that is frequently asked and often answered, but very rarely retained in the mind—that is, what does an electric lamp cost per hour? The answer is, that at the cost of 8d. per unit, which is about the price charged, more or less, over London—and I presume it will be about our price—an eight-candle lamp costs as nearly as possible ¼d. per hour. This is decidedly not an unreasonable sum, for gas at about 5s. or 4s. 6d. would be that amount, and gas has many disadvantages which the electric light has not. Landlords must also bear in mind that by adopting the electric light they improve their rentals to a considerable extent. There are many buildings with cellars—storeys of cellars—in one case I know of three storeys of cellars; and these places are now used for storing wine and beer barrels, whereas, by the electric light, they might be made habitable as offices, which hitherto with gas could not be done. I hope the landlords will take advantage of this, and give us the benefit which we should derive from their using the electric light, especially as they would at the same time be benefitting their own pockets. I do not think that the gas companies need have anything to fear from us. They have been decidedly good-natured to us. They have not raised any difficulty in our way where we have been laying the conduits. The electric light is decidedly a cold light, and people trying it will not use any other afterwards. You see, too, that everything looks clean where the electric light is used. People will use gas stoves to a much larger extent in future, I believe, and in that way gas companies will gain instead of losing anything through the electric light. Where the electric light is used there will not be the present necessity for so many holidays through sickness, and clerks and others will be able to work with clearer heads. We shall in the first instance endeavour to satisfy our shareholders as regards dividend, but we hope we shall be able to satisfy everyone. I am reminded that we found at the outset that it was very desirable to have a few technical points answered. We believed we were right in regard to them, but at the same time we wished to have them confirmed, and as a result we called in Prof. Silvanus Thompson as our consulting electrician; and if any point should arise in electrical matters on which we should feel the smallest doubt, or in any way think it would be desirable to obtain further advice, Prof. Thompson will be asked to assist us, as a gentleman in whom we all have confidence—the Directors, our contractors, and engineers—and we shall work together without the least friction.

Mr. W. W. BRUCE said that there appeared to be an idea prevalent in some quarters that the Company's communications through the streets were better adapted for arc than incandescent lighting. He did not know whether this opinion could be dispelled.

The CHAIRMAN replied that the answer to the question was very simple. Whether it was for arc lighting or the incandescent system it was only a question of putting the tubes in the ground. In Queen Victoria-street, with the subway the difficulty was very small, and provided there was room to get in the tubes no difficulty existed.

A SHAREHOLDER asked how much of the capital had been subscribed.

The CHAIRMAN: £301,000.

A SHAREHOLDER: Can we have a few more shares at par?

The CHAIRMAN said he doubted it. The shares were nominally at a premium that day on the Stock Exchange. If they did not stand at a premium when the time came for issuing the balance of the capital they would not be able to get a premium, but if the price were maintained they hoped they would be able to offer the fresh issue of shares to the shareholders at a premium but giving the shareholders a slight advantage. Continuing the Chairman said: Everything is ready to obtain a quotation on the Stock Exchange except for one little difficulty that has occurred, and the meeting will now be asked to remedy that by passing the following resolution:

"*That Article No. 13 of the Company's Articles of Association be altered by inserting after the words 'each call' at the end of the fourth line the following: 'And that no call shall exceed one-fifth of the nominal amount of a share or be made payable within two months after the last preceding call was payable.'*"

Well, that desire already exists, and is upon the prospectus for the present issue. Therefore, by inserting this we do not alter our position at the present moment, and we shall obtain a quotation on the Stock Exchange. Personally, I do not care twopence for the quotation one way or the other. I only hope that by our obtaining it a great many persons will be given an opportunity of acquiring shares in the Company who have an interest in the subject, and who on that account will support the Directors, and that at the same time an opportunity will be given to those who have simply taken shares in the Company as a financial speculation, and who have no interest in our well-being, to dispose of their holdings. If the result of this alteration will be, as I trust, to get around us a body of shareholders who will take an active and intelligent interest in our proceedings, nothing will give me more pleasure than to see our shares have a Stock Exchange quotation; and if this resolution is passed I believe that that will soon be the case.

On the motion of Mr. BRUCE, seconded by Mr. JOHN MORRIS, the resolution (which was put to the meeting by the Chairman) was carried unanimously.

The proceedings then terminated in the usual way.

Electric Arms and Ammunition Syndicate (Limited).

The first ordinary general meeting of the shareholders in this Syndicate was held on the 9th inst., at Winchester House, Old Broad-street, under the presidency of Major C. B. Waller.

The SECRETARY (Mr. W. F. Branston) having read the notice convening the meeting,

The CHAIRMAN observed that they met in rather exceptional circumstances. A petition had been presented to the Court for the compulsory winding-up of the Syndicate. It had been presented by five of the shareholders, three of whom he did not know personally, the fourth was their late manager, Mr. James Ronald Watson, and the fifth was an intimate personal friend of his own. The petition came upon the Board not exactly as a surprise, because they knew what was going on beforehand, but it was a surprise in this sense—that they were excluded from the deliberations of the gentlemen by whom the petition had been presented. The Directors had opposed it in the interests of the shareholders generally, feeling that no liquidation should take place until the general body of them had had the opportunity of expressing their views on such a course. With the exception of two or three shareholders outside of those who had presented the petition, the Directors had been supported by the whole body, and the matter stood thus—the first hearing took place on the 30th of September; and the Judge, after hearing the arguments of counsel and the various documents produced in the case, ordered it to stand over until after that day's meeting, so that he might hear at the adjournment what the feeling of the shareholders might be. That was what he might call the "political situation," upon which he proposed to offer a few comments later on. Passing to the Directors' report, he stated that the first paragraph referred to the competitions which were instituted at the annual meeting of the National Rifle Association at Bisley, last July. It had been the Directors' intention to make this a considerable demonstration of their system of electrical discharge; and to a certain extent they succeeded. They had intended to have two competitions—one with the Service weapon, the Martini-Henry, and the other with the miniature saloon rifle, which they had made for the purpose of showing how the electrical system worked. It was a question only whether the electrical current sent through their circuit would discharge powder or not, for if it would it mattered little whether the charge was 5 drams of powder in a fowling-piece, or 150lb. in a great gun. The competition, as far as it went, was successful in the sense that several thousand shots were fired. Unfortunately, however, they were unable to use the Service weapon, and they were, therefore, obliged to put all these shots through the miniature weapon. The reason they had not been able to use the Service weapon was that they had expected to receive some months before the Bisley Meeting a primer machine which the American Company had undertaken to supply them with; but delays occurred, in connection with which he would not say who was responsible. Finding that the time was approaching for their demonstration, and that they had not the necessary number of primers for the two rifles, they were compelled, reluctantly, to abandon the use of the Martini-Henry rifle, and to restrict their operations to the little rifle mentioned. Eventually they got the primers sent over from America, because they could not get the machine, and, as a matter of fact, their machine had been retained in America to make these primers. They showed their gun to probably 1,500 or 2,000 of the best rifle shots in the country—the men who generally attended the meetings of the National Rifle Association, and among them were naturally some experts and machine gun makers. Those gentlemen were very much struck by the Syndicate's system of electrical ignition, which was, undoubtedly, the only one of its sort that was ever likely to be a thorough success. The ignition of the powder and the shooting of the gun attracted a great deal of attention, and when the Directors returned to London, and had their late manager's report, he told them how very promising had been the applications made to him by the gunmakers of eminence at Bisley, and gave very great hopes of the future of electrical ignition, and more particularly their own system. At the same time he brought a tale to the Directors that was very disquieting. In the course of the shooting the battery had exploded, and had shattered the wood of the gun. They

were then face to face with an incident which in practice would have proved fatal to their system. They set to work to inquire into the cause of the occurrence, and their investigation showed that the defect which had been developed was in the mechanical construction of the battery cases, and not in the principle of the battery. Their manager was not at all dismayed, but saw that he was face to face with a difficulty, and set himself to work to overcome it. They entered into correspondence with their friends in America, who were very large proprietors in the concern, because their patents were sold to the Syndicate practically for shares, cash being a very small item in the consideration. They made various attempts to overcome the difficulty, and they thought they had succeeded by making a plug of porous material. That, however, failed, and eventually their manager found a gentleman who was working on the same lines as themselves—a man who, from what he (the Chairman) knew of him now, had considerable knowledge of electrical science. Mr. Watson brought them a battery from this gentleman, and it was tested. It had this peculiarity, that it dispensed with the liquid. Their charge was no longer a fluid charge, but a gelatinous charge, and they had not anticipated any bother in making this compound. When they got the battery from him he failed at first—not in the manufacture of the battery, but in one or two details; and, like all men who could only make a thing of this sort by hand, he had to depend very much on what he could get from small dealers, and he had to find out the just proportions of the two elements which made up this jelly. This took him considerable time, but eventually he put half-a-dozen batteries or so in their hands, and they appeared to be just what was wanted. They then put this battery into the hands of one of the most eminent scientists of the day, Dr. Fleming, who examined it with the most scrupulous care, and put it under the most severe tests. Their battery had to give an instantaneous flash and discharge the moment one put one's finger on the trigger. Dr. Fleming eventually succeeded in getting between 7,000 and 8,000 shots out of one of these little batteries, and, more than that, he got some continuous effects lasting some four or five minutes. Dr. Fleming had not yet given them a final report, but he had told him (the Chairman) that he thought the battery was a very remarkable advance on anything he had seen before, and had advised the Directors that it was worth prosecuting. The Board felt that they were justified in testing it thoroughly. They could imagine that while these tests were going on, the Directors were expecting every day — certainly at every Board meeting—that there would be a further advance, but a great many unforeseen things occurred in electrical matters. They had hoped to meet the shareholders and to give them all this information some months ago, but their desire had been not to tell them an incomplete story. About May last, when Dr. Fleming was fully engaged on the tests referred to, their manager announced to the Board—with, as he (the Chairman) thought, no preliminary observations—his desire to resign. He (the Chairman), however, asked for a reason, when Mr. Watson threw doubts on the whole concern; but, in order not to put them to any trouble, he expressed his willingness to carry on what business he might be asked to do for the Company pending the appointment of another officer. Of course he had desired to know the reason why Mr. Watson wanted to resign; and the latter produced a letter from his father, who was one of the largest shareholders outside the American Company. He believed it was under the influence of the father that the son wished to resign; but however that might be, Mr. Watson expressed his desire to leave them. That was the position of matters when some letters arrived, which there was some delay in replying to, though this had not been intentional. These letters were pretty closely followed up by notices to shareholders, asking them to meet Mr. Pooley at his chambers. The invitation was not sent to him (the Chairman), or, at all events, he received no invitation, and he believed his colleagues would say that they received no invitation to attend the meeting in question. A friend of his, Colonel Bird, was present at it, and told him what took place—that there was, generally speaking, a feeling of dissatisfaction at the management, and Colonel Bird suggested that the Directors should be approached; but this was not listened to. After this meeting a circular was issued to the shareholders, asking them to approve the petition for winding up. The Directors naturally opposed the petition, feeling that, however desirable liquidation might be, it was a matter to be decided by the general body of the shareholders; and their solicitor sent out a circular to the shareholders, asking those other than the petitioners whether they approved such course of action, or if they preferred to sign the following statement: "I, being a shareholder in this Company, support the opposition of the petition to wind up the said Company, and desire the same to be dismissed." The result was that every shareholder was with the Directors, and, that being the case, it would not require any words from him to point out how lamentable it would be if the petitioners persevered with their action. Theirs was a Company which was simply an introductory company to a big thing; it had only been intended by them, with their capital, to prepare a new thing of great promise, to perfect its details, and then to offer it to some large combination of capitalists. Among the people whose views they asked for were the American Company, who had sent the Directors their proxy, and had expressed their wish that the petition should be opposed. When it came before the Judge, his lordship expressed the opinion as reported in the newspapers—this was what it came to—that clearly no one could pretend that the substratum of the Company was gone. With reference to their future, he (the Chairman) thought there was little doubt that when they had got the battery already alluded to perfect—which he believed they would not fail to do—the business would be a practical one. As to perfecting the battery, he would read them a letter, dated October 8th, which he had received from Dr. Fleming:—

"In reply to your request for a brief statement as to the present condition of the tests I am making with the small battery for the electric ammunition, I may say that I am continuing to test samples of the battery furnished by the inventor. He has not yet entirely satisfied the conditions as to durability and permanence which I have insisted upon as essential before I can inform your Board that his battery will meet all your requirements; but he has produced samples which give a number of discharges amply sufficient for the practical necessities of small arms electric ammunition. Although the inventor has yet to overcome some difficulties in the construction of the battery, it seems to me that he is on the way towards a satisfactory solution of them, and I think it would be a pity to arrest the work at this stage. The question really at issue is the permanence of the battery, and hence these tests necessarily take some months; but I think that the results to be obtained, provided these time-tests can be endured, make it desirable not to terminate them when success is still possible."

Continuing, the CHAIRMAN said that what the Directors really asked the shareholders to do was to have a little confidence in the Board, who were working to the best of their ability, and they proposed that those gentlemen who had not paid up their calls should do so. They desired that Dr. Fleming might have the time given him which he required for the tests he was making. They proposed, in any case, to call the shareholders together again, in about three months, to tell them how they then stood, and not to make any other call without consulting the shareholders. He hoped that he would be able to prevail on those who had presented the petition to withdraw it; otherwise, the Directors would persevere with their opposition, and ask that it might be dismissed. The expenses in the next two or three months would be about £200 or £300. He concluded by proposing the adoption of the report.

Colonel ERNEST VILLIERS, in seconding the motion, observed that the Directors entirely concurred in all that the Chairman had said. In the shareholders' interest he thought it was distinctly advisable that the experiments now going on should be proceeded with, and that the seed they had sown in the past months should not be thrown away until they were quite certain that it would not lead to anything.

Mr. UNDERDOWN, Q.C., said it seemed to him that there were two questions to consider—to receive the report or not. If they did not receive it they would then proceed to propose that the Company be wound up in some way; but he saw no necessity for a compulsory winding up.

Mr. WATSON, sen., assured the Directors that in any proceedings which he and the gentlemen with whom he had been acting had taken, there had been not the least idea of being discourteous to the Board. Their calls were due by a certain date, and unless they had taken some action, they would have had to pay them. The Directors in their report said, respecting the competition at Bisley, that it "attracted many of the most famous rifleshots of the country, and was completely successful." His own information might not be as good as the Directors', but it was in consequence of what he had heard had occurred at Bisley that induced him to write to his son the letter to which the Chairman had referred. The Directors had been so kind to his son that he thought they might feel even influenced to go on with the Syndicate's system longer than they otherwise might, and he therefore urged his son to resign. What he had heard concerning the meeting at Bisley, which wrecked his confidence in the eventual success of the system, was practically this,—the Company allowed so many shots to be fired at their stand for a certain payment, and gentlemen took a rifle and fired. His information was that although they had a right to fire seven shots for their payment, it was exceedingly rare that any man got seven shots that went off out of the gun before he had had a number of miss-fires, and that they were very numerous.

Mr. UNDERDOWN pointed out that the Directors further on in the report alluded to this defect.

The CHAIRMAN maintained that there was no doubt whatever that the competition was sucessful, but they had distinctly drawn attention to the defect which was developed. This, however, had been seen to be in the mechanical construction of the battery cases, not in the principle of the battery.

Major FLOOD PAGE agreed with Mr. Underdown that the important point for their consideration on that occasion was whether the Company was to continue.

Mr. UNDERDOWN thought that the best course for the shareholders to take was to go on with the experiments, and at all events to keep out of the Courts. He was a lawyer himself, but that was his advice to them.

The CHAIRMAN said that, with the permission of the meeting, he would vary the resolution he had proposed in accordance with Mr. Underdown's suggestion; and the motion would then be:—

"That the report and accounts be received and adopted, and the business of the Syndicate be continued."

Colonel VILLIERS said he would second the resolution as amended.

Mr. WATSON, sen., said he had no desire to occupy the time of the meeting, and his purpose in speaking had been to see if they could come to an agreement.

The CHAIRMAN asked Mr. Watson the name of the informant from whom he had received such adverse statements respecting the Syndicate's system.

Mr. WATSON: A gentleman in Belgium—a personal friend.

The CHAIRMAN: No one connected with the Company?

Mr. WATSON: No.

The CHAIRMAN: Had he been to Bisley?

Mr. WATSON: I do not think he had. Continuing, the speaker said he had been much struck with the information he had received about the miss-fires, for he had not put his money into the concern without seeing the experiments, and he himself had seen no miss-fires. The fact, however, was that the laboratory experiments and the shooting at Bisley were carried out under different conditions.

Captain PIXLEY observed that he had fired many shots at Bisley, and he did not have a single miss-fire.

Mr. ACCLES expressed his conviction, from his own experience, that

Digitized by Google

the system would not answer. With the best battery in the world he did not see how they were to get a contact; and the great thing was the contact.

Mr. POOLEY read a letter from a firm of gunmakers, who intimated their opinion that the invention could only be used for toy purposes. He proposed an amendment to the effect that the report of the accounts be not adopted, and that the petition before the Court be persevered with. Even if they had a perfect battery now they had not, he said, sufficient money in hand and uncalled to do any good with the invention.

Mr. ACCLES seconded the amendment.

Major FLOOD PAGE hoped the amendment would not be proceeded with. The object for which the Company had been established, as stated in the first article of the Memorandum of Association, was to enter into and carry into effect, with such modifications, if any, as may be agreed upon, the agreement with the American Electric Arms and Ammunition Company, and to purchase or otherwise acquire any other inventions and patents. Although their Syndicate came under the action of the Limited Liability Acts, they were not a trading company. If it was a trading company and had done no business, it might be reasonable to wind up; but the object of the Syndicate was to form another company, and to develope its electrical patents as far as they could. It was within the knowledge of some of those present that he had to do with electrical patents, and he considered that instead of having been a long time, they had been very prudent and careful, and it would be an act of lunacy on their part to wind up the Company. Mr. Accles had remarked that their money was lost, and it certainly was lost if they wound up. If, too, that proceeding were taken, the first thing the liquidator would do would be to make them pay something for the winding up expenses. He was himself in frequent communication with Dr. Fleming, and he believed it was well within the range of probability that they might be successful. Against what had been said by Mr. Accles they must set the practical experience of Mr. Pixley. If they succeeded there would be an immense field for them. They might succeed if they went on, but they could not succeed if they wound up. They had paid seven-tenths of what they would have to pay, and he objected to losing his money by the winding-up of the Company, especially as the Chairman had informed the meeting that no call would be made without their being called together again. The nature of all syndicates was speculative, and the shareholders had speculated in the present case in the hope that by careful experiments they would be able to get a solution of the question affecting the invention in which they were interested. If they did not they must wind up; but if they did they could hand the concern over to another Company, when they might hope to obtain cent. per cent. for their money.

The SOLICITOR, in reply to Major Flood Page, stated that under the Memorandum and Articles of Association of the Company, Table A was adopted except in certain points. Table A was adopted with respect to voting, and by Table A, section 47, no member was entitled to vote at any general meeting unless he had paid his calls. The petitioners had not paid their calls.

The CHAIRMAN stated that it was thus out of the power of the Chairman or the Directors to accept the votes of those who had opposed them who had not paid their calls. He had certainly not anticipated this, and their opponents appeared to have got into a trap of their own setting. The sense of the meeting was clearly in favour of the Syndicate's going on. No doubt they had a difficult task, but it was ten times more difficult when they started. He thought that the Belgian gentleman referred to by Mr. Watson must have received his information from the latter's son. The Directors knew that there had been some miss-fires, but their late manager had not informed them that they had been as numerous as had been stated. He would appeal to the gentlemen who had brought forward the amendment to withdraw it, as they could not vote; and he suggested that the resolution should be passed.

Mr. POOLEY declined to withdraw the amendment; and

The CHAIRMAN stated that he should receive under protest the votes of those who were not entitled to vote. He then put the amendment, and declared it lost on the show of hands, four shareholders voting in favour of it, and the votes of three being received under protest. The resolution was afterwards put and declared carried.

Colonel VILLIERS then proposed the re-election of Major Waller, remarking that that gentleman had given them great assistance. His electrical knowledge was very considerable, and his knowledge of gentlemen who were likely to be of assistance to the Company was also very great.

Colonel the Hon. G. VILLIERS seconded the motion, which was agreed to.

After the Auditors had been re-appointed, the proceedings closed in the usual manner.

In the Court of Queen's Bench on Wednesday, before Mr. Justice Jeune, the hearing of the petition was ordered to stand over for a week, there not having been time for the Company's counsel to read some affidavits which had been sworn on the other side.

International Okonite Company (Limited).

The first annual general meeting of this Company was held on Wednesday last, the 14th of October, at the Cannon-street Hotel, having been adjourned from October 9th.

Mr. SAMUEL POPE, Q.C., presided, and in opening the proceedings said: Gentlemen, in the absence of the Chairman, Lord Greville, whose doctor will not allow him to travel, he being in Ireland suffering from an attack of gout, it has fallen to my duty as Deputy Chairman to take his place, and I therefore call upon the Secretary to read the notice calling the meeting.

Mr. R. COOPER (the Secretary) then read the notice.

The CHAIRMAN said that the shareholders had the reports and accounts before them, and he presumed that they would take them as read, and in moving their adoption it would be his duty to offer just a few remarks. He did not think that they would be many, because the report which he had no doubt they had all read, and which they had just agreed to take as read, was so very full. The fact that the Directors were unable to recommend the shareholders to declare a further dividend on the ordinary shares of the Company was not so satisfactory a one as they could desire it to be; but they must bear in mind, even with this disadvantage, that the amount that had already been paid upon the ordinary stock represented 5 per cent. upon their investment. The idea of the Directors had been that it was more desirable to maintain the prosperity of the Company than to further the desire of individual shareholders for the declaration of a further dividend; and while they looked forward to very great success for the Company they deemed it better not to declare a further dividend in anticipation, but rather to be quite legal in what they did, and to see that the amount distributed was only the amount actually earned, because, although it would have no doubt increased the value of the shares, it would not have been to the true interests of the Company; and the unanimous opinion of the Board was that the Company ought to be managed without "dodging" the accounts and without paying any dividend beyond the actual result of the year's trading; and in the accounts they did propose a dividend which was the actual result of their trading, and which could be fairly and honestly placed before the shareholders. In the period that was embraced in the accounts now under review, the shareholders must bear in mind the special circumstances which attached to it. In the first place, they would remember that they purchased the profits which had accrued from the 1st January to the 13th June, 1890, which amounted to £21,711, which of course not being profit earned by the Company since its constitution, was not a sum that could be legally distributed amongst the shareholders as dividend, and the Directors therefore recommended that as they could not pay a dividend out of it, and as it really was profit made in the past year, it should be used, so to speak, in the reduction of the purchase money, and so as to diminish the ultimate capital expenditure of the Company. In the accounts which were presented, the American accounts were only made up to the 31st of May, 1891, but the English accounts covered a period ending the 30th June, 1891, and the reason of that was that it had been arranged as desirable that the American stock-taking should be to a period a month earlier than the English. Had the American accounts also been carried up to the end of June, they would have had a much larger sum as profit available in the present accounts, indeed the profits would have been increased to the extent of some thousands of pounds that would have enabled them to declare a dividend to the ordinary shareholders beyond what they had already received. They must also bear in mind this, that in common with all industrial undertakings, especially in America, the last nine months, or rather the nine months between September, 1890, and June, 1891, was a time of exceptional difficulty, and they knew that the finances of America, as far as industrial undertakings were concerned, had been very bad indeed. He wished to be allowed to offer an explanation in regard to the following paragraph in the report of the Directors:- "Up to the end of the year 1890 the business was progressive and satisfactory, and the interim dividend then declared was justified by the business done. Since that time the Company had suffered from the results of the severe crisis which took place in the United States in all electrical, engineering, and kindred industries, and which culminated in the failure of the Westinghouse Company." It was the desire of the Board that they should state nothing wrong in their report, and they felt that the word "failure" in this case was too strong a term, as, with outside help, the Westinghouse Company had been reorganised, and the new Company, it was hoped, would become a prosperous concern in the future. Bearing in mind, then, this state of things in the nine months, he thought that they might be very hopeful, having regard to the better condition of things and that their works were fully employed in the manufacture of their specialty, okonite wire. Since the accounts were made up there had been a considerable increase in the business, and there was every evidence that the business itself was healthy and profitable, and when he met the shareholders again (if nothing unforeseen took place) he believed and trusted that, now that a reaction was taking place, they would be able to lay before them a very much more satisfactory statement than they did at present. Their Manchester business had been very much curtailed by their having had to institute a number of alterations, and to introduce new machinery in order to properly carry out the manufacture of their okonite specialty. These were now completed, and the business was in first-rate working order, and they had the assurance of their manager there (Mr Shaw) that there was a prospect of a very healthy English business, and that they were very glad to hear, because they believed that it would not be subject to such fluctuations as was the case on the other side of the Atlantic. As he had already said, the policy of the Board was unanimously to take the shareholders into their confidence, and to deal fairly and honestly by them, and not to have any "dodging" in the management of the Company. He really did not know that he had much more to add; but, as the Chairman of that meeting, he might say that the most cordial co-operation prevailed not only amongst the members of the Board in England, but between the members of the Board of the American Committee of Management, who were themselves Directors. He must express the hope, which was their unanimous hope, that they would have as valuable a business in Manchester as had proved to be the case in America; and they would, he hoped, be enabled to present to the public such a class of manufacture as would make them one of the most successful and one of the best manufacturers of insulated wire. He would be happy to answer any questions that any of the shareholders desired to ask, and he concluded by moving the adoption of the report.

Sir ALEXANDER ARMSTRONG, K.C.B., F.R.S., seconded the motion.

Digitized by Google

The CHAIRMAN invited discussion.

Mr. FRANK SQUIRES said that he thought that although the Chairman had given a very fair explanation of the reason of their not paying a dividend on the ordinary shares, that there had been a large outlay at Manchester for machinery, which, he presumed, was to replace obsolete machinery. He wished to know the amount at which their goodwill stood, and in regard to the non-payment of any further dividend upon the ordinary shares, he would like to know whether the legal gentleman who looked into the matters before the formation of the Company was aware that this sum of £21,711, which they purchased as profit made between January and June, 1890, was an amount which could not be legally divided amongst the shareholders. He thought it ought to have been stated in the prospectus, because the statement that they had made that amount of profit had induced him to take shares. He thought the prospectus led them to believe that this amount of money was available for distribution among the shareholders, and he wanted to know whether their legal adviser was aware that it was not.

The CHAIRMAN: Of course he was.

Mr. SQUIRES said he would like an answer to that question, and also as to the machinery at Manchester, which appeared to be obsolete, and had had to be replaced by new plant when they made their alterations.

The CHAIRMAN: Not at all, not at all. I did not say obsolete. It had been shifted in the works. The new plant is the plant for our specialty, our okonite wire.

Replying to further remarks, the CHAIRMAN stated that there was not a single machine which they had purchased but what was fully at work, and doing good work, and most of the machinery was the very best of its class for the production of insulated wire.

Mr. SHAW, the Manager of the Manchester Branch, corroborated the remarks of the Chairman.

Mr. SQUIRES expressed himself satisfied with the explanation, but said that he would like to have an explanation of whether their lawyers were aware that the £21,000 would not be distributed as dividend.

The CHAIRMAN: That is a fair question.

Mr. PETERS said that he much approved of the view which had been expressed by the Chairman of the desire of the Directors to give a fair, clear, and straightforward statement of everything to the shareholders; and he therefore wondered why they had not, as was the case in many Companies, given a trading account. He thought, having regard to the large capital of the Company, £400,000, that the shareholders were entitled to a trading account, in order that they might see how the profits of the Company were made up. He wanted also to be informed how much of the large sum of £218,000 was really represented by *bonâ fide* goodwill. When the Directors declared the interim dividend on the ordinary shares up to December, 1890, which took £10,000, he naturally assumed that they had a large amount still left before they would have ventured to do so, and he thought therefore that they could have made during the second six months hardly any profit at all.

The CHAIRMAN said he thought that in the original prospectus some announcement was made to the £21,000 not being divisible, but he had been looking through it and could not find it.

A SHAREHOLDER asked when there was the likelihood of giving a quotation of the Company's shares upon the Stock Exchange.

The CHAIRMAN: We have a quotation.

The SHAREHOLDER: I have not seen it.

The CHAIRMAN: That is because no one wants to sell, we have had it a good many months.

A SHAREHOLDER: Perhaps Mr. Stevens, the Managing Director, could give us some information, without reflecting on you.

The CHAIRMAN: Upon what point?

The SHAREHOLDER: About the Company generally.

The CHAIRMAN: No doubt, and he shall have an opportunity, but I am quite familiar.

A SHAREHOLDER: It does not reflect upon you at all.

The CHAIRMAN, replying to the remarks that had been made, said that as to the question of providing a trading account, the Directors did not think that such a course would be desirable, because if they made these statements public it would let their competitors and their customers know what they were doing, and they would endeavour no doubt to cut down their profits. There were many industrial undertakings, Armstrongs, for instance, which did not publish a trading account; but he might say at once that if any shareholder desired any information upon any point, and would call at the office, the Managing Director would be happy to give that information if it was not detrimental to the interests of the Company. As regarded the question raised by Mr. Squires as to the matter of what they might call the indivisible profit of £21,000, that was a thing which, of course, every lawyer knew they could never divide profit which had not arisen from trading. The purchase of 21,000 sovereigns for £21,000 was not a profitable transaction, but as far as it went it was satisfactory. The reason that it was such a large sum had arisen in the following way. It was originally fixed that the American Company should be taken over at January 1, 1890; but owing to circumstances on which he need not enter now, there was a considerable delay in regard to the registration of the Company, and although the date of their being entitled to profits was from the adoption of the contract, they stood to take the profits from January 1st, although the registration was not completed till about the month of June.

Several other shareholders expressed the view that it should have been clearly stated in the prospectus that they were not entitled to have this sum of money divided amongst them.

Mr. SMITH said that he thought that the greater part of the shareholders entertained the view that this money would be divided.

The CHAIRMAN said that he felt with shareholders who had entertained that view, but they must exercise the Englishman's privilege and grumble, and he feared, speaking as a lawyer, that it must end with the grumble; because they could not pay the dividend, however much they would like to do so.

Mr. SQUIRES said did their legal adviser know this at the time?

The CHAIRMAN said that of course he knew it.

Mr. SQUIRES thought that it ought to have been mentioned in the prospectus.

The CHAIRMAN said that he had no doubt that a statement like that in a prospectus would lead the lay mind to believe that that profit was divisible. After all, the shareholders had the advantage, for, although these £21,000 did not go into their pockets, they had them in the accounts, because they would be utilised for the purpose of reducing the amount that they had paid for their property, instead of that sum having to come out of the money available for dividend in the future.

A SHAREHOLDER: It would have been very much better if it had been put in the prospectus that the money was not divisible. It would have been more satisfactory to us. I became a shareholder because I thought that this £21,000 would be divided, and that it was a sort of nest egg.

The CHAIRMAN said that with all respect to the shareholder who had just spoken, if that gentleman bought his shares on the idea that they would declare a dividend out of that £21,000, and then wanted to sell his shares at the improved price which such a declaration would bring about, then he (the Chairman) wished to say that such shareholders were most undesirable in an industrial company, and their desires ought not to be encouraged.

The SHAREHOLDER repudiated having any such idea.

The CHAIRMAN said that, with regard to the question of the trading account, he had already answered it—it would be undesirable. As to the item of £218,000, the matter was fully set out in the prospectus, and the value of the real estate given, so that by a simple calculation they could arrive at the amount of the goodwill; but roughly it might be taken that out of the £218,000, £90,000 represented the value of goodwill, processes, patents, &c., and other matters of that kind in England and America.

A SHAREHOLDER: I should like to know when the Manchester business is likely to be in full working order.

The CHAIRMAN: It is now at the present time. It is in full working order; and Mr. Shaw, the manager, tells us that the okonite samples are now before the customers, and he expects orders almost immediately.

A SHAREHOLDER asked: How long the new works at Manchester had been going?

Mr. SHAW: Within the past 14 days.

The SHAREHOLDER: We shall have nine months trading this year at Manchester?

The CHAIRMAN: Yes.

A SHAREHOLDER: Have you many orders on hand?

The CHAIRMAN: Oh, yes, a considerable increase over any previous record of the Company.

Another SHAREHOLDER said that at the statutory meeting the question was raised as to whether this Company's process was likely to be adopted by any of the large electric cable companies; and he wanted to know whether the Chairman could give them any further information upon that point that day.

The CHAIRMAN said they were endeavouring to get their okonite wire adopted in every possible direction, but he believed as yet that the opinion of electricians was that gutta-percha was the best insulating medium for submarine cables, and he did not know whether or not they would be able to disabuse the minds of electricians of that prejudice.

The report was then adopted.

The CHAIRMAN said that acting upon the suggestion made by one of the shareholders, that the Managing Director should give his views, and that Mr. Shaw, the manager of their commercial department in Manchester, should give his opinion of their prospects there, he begged to call upon Mr. Stevens to address the meeting.

Mr. ALFRED VAUGHAN-STEVENS said that there was very little indeed that he could add after the able statement which had been made by their Chairman, and he did not desire to go into particular details at all, or to go into any information as to their accounts or the prospects of their business. They were very closely watched, and were in competition with many firms of great standing and considerable wealth, and it would be highly improper to go into questions of details or the amount of their sales in England or America and to give away knowledge to their competitors. There was one thing he would like to say, they were not relying upon any particular branch of their business. Their works at Manchester were solid, sound, and healthy, as Mr. Shaw would be able to tell them later on, and not only were they making their okonite specialty, but every kind of electrical wire. One of the reasons why the large electric lighting companies had not adopted their okonite wire for their large mains and heavy cables—indeed, the chief reason—was that it was very expensive; and they had therefore been manufacturing other kinds of insulated wires, covered with cotton, paper, &c., and insulated with oil. They had also been laying down in their English works special and important machinery for lead covering. They were very cautious in the manufacture of these machines, having the castings made all over the country, and put together in their own workshops. He was pleased to be able to announce that they were now upon the list of contractors to the Admiralty, which was a very important consideration, and they believed that the War Office would also follow. It was a very important matter because, before they could get on the list, their works had to be examined by an inspector sent down for the purpose, and the Government would not allow any firm to contract unless they were sure they were in a solid position to execute any large orders in a short time which might be sent to them. He believed that at the present time there were only three contractors for insulated wire upon the Admiralty List; it was a very "close borough," but they meant to creep in and get their proportion, which he had no doubt they would

Digitized by Google

do, and, if they were successful, that of itself would give a very respectable dividend upon their capital. There was also a very large business to be done in regard to the railways. Naturally, the railways were very conservative bodies, and having tested wires and found them satisfactory they did not care about moving until they were perfectly satisfied that they could do better. They had received some small sample orders and had had no complaints; indeed, everything seemed to be very satisfactory, and they had laid down one large installation. He trusted before very long that they would have a large development of business in this direction. This Company possessed, with one exception only, the finest and most complete factory for the manufacture of electric wire in this country, and they were far and away the largest company of the kind in America. Indeed, with one exception, he thought he might call themselves the largest and most powerful insulated wire-making company in the world. He had been over to America twice since they took the Company over, and he had found the business there to be admirably managed. It was managed by people who had taught themselves in a great measure. They were experts in india-rubber, and also experts in electricity, but they did not possess the experience which came from a long handling of a very technical matter such as insulated wire. Mr. Connolly, their works manager, had been connected with the business of insulated wire making for a great many years, and when he first went out there and learnt the technical part of the business thoroughly in regard to the okonite wire, he taught them in return a great many processes of which they were unaware, and which would now be very useful in the business. In concluding his remarks, Mr. Stevens referred with satisfaction to the growth of the sales, and pointed out that had it not been for the severity of the winter, which entirely stopped building operations for many months, they would be in a much more advanced condition in regard to Manchester. At the present time, however, they were in full working order, and the prospects, as Mr. Shaw, their works manager, would tell them, were very satisfactory indeed. He concluded by expressing his willingness to afford any further information that any of the shareholders might desire to ask.

The CHAIRMAN called upon Mr. Shaw to address the meeting.

Mr. SHAW said that he did not know that he could add much to what their Managing Director, Mr. Stevens, had already said, with regard to the management at Manchester. There was one point which he would like to be allowed to touch upon, and which had been alluded to by the Chairman in reply to a shareholder asking for a trading account. He, the speaker, thought it would be most unwise for them to enter into any statements upon matters of detail, because it let the public into the details of their business, and it at once placed a weapon in the hands of his competitors to be used all over the country against him. With regard to the growth of their business, since it became their property it had gone on very well indeed, and the prospects this year were most encouraging. Still, it had to be borne in mind that the past year in the United States and, indeed, elsewhere, had been one of the worst for electrical undertakings since the year 1887. The firm of Mathers and Platt, with whom he was for twelve years as chief estimate clerk, had done in the last year 50 per cent. less business than in the year 1890, in their electrical department, and what was their case was the case of other people. He was pleased, however, to see that there was a revival of a very marked type, and the results so far of their working were most satisfactory. Having, as they had, a specialty in this okonite wire, they would be able to take advantage of this revival, and they would not be affected so much by the competition of other manufacturers, because, if you were manufacturing an article which other people could also manufacture, the competition then became a matter in regard to price; but if you possessed (as they did) a specialty, it was not so much a matter of price as it was a matter of satisfying the consumer that the article you produced was the best which could possibly be got. He was confident that during the next twelve months they would do much better than had been the case during the past year. As Mr. Stevens had told them, the very severe winter had affected their building operations at Manchester, but now all that was over and they were in full working order, and they were manufacturing okonite and gutta-percha and all kinds of electrical wire. As had also been mentioned, they had been entered upon the Admiralty list, which was an exceedingly satisfactory matter. The Inspector announced himself as exceedingly satisfied with what he saw on his visit to the works, and he was coming down again at an early date to inspect another branch of their business, and they therefore expected that they would be placed upon another branch of the Government service, and would be able to compete satisfactorily with other large contractors.

The CHAIRMAN said he thought the meeting ought to be very much obliged to the gentleman who had requested that the Managing Director should give some further information than he (the speaker) was able to supply, as occupying the position of Deputy-Chairman of the Company. It was, and it would always remain, the desire of the Directors at the annual general meetings to take the shareholders entirely into their confidence, and to allow them to ask any questions, and to obtain any information that could be given without detriment to the interests of the Company.

A SHAREHOLDER: We are very much obliged to you, Sir.

The CHAIRMAN said that the next resolution that he had to propose was—

"*That this meeting sanctions the recommendation of the Directors as to the declaration of a dividend up to the 30th June, 1891, at the rate of 8 per cent. per annum, less income-tax, on the preference shares, leaving a balance of £259. 7s. 2d. to be written off preliminary expenses.*"

Mr. HUMPAGE seconded the motion, which was carried.

A SHAREHOLDER: When will the dividend be paid?

Mr. STEVENS: We have to make some arrangements with America.

The CHAIRMAN: I should think in a week or ten days. It will be necessary to make some arrangements to pay it simultaneously in America and in England. The only other matter is the reappointment of the auditors, Price, Waterhouse and Co., and I can only say about them that they are very strict. Perhaps some shareholder will propose it, as it comes from that side of the table.

Mr. STEVENS: I can only say they gave me a great deal of trouble.

A SHAREHOLDER: What is the remuneration?

The CHAIRMAN: It is not fixed.

It was then moved, seconded, and approved that Messrs. Price, Waterhouse and Co. should be re-elected as the Auditors of the Company, at a remuneration to be agreed upon between them and the Board.

A vote of thanks to the Chairman terminated the proceedings.

Eastern Extension, Australasia, and China Telegraph Company (Limited).

The following report has been issed by the Directors of this Company for the half-year ended June 30th last, to be submitted to the thirty-sixth ordinary general meeting to be held at Winchester House, London, E.C., on Wednesday next, the 21st inst., at 2 o'clock:—

The gross receipts, including Government subsidies, have amounted during the half-year to June 30th to £264,878. 6s. 11d., against £254,856. 18s. 10d. for the corresponding half-year of 1890. The working expenses, including £17,318. 5s. 11d. for cost of repairs to cables and expenses of ships, absorb £71,476. 15s. 8d., against £76,670. 9s. 3d. for the corresponding period of 1890, leaving a balance of £193,401. 11s. 3d. From this is deducted £2,981. 17s. 1d. for income tax, £33,074. 14s. 5d. for interest on debentures, debenture stock, and contribution to sinking fund, and £2,179. 10s. 2d. for special expenditure as shown in the revenue account, leaving £155,165. 9s. 7d. as the net profit for the half-year.

One quarterly interim dividend of 1½ per cent., amounting to £31,250, has been paid during the half-year, and another of like amount will be distributed on the 15th instant, leaving £92,665. 9s. 7d. to be carried forward.

All the Six per Cent. Debentures that were outstanding when the last report was issued have been paid off and cancelled, and the Stock Exchange have granted an official quotation in the New Four per Cent. Debenture Stock, which now stands in the market at a considerable premium.

It is with deep regret that your Directors have to record the death, on the 12th ultimo, of their much esteemed colleague, Sir Thomas Fairbairn, Bart., who had been associated with the Company from its inception. It is not proposed to fill the vacancy in the directorate thus occasioned. As, however, Sir Thomas Fairbairn was also one of the trustees for the Five per Cent. Australian Subsidy Debenture Holders, it has been deemed advisable to appoint a new trustee, and Mr. John Denison Pender has undertaken to act in this capacity.

The guarantee arrangement made with certain of the Australasian colonies for testing the effect of a 4s. rate to Australia came into operation on May 1st last, and the increase of traffic resulting from the reduction of tariff is so far encouraging. As, however, the accounts embrace only two months' receipts at the reduced tariff it is too early to form any reliable opinion as to the result of this important experiment.

In accordance with the arrangements entered into with the Indian Government the Company's station at Elephant Point (Rangoon) has been closed, and a considerable portion of the cable between Elephant Point and Penang picked up and utilised elsewhere.

An arrangement has been concluded with the Dutch Government for connecting by submarine cable Sumatra with Penang, so as to bring the Netherlands Indian Government telegraphs into direct communication with the Company's system at Penang. The cable for this purpose will be taken from the Company's depot at Singapore, and laid in the course of the next few months.

Brazilian Submarine Telegraph Company (Limited).

The following is the report of the Directors of this Company for the half-year ended 30th June last, to be submitted to the thirty-sixth ordinary general meeting of shareholders on Wednesday next, the 21st inst., at 12 o'clock:—

The revenue for this period amounted to £158,905. 3s. 1d., and the working expenses to £25,449. 5s. 0. This very exceptionally increased revenue mainly arises from the disturbed state of affairs in South America. After providing £12,880 for debenture interest and sinking fund, and £2,320. 2s. 9d. for income tax, there remains a balance of £118,255. 15s. 4d.; to this is added the sum of £11,121. 4s. 0d. received in respect of traffic receipts between March, 1889, and December, 1890, hitherto under dispute, and £23,833. 17s. 5d. brought forward from 31st December last, making a total of £153,210. 16s. 9d. A quarterly interim dividend amounting to £32,500 has been paid, and £60,000 transferred to the reserve fund, increasing that fund to £474,878. 7s. 0d.

The Directors now recommend the declaration of a final dividend of 1s. per share, making with the interim dividends a total dividend of 6 per cent. for the year, and also the payment of a bonus of 4s. per share, both free of income tax, which together will amount to £32,500, leaving a balance of £28,210. 16s. 9d. to be carried forward. The dividend and bonus will be payable on the 22nd instant.

On the 31st July last the sum of £16,000 was transferred to pay off the 160 bonds of the 1884 issue, drawn for redemption in April last. This repayment reduces the debenture debt to £128,200.

The receipts for the half-year include the sum of £1,500 dividend to 31st December, 1890, on the Company's shares in the African Direct Telegraph Company, Limited.

Digitized by Google

An interruption occurred on the 11th August last in the 1874 cable of the St. Vincent-Pernambuco section, about 50 miles from the coast of Brazil. By arrangement with the Eastern Telegraph Company that Company's s.s. "Mirror" was sent out, and a repair effected on the 17th September. A fault was also cut out of the same cable, the tests of which are now highly satisfactory.

The Directors have made arrangements for applying the Duplex system of working to the three sections of the No. 2 cable, whereby its power of transmission will be greatly increased.

The various sections of the Company's line are in good working order.

The Hon. W. St. John F. Brodrick, M.P., and Lord Sackville A. Cecil retire by rotation at this meeting, and being eligible for re election as Directors offer themselves accordingly. The auditors, Mr. Henry Dever and Mr. John Gane, also offer themselves for re-election.

NEW COMPANIES, STATUTORY RETURNS, &c.

BRITISH ELECTRIC INSTALLATION CONTRACTORS (LIMITED).—This Company was registered on October 12, 1891, with a capital of £20,000, in £5 shares, by Messrs. Waterlow Brothers and Layton (Limited), Birchin-lane, E.C. The objects are:—To carry on, in the United Kingdom, the business of an Electric Lighting Company in all its branches, and to undertake the lighting of streets and buildings (both public and private); to produce and supply electricity for light, heat, motive power, and other purposes; to manufacture and deal in engines, machinery, wires, lamps, instruments, and apparatus necessary for the production, storage, supply, measurement, and application of electricity, or electrical energy. The subscribers are (with one share each), J. Millington, J. Duce, A. H. Parker, W. H. Walter, S. T. Castle, H. Webb, and H. A. Leicester, all of Worcester. The number of Directors is not to be less than three nor more than seven, the first to be appointed by the subscribers. Qualification, £125; remuneration to be fixed by the Company.

PERFECTA STEEL TUBE COMPANY (LIMITED).—This Company was registered on the 12th October, 1891, with a capital of £30,000 in £10 shares, by Beale and Co., 28, Great George-street, Westminster, S.W. The objects are:—To carry on the business of manufacturers of weldless steel tubes for locomotive, marine, and other boilers, shafting, projectile, torpedoes, &c. The number of Directors is not to be less than three nor more than five, the first being W. Pearce, H. Lea, P. A. Hopkins, and R. C. Hopkins, all of Birmingham.

RAILWAY AND WORKS CONTRACTORS (LIMITED).—This Company was registered on October 6, 1891, with a capital of £102,620, in £10 and £1 shares, by Messrs. Norton, Rose, Norton, and Co., 57½, Old Broad-street, E.C. The objects are:—To undertake in any part of the world the construction, maintenance, equipment, or working of any railway, tramway, dock, harbour, water or gas works, system of electrical lighting, chemical works, &c.

READ, CAMPBELL AND COMPANY (LIMITED).—This Company was registered on October 8, 1891, with a capital of £150,000, in £10 shares, by Messrs. Budd, Johnsons, and Jecks, 24, Austin Friars, E.C. The objects are:—To take over the business of engineers and contractors for public works, carried on by Messrs. Read and Campbell at Broad-street-avenue, E.C., and to contract, carry out, develop, and control railways, tramways, electric light, telephonic, telegraphic and power supply works, &c. The first Directors are Messrs. H. V. Rudston Read, A. Johnstone Campbell, and G. St. John Mildmay.

VULCAN ENGINE COMPANY (LIMITED).—This Company was registered on October 12, 1891, with a capital of £3,000 in £1 shares, to carry on the business of engineers, contractors, brass, iron, and metal founders, gas engine manufacturers, electricians, electric light contractors, dynamo manufacturers, manufacturing chemists, &c. Edward W. Field, of 52, Bedford-road, Reading, is the first Managing Director, with a remuneration of £12 per month. Registered by George Tilling, Devonshire-chambers, Bishopsgate-street, E.C.

ELECTRIC INSTALLATION AND MAINTENANCE COMPANY (LIMITED).—An agreement (filed on October 6, 1891), made August 13, 1891, between J. E. H. Gordon and Company (called the contractors) and the above Company, states that whereas this Company have arranged with the Crystal Palace Company (Limited) for the supply of electric light by means of electric motors to exhibitors and others at the forthcoming Exhibition, and whereas this Company have obtained a Provisional Order (August 14, 1891) relating to the electric lighting of the Crystal Palace and District; and whereas this Company have entered into an agreement with R. C. Adams Beck for the acquisition of certain premises known as the Springfield Brewery, Wells-road, Sydenham, intended for a central station; and whereas the contractors are willing to contract for the execution of certain works for £51,175, it is agreed that works comprising a central station, with buildings, chimney, foundations, boilers, engines, dynamos, switchboard instruments, &c., capable of supplying current for 20,000 8 c.p. lamps connected, or for working 400 break horse-power in the Crystal Palace; a main to be run from the central station to the transformer room in the Crystal Palace, capable of carrying the whole of the current which the Company can generate, the main to consist of five positive and five negative cables; a complete set of motor dynamos, for transforming the current from 1,000 volts to 100 volts, are to be executed by the contractors, ready to supply electricity as may be required on the 1st January next. A penalty of £10 is to be enforced for each day after time. The payments for the above to be as follows:—£2,500 within a week of the allotment of the shares recently issued by the Company; £2,000 on the 5th October; £2,000 on the 5th December; £4,717. 10s. on the 5th February, 1892; £2,500 on the 5th March, 1892; £4,717. 10s. on the 5th April, 1892; £1,500 on the 5th August, 1892; £20,000 at the option of the Directors; and the balance (£11,240) to be satisfied by the allotment of 1,124 fully paid £10 shares. An agreement, dated the 13th September (filed 6th October), between the same parties, directs that the payment of £19,935, instead of as above, shall be as follows:—£2,500 to be paid on the 15th September; £1,666. 13s. 4d. on the 15th October; £1,666. 13s. 4d. on the 15th December; £4,550 16s. 8d. on the 15th February, 1892; a similar sum on the 15th April, 1892; and the remainder (£5,000) by the allotment of 500 fully paid £10 shares. Office: 4, Great Winchester-street, E.C.

ELECTRIC WELDING COMPANY (LIMITED).—An agreement made 20th August, 1891 (filed October 6th), between the City of London Contract Corporation (Limited), the vendors, and the above Company ("the English Company"), states that whereas the vendors have agreed to purchase from the Thomson European Electric Welding Company of Boston, U.S.A. (the Thomson European Company), certain letters patent, Nos. 10,241 of 1886, 9,686 of 1888, 361 of 1889, 377 of 1889, 8,038 of 1889, 14,880 of 1889, 20,962 of 1889, and 4,657 of 1890; and from the Thomson Electric Welding Company, also of Boston, U.S.A., certain letters patent, Nos. 9,300 of 1889, 8,229 of 1890, 8,242 of 1890, 18,625 of 1890, and 20,510 of 1890; and have also purchased certain machinery from the above companies, it is agreed that the vendors shall sell, and the English company shall buy, the above-mentioned patents and machinery, and in full satisfaction thereof £128,670 in cash and £83,330 by the allotment of 8,333 fully paid shares, numbered 1,001 to 9,333, to the vendors or their nominees. An agreement between the Thomson Electric Welding Company, of Boston, U.S.A., and the above Company, undated, has also been filed. The statutory return of this Company, *made up to August 4, 1890*, was filed on October 8, 1891. The Company, which was registered on May 1, 1890, has a capital of £460,000 in £10 shares, seven shares had been taken up at the time of the return, the original subscribers being the only members of the Company. No payments have (according to the return referred to) as yet been made. Office: 2, Tokenhouse-buildings, E.C.

ELECTRICAL SUPPLIES AND FITTINGS COMPANY (LIMITED).—The registered office of the above-named Company has been removed from 15, St. Helen's-place, Bishopsgate-street, E.C., to Faraday House, Charing Cross-road, London, W.C. This Company was registered on October 31, 1890, with a capital of £20,000, divided into 3,800 ordinary and 200 founders' shares of £5 each. At the date of the statutory return, March 17, 1891, 127 ordinary and 76 founders' shares were taken up, 30s. per share called up on the ordinary and the full amount on the founders' shares, and £560 paid, leaving £10. 10s. unpaid.

FREEDMAN BATTERY COMPANY (LIMITED).—The registered office of this Company has been removed from 276, Strand, London, W.C., to 66, Berners-street, Oxford-street, W. (Filed August 1, 1891.) This Company was registered on Sept. 1, 1890, with a capital of £2,000 in £1 shares.

W. T. HENLEY'S TELEGRAPH WORKS COMPANY (LIMITED).—At an extraordinary general meeting of the above Company, duly convened and held at the Cannon-street Hotel, E.C., on September 1, 1891, the following special resolution was duly passed, and at a subsequent extraordinary general meeting, duly convened and held at the offices, 27, St. Martin's-lane, E.C., on Sept. 18, 1891, confirmed:—That the capital of the Company be increased to the sum of £100,000 by the creation of 3,000 new Seven per Cent. Preference Shares of £10 each. (Filed on October 1, 1891.)

INSTITUTE OF MEDICAL ELECTRICITY (LIMITED).—At an extraordinary general meeting of the above Company, duly convened and held at the registered office of the Company, 35, Fitzroy-square, London, W., on September 15, 1891, the following resolution was passed; and, at a subsequent extraordinary general meeting of the said Company, also duly convened and held at the same place, on October 1, 1891, duly confirmed:—"That the Institute of Medical Electricity be wound up voluntarily, and that John Walter Biggs, of 12, Delahay-street, Westminster, be appointed liquidator to conduct such winding-up." (Filed October 10, 1891.) The above Company was registered on February 11, 1888, with a capital of £20,000, in £1 shares, to carry on the business of "The Electrified Rooms Company (Limited)." The first Directors were:—Dr. Wm. Lant Carpenter, H. E. Upton, Major-General E. A. Berger, and H. Newman Lawrence. At the date of the last return, February 17, 1891. 5,362 shares were taken up, 2,025 of which were fully paid. Upon 2,077 of the remainder the full amount was called, and 12s. per share was called upon the rest. £2,833 was paid, leaving £98. 15s. unpaid.

NATIONAL ELECTRIC SUPPLY COMPANY (LIMITED).—The registered office of this Company has been removed from 12, Coleman-street, London, E.C., to Victoria-buildings, Preston (filed on October 9, 1891). This Company was registered on October 28, 1889, with a capital of £100,000, in £5 shares, but no annual return has as yet been filed. The statutory return, filed March 14, 1890, shows that 98 founders' and 490 ordinary shares have been taken up, £1 per share called on the ordinary, and the full amount on the founders' share, and £970 paid, leaving £70 unpaid.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY (LIMITED).—The traffic receipts for the week ended October 9th were £4,901.

CITY AND SOUTH LONDON RAILWAY COMPANY.—The traffic receipts of this Company for the week ended October 11th amounted to £747; aggregate receipts for half-year to date, £10,410.

DIRECT UNITED STATES CABLE COMPANY (LIMITED).—The Board have resolved upon the payment of an interim dividend of 3s. 6d. per share, free of income-tax, being at the rate of 3½ per cent. per annum, for

Digitized by Google

the quarter ended September 30, 1891; such dividend to be payable on and after the 24th inst.

MIDDLESBOROUGH (KENTUCKY) ELECTRIC LIGHT COMPANY.—At a meeting on Monday last, at Winchester House, of the English shareholders of the Middlesborough Town Company, which may be termed the parent Company of the Middlesborough Electric Light Company, it was announced by the Chairman that the whole of the companies affiliated to the Town Company were to be reconstructed, and that it was proposed that Mr. Powers, at present a Director of the Town Company, would accept the presidency and managing directorship of the Electric Light Company. The reconstruction is necessary, owing, it is alleged, to the excessive expenditure of the American directorate. The new Company will be reconstructed on English models, and the English shareholders will have the control of their own property.

ST. JAMES'S AND PALL MALL ELECTRIC LIGHT COMPANY (LIMITED). The electric current sold for the quarter ended September 30th last amounted to £5,279, as against £1,818 for the corresponding period of last year.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended October 9th, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £3,797.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 701.—Vol. XXVII. FRIDAY, OCTOBER 23, 1891. Price Fourpence.

NOTES.

On Monday evening last the Frankfort International Electro-technical Exhibition was closed with due ceremony. About one and a quarter million visitors have passed the turnstiles since the opening of the Exhibition in May last, and the financial results are said to afford no cause for anxiety to the guarantors. In spite of its official title the Exhibition was distinctly national, and was none the worse for being so. We all knew that electric lighting was making rapid progress in Germany, and we have now had an excellent opportunity of making ourselves acquainted with the machinery employed. German methods differ from our own, and apart from national idiosyncracies have no doubt substantial commercial reasons for so doing. Some English electrical engineers have probably returned from Frankfort with the conviction that the Exhibition was interesting rather than instructive, while others may have picked up a useful wrinkle or two. Our German friends shake their heads at some of our recent improvements; concentric cables, for example, they say they have tried, and found to be more troublesome than useful—they have got beyond them.

Perhaps the one thing which more than any other contributed to the success of this Exhibition was the, to us, arbitrary manner in which exhibitors were treated; the Executive Committee went, we believe, so far as to exclude certain exhibits on the ground that there was already enough of them. The exhibits of different firms were in this way prevented from overlapping each other, and a coherent Exhibition was the outcome; but, of course, nothing of the kind is possible in this free country. However, this and other difficulties notwithstanding, we trust our own Electrical Exhibition, now that it is irrevocably fixed for the beginning of next year, will reflect national industry as thoroughly as the one on the Main.

It seems necessary to explain that the whole of our leading article of last week was not intended to be taken *au pied de la lettre*. Mr. Kapp has, we fear, from his letter to us, not only been puzzled but rather hurt; and it is to be hoped that the pioneers in general, and the "multiphase contingent" in particular, are not quite so sensitive, and that at the worst they may be only puzzled. It seems that the statements of a professor on a no more serious occasion than a meeting of the British Association "must have caused them some anxiety;" that he was so cruel as to "dishearten them at a time when they most want support," and that these unhappy pioneers are offered "discouraging advice." We have searched the leader through for anything that can be said to be "advice," and find only these words, "If anybody wishes to transmit power for industrial purposes on the scale on which it is done at Frankfort, he has only to give an order for a reproduction of the admirable plant which is running so well." It is hardly necessary to disclaim any intention of launching the retort to which Mr. Kapp says that he lays himself open. We are by no means "convinced that the multiphase current is of little practical use;" but we think that it seems to be limited to large or difficult undertakings, where it can be well looked after, and that there is probably a great future for it for mining and other special purposes. Mr. Kapp's own word, "intricate," exactly describes the main objection which we raised. But even this is no great matter. True, an engineer will naturally avoid intricacy, but a watch is undoubtedly intricate. We could add several mechanical reasons to those which Mr. Kapp supplies to account for the delay in the delivery of the water. Every engineer knows that an engine will not run away when started on a centrifugal pump. Mr. Brown's information as to the torque of his new motor practically settles the question, but the Lauffen-Frankfort transmission cannot be said to exemplify starting on full load.

There seems to be an impression in some minds that a special license is granted to reviewers, and that a book, an author, his work, and his opinions may be dissected, criticized, and characterized as worse than rubbish, that the book-buying public may be warned off, and that nothing short of personal abuse is out of place in a review. We venture to differ with this opinion; and though there would be a serious outcry if the same treatment were offered to a new switch or dynamo, that is considered fit for a text-book, we hold that criticisms in a technical or other journal are not necessarily confined to reviews, and that when they are made, they need not be treated as gratuitous advice; on the contrary, the fee is clearly stated on the cover. The writing of leading articles would indeed be a matter of grave anxiety if "the weight of an editorial pronunciamento" fell so heavily as Mr. Kapp seems to think.

Since writing the above, we have received a letter from Mr. Brown, which is in itself a sufficient reply to Mr. Kapp.

The method of testing the electrical efficiency of a transformer, described by Mr. Cuthbert Hall in another column, has certainly the advantage of avoiding the difficulty always arising in the measurement of the power supplied to an inductive circuit by alternate currents. Its application is, however, much limited by the fact that a suitable motor is required; and even when this can be obtained the power needed to overcome friction in the motor and dynamo may far exceed that needed for the transformer tests, so that the method becomes insensitive. In calculating the efficiency Mr. Hall makes no distinction between the two transformers, though one is transforming up and the other down, and the former works at a greater load than the latter. That it is sometimes quite wrong to assume that the losses in the two transformers are equal is clearly shown in the last case referred to. If the losses are equal the efficiency of the step-up transformer is 50 per cent. at a load of 268·875 watts; whereas, according to the immediately preceding test, the efficiency is as much as 67 per cent. for a *smaller* load of 206 watts.

The Edison Pressure Indicator is the latest thing in the United States. Most of the electrical journals illustrate it, but the description is even more vague than is usual with our American contemporaries. The instrument is contained in a box, and is apparently made to hang against the wall. It is surmounted by two glow lamps, one marked Test, the other Work. Below these is a handle or lever, and another one, barrel-organ fashion, is to be found on the side of the box. A glass pane allows a drum or curved scale to be seen, and in front of this is a pointer. A scale, marked from 100 to 120, with an index sliding in a slot, is fastened to the front of the box. Below this is a label—"Never leave the test lamp burning," and below this again is another slot and a sliding index, which has nothing but the letters of the legend to point to. Three ventilating holes under the organ handle suggest that something gets warm inside. We have read all the "descriptions"; they chiefly consist of information of this kind:—"Dim lamps can never be satisfactory; neither will lamps operated at a high pressure, as they deteriorate and break." We can only make a guess as to what it is all about, and yet people say that we have nothing to learn from Americans! We believe it to be a substitute for an engine-room voltmeter.

The regulator socket for glow lamps, which will be found described in our American notes column, is certainly ingenious, but it is not clear that any perceptible saving will be effected by its use. Even if the meter correctly indicate the power supplied by the alternate current, the efficiency of lamps when burnt very much below their normal brightness is so low that the saving is hardly worth consideration. The candle power of lamps varies roughly as the sixth power of the voltage and as the cube of the watts supplied, so that when the illumination is reduced to about one-half of its normal amount the power absorbed in the filament is only reduced by about 20 per cent. But with most meters the power supplied under these circumstances will be over estimated. Coulomb meters measure current without reference to the voltage, so that the volts absorbed by the choking coil, which correspond in reality with but a very small amount of energy, will be fully charged for; while such alternating-current wattmeters as exist are not at all correct when used on inductive circuits, owing to the difference of phase set up between the current and the volts. The saving as recorded on the meter would probably be less than 10 per cent. It is true that the impracticability of turning down a glow lamp has been treated by its opponents as a defect, but precisely the same defect is to be found in most oil lamps, and even with gas jets the object is not so much to economise as to avoid the trouble of relighting. With electric lamps this trouble does not exist. Is it possible that, knowing the reduction in power is nothing like so great as the reduction in light, and being aware that even first-rate meters as at present constructed change in favour of the company when choking coils are used, this is an ingenious device of a central station manager to encourage a saving of an imaginary character?

Hammersmith Vestry.—This Vestry has decided not to apply for a Provisional Order.

Rio Janeiro.—We learn from *Industria é Invenciones* that an electric tramway is being built in Rio Janeiro.

Battersea.—The Vestry have appointed a special committee to consider the question of lighting the parish by electricity.

Prof. von Helmholtz.—The German Emperor has appointed Prof. von Helmholtz a member of the Privy Council, with the title of Excellency.

Electric Cranes.—An electric crane has been built for the Petersenquai at Hamburg. The current is supplied from the central station on the quay.

The Khotinsky Lamp.—Captain Khotinsky, of the Gelnhausen Incandescent Lamp Works, has proceeded to Brazil in order to start a lamp factory in that country.

Institution of Electrical Engineers—Annual Dinner.—The third annual dinner of this Institution will be held at the Criterion Restaurant, Piccadilly, on Friday, November 13th.

Appointment.—Electric Inspector.—The London County Council is about to appoint an electric inspector at a salary of £200 a year. For further particulars see our advertisement columns.

Church Service by Telephone.—On Sunday, the 11th inst., the whole of the morning service at Christ Church, Birmingham, was successfully transmitted by telephone to the Loughborough exchange.

Preston.—The National Electric Supply Company has resolved to put down mains and erect a central station. It is estimated from orders in hand that the company will start with about 7,500 lights.

Personal.—Mr. D. Morgan Lewis, M.A., Demonstrator of Physics in the University College of North Wales, Bangor, has been elected to the Professorship of Physics in the University College of Wales, Aberystwith.

International Telephonic Communication.—At the beginning of next year telephonic communication will be opened between Brussels and Amsterdam (125 miles). The line will pass through Antwerp and Rotterdam.

Interurban Telephone Extensions in Germany. — The Berlin-Eberswalde and Hamburg-Magdeburg (130 miles) telephone trunk lines are now completed, and will be opened to the public in the course of a few days.

Glasgow.—On the recommendation of Sir William Thomson, the Glasgow Corporation Electric Lighting Committee have asked Prof. A. B. W. Kennedy to devise a scheme of electric lighting for the compulsory area which is scheduled in the Glasgow Provisional Order; and that gentleman has agreed to act as requested.

Digitized by Google

Dover.—A local company is to be formed, under the auspices of the Brush Company and the Town Council, to take over the municipal electric lighting order and supply current for both public and private lighting purposes.

Lightning.—The vicarage of Woodville, near Burton-on-Trent, was struck by lightning during the storm on Thursday last week. The chimney was utterly demolished, and a portion of the roof stripped.—The central tower of Lichfield Cathedral was struck by lightning last week, but up to the present no serious damage has been discovered.

Electric Lighting in Berlin.—The report of the Berlin Electrical Works shows that from June 30, 1890, to July 1, 1891, there was a large increase in the number of consumers, namely, from 872 to 1,314, being about 44 per cent.; the connected lamps have increased from 74,959 to 104,100, and orders for an additional 25,000 to 30,000 lamps have been secured for next winter.

The Chicago Exhibition.—Forms of application for space and prospectuses with detailed information are now in preparation, and will be sent out almost immediately. In the meantime, intending exhibitors can apply to the Secretary of the Royal Commission, Society of Arts, John-street, Adelphi, and their names will be noted at once, with a view to their receiving early copies of the prospectus when ready.

The London County Council and Electric Light Wires.—At the last meeting of the Council the Parliamentary Committee reported that they had instructed the Council's agent to prepare a Bill giving the Council power to require that where there are subways in any thoroughfare, gas, water, electric light, and other companies shall lay their pipes, wires, &c., in such subways, and shall pay the Council a rent for using them.

Glasgow Town Council and Mechanical Haulage.—The deputation of the Glasgow Town Council who visited the Frankfort Exhibition, and who have had interviews with representatives of the General Electric Power and Traction Company and of the Electrical Power Storage Company, have reported in favour of the adoption at an early date of mechanical haulage (cable or electric) on the Glasgow tramway system.

Institution of Civil Engineers.—Premiums Awarded.—The following are some of the premiums awarded by the Council of this Institution for original communications submitted during the past session:—Telford Medals and Telford Premiums to Messrs. Llewelyn B. Atkinson and Claude W. Atkinson for their joint Paper on "Electric Mining Machinery;" a Telford Medal and a Telford Premium to Mr. R. E. B. Crompton for his Paper on "The Cost of the Generation and Distribution of Electrical Energy;" a Telford Premium to Mr. William Langdon for his Paper on "Railway Train Lighting."

The Crystal Palace Electrical Exhibition.—We are informed that the requests for space—which already exceed a total of 200—include electric lighting plants for country and town houses, for mines, for steamships, for railway trains, and for private carriages. The newest forms of motors, generators, accumulators, and other machinery employed for producing and storing electricity are to be shown. Not only will the most eminent British electrical and engineering firms, with scarcely an exception, be represented, but several of the more important exhibits at the Frankfort Exhibition will be transferred to the Crystal Palace.

Obituary.—The Abbé Jean Caselli died a few days ago at the Santa Maria Hospital in Florence. He was born at Sienna in 1815, and took orders when he was twenty. After having made politics his study for some time, he devoted himself entirely to science, and in 1856 he achieved celebrity by his invention of the *pantelegraph*, in which, by a combination of styles oscillating in synchronism over drums covered at the transmitting end with metallised paper, and at the receiving end with Bain's chemical paper, handwriting and designs could be reproduced facsimile at a distance. Caselli's ingenious system was in use for some years at Havre and Lyons, but difficulties of synchronism and the frequent illegibility of the despatches led to its abandonment.

Telegraphic Communication with Lighthouses.—At the August meeting of the Cape Town Chamber of Commerce the attention of the management committee was called to the advisability of having telegraphic communication with Dassen Island, some 30 miles north of Table Bay. It was stated that if there had been smart communication on the Saturday preceding the day of the Chamber's meeting, property to the value of £80,000 might have been saved. Although a lighthouse is going to be built on the island, it was thought that there should in the interim be telegraphic communication with Cape Town, and that a short sea line might be laid down from Dassen Island to Izyerfontein, a distance of five miles in shallow water, and from there to Malmesbury, at a cost of £1,700. The matter was referred to the management committee.

Paper on Hertzian Oscillations.—In the list of subjects upon which Papers may be addressed to the Dutch Society of Sciences of Haarlem, up to January 1, 1893, it is stated that since Hertz's researches it has become very important to determine the period of the oscillations generated in conductors of different shapes; and the Society, therefore, calls for a communication setting forth either the necessary equations for a few cases, or the results of experiments made with this object in view. The Papers must be anonymous, and must *not* be in the author's own handwriting; they may be written in Dutch, French, Latin, English, Italian, or German, and must be sent, accompanied by a sealed envelope containing the author's name, to the Secretary of the Society, M. J. Bosscha. The writer of the best essay may have either a gold medal or 150 florins.

The Tommasi Accumulator.—In the *Comptes Rendus* of October 15, M. D. Tommasi has a brief note on his "multitubular" accumulator (*Electrician*, Vol. XXVI., p. 130), the distinguishing feature of which is that the electrodes consist of rows of perforated tubes (lead, ebonite, porcelain, or celluloid), filled with active material, and suspended from slots in the lid. M. Tommasi claims that by reason of the thorough utilisation of the active material, the weight of one of his cells is, *ceteris paribus*, from two to six, and the volume from four to eight times less than that of an ordinary accumulator. The maximum permissible charging current is as high as 60 amperes per kilogramme of plate (27·3 amperes per pound). For traction purposes, M. Tommasi prefers rectangular celluloid tubes; and for lighting work he finds leaden rectangular tubes give the best results. A capacity of 16 ampere hours per kilogramme (7·3 ampere hours per lb.) of electrode is claimed.

Paignton (Devon).—We learn that Mr. William Robertson, the Director of the Paignton Promenade Quay and Torquay Ferry, contemplates the introduction of electric launches in Torbay. It is also proposed to lay down electric plant to light Paignton. At a meeting of the Local Board on Monday the question of electric lighting was the principal subject discussed. It arose from a letter received from Mr. Robertson, who said that in order to charge the electric launches he proposed running between Paignton and Torquay it was necessary to put up a charging station properly equipped with steam engines of sufficient power and suitable dynamos. The same establishment could, he pointed out, be arranged so as to supply electric light to the town of Paignton, or to certain portions of it. Before deciding upon the power of the engines and dynamos to be put down, Mr. Robertson said he should be glad to have the views of the Local Board on the subject. The matter was referred to a committee.

Institution of Civil Engineers.—Subjects for Papers.—The following are some of the subjects upon which the Council of the Institution of Civil Engineers invites original communications:—The Continuous Running of Steam and other Engines, with details of construction; the Increased Efficiency to be derived from Superheated Steam; the best Arrangement of Engine for any given Electric Light Station; the Application of Electricity to the Treatment of Sewage; the Electro-Deposition of Copper; Pyrometers of various kinds, the different objects they are applied to, and their practical use and working; Electrical Traction for Roads and Railways, and the adaptation to such purposes of the vehicles at present in use;

Digitized by Google

Electrical Motors for (*a*) Inland Navigation, (*b*) Ocean Vessels; the most suitable Form of Electric Light Mains, having regard to durability, economy of conducting material, and facility of making and laying house connections; the Application of Electricity to Smelting and Metallurgical Operations; Electrical Measuring Instruments—such as Ammeters, Voltmeters, Power-meters and Supply-meters.

Electric Coal Mining in America.—Electric coal mining machines were introduced in the Monongahela coal fields, according to the *Electrical Age* of New York, nearly two years ago, since which time they have been rapidly adopted. One of the latest mines to be operated with these machines is the O'Niel and Peterson mine at Bunola, on the Pittsburg and Belle Vernon Railroad, on the Monongahela River. The contract for equipping the Bunola mine was made with the Michael's Electric Coal Mining Machine Company, of Pittsburg. The plant consists of one 50 H.P. steam-engine, one 30 H.P. Westinghouse alternating-current generator, and eight mining machines, with the Tesla motor of the Westinghouse Electric and Manufacturing Company attached to each. The success of the Michael's coal mining machine, says our contemporary, has long passed the experimental stage, as it has been in practical operation for fifteen months. The capacity of each machine per day is 65 tons of coal, or about one square foot of undercut per minute for ten hours each day.

Dynamos and Accumulators in Telegraph Work.—At a recent meeting of the Vienna Electrotechnical Society Herr E. Kœffler read a Paper on the subject of the employment of dynamos and accumulators for telegraph purposes. Herr Kœffler is against the use of dynamos, their great first cost and the cost of maintenance and superintendence only permitting of their economical employment where, as in the United States, comparatively strong currents are used. The author admits, however, that the substitution of dynamos for batteries at the Central Telegraph Office at Paris has effected a saving. The examples of the London and Berlin telegraph offices are cited in support of the economy of accumulators. By employing 12 ampere-hour storage cells on open circuit lines, and 50 ampere-hour cells on closed circuit lines at the Vienna Central Telegraph Office, Herr Kœffler makes out a saving of 38 per cent. over Daniell cells, in the case of busy wires. He also alluded to the new departure now being made in Germany, where, at the numerous translating stations between overhead and underground lines, which exist in that country, accumulators are substituted for primary batteries.

Frankfort Exhibition.—Our Frankfort correspondent writes us that the Exhibition was closed on Monday night, October 19th. The number of visitors has exceeded 1,200,000, which is about the estimated number. It is thought that the finances will, when everything is settled up, be found satisfactory, and that it will not be necessary to call upon the guarantors. The testing jury is at present at work on the Lauffen-Frankfort transmission plant, and they will probably push the voltage gradually higher and higher till the insulation breaks down. Siemens and Halske made some experiments on Saturday with a pressure exceeding twice that used by them up till then, in the high-voltage experiments they have been showing during the course of the Exhibition. Two oil-insulated transformers were connected in series, and current was taken at 2,000 volts from their large alternator, and transformed in each transformer up to 20,000 volts. Four hundred 100 volt glow-lamps in series showed that the pressure of 40,000 had been reached. The Siemens (London) cable held out, even though at one time 48,000 volts were on. It is remarkable that the arc produced by this enormous pressure was inferior in point of brilliancy to that made by half the pressure.

Crystal Palace and Sydenham District.—On Saturday last the foundation stone of an electric light generating station in Wells-road, Sydenham, was laid by Col. L. V. Loyd, chairman of the Electric Installation and Maintenance Company, in the presence of a large and influential gathering of residents and friends, who afterwards partook of luncheon at the Crystal Palace. The speeches were received with much enthusiasm, the project being very popular in this locality. The station building will be 80ft. long by 70ft. wide, and the plant will comprise five 160 H.P. engines, each driving a direct current dynamo of the Parker type. This plant will be able to supply about 20,000 8 c.p. lamps. The system adopted is that of continuous current transformer sub-stations feeding into a low-pressure network. Storage batteries will also be used. In the first instance, about 500 H.P. will be transmitted electrically from the generating station to the Crystal Palace, which is about 1¼ mile distant, in connection with the Electrical Exhibition. The plant is being laid down by the Electrical Installation and Maintenance Company, the contractors being Messrs. J. E. H. Gordon and Co. The order for the work was given to the contractors at the end of August last, and the building was commenced on September 16th, and is expected to be roofed in in about a fortnight. The whole of the electrical and steam plant is ready, and will be delivered as soon as the building is in a condition to receive it.

Electrical Exhibition at St. Petersburg.—MM. J. Pierson Fils, of 2, Rue de Canteleu, Lille, and 13, Wladiminsky-prospect, St. Petersburg, inform us that they have been appointed representatives of the Société Imperiale Polytechnique Russe in connection with the forthcoming Electrical Exhibition at St. Petersburg, organised by that body. The Exhibition will be held in the centre of the capital, and will be opened about the middle of December next, closing March 15, 1892. For the first time in the history of Russia foreign firms have been granted the Imperial permission to exhibit; and applications for space have, it is stated, already been received from Ganz and Co., Siemens and Halske, MM. Richard Frères, the Société Générale des Téléphones, the Compagnie Continentale Edison, &c., &c. The principal object of the Exhibition is said to be to enable the Russian Government to choose the best system, with a view to the inauguration of comprehensive electric lighting schemes in the principal towns of Russia. The charge for floor space is at the rate of 36fr. per square metre, 18fr. per square metre being asked for wall space. Exhibitors are recommended to insure their exhibits. Exhibits will not be allowed to be sold and handed over immediately to the purchaser without the permission of the Executive Committee, to whom 10 per cent. on the selling price will have to be paid. Foreign exhibits will be allowed to enter Russia duty free on the condition that they recross the frontier within a month of the close of the Exhibition. All objects sold at the Exhibition will have to pay the usual duty. The railway companies have granted a reduction of 50 per cent. on their usual transport charges in the case of all goods intended for the Exhibition.

The St. James and Pall Mall Company.—The following letters appeared respectively in *The Times* of Monday and Tuesday last:—

TO THE EDITOR OF "THE TIMES."

SIR: It is early, but not, I think, premature, to warn the public, and especially the sanitary authorities, of an intolerable nuisance and a seemingly great danger with which we are threatened by the extended use of the electric light. In Mason's-yard, St. James's-square, there is an engine-house of one of the companies, the machinery of which has been in use for some time, and until quite recently with no reason to complain of or to suspect any mischief from it. But the increased use of the light and the shortening of the days are now throwing more and more work upon the engines, and there is hardly any room to doubt that to this is due an effect upon the sewers which is becoming unendurable and probably perilous. As the night advances the smell as from drains continually increases, until soon after midnight it becomes strong enough to awake many from their sleep and make them feel (as they say) "quite ill." It is supposed that this arises from the forcing of waste steam into the sewers; but even if it should be attributable only to that steam itself, unconnected with sewage, it is so bad as an olfactory nuisance, if not as an atmospheric poison, as to demand prompt and decided measures on the part of the parochial authorities to put an end to it.

October 17th. PICCADILLY.

SIR: My attention has been drawn to a letter under the heading, "A Nuisance in St. James's," in to-day's issue of *The Times*.

Your correspondent "Piccadilly" should in fairness have taken the trouble to inquire into the cause of the alleged nuisance before committing himself to print, as he might easily have ascertained that my company does not, either at its station in Mason's yard or elsewhere, force any waste steam into the sewers, but discharges it from a chimney shaft at a height of 130 feet above the ground.—I am, Sir, yours obediently,

F. J. WALKER, General Manager.

The St. James's and Pall-mall Electric Light Company (Limited), Mason's-yard, Duke-street, St. James's, S.W., October 19th.

MAGNETISM IN IRON AND OTHER METALS.*—LIV.

BY PROF. J. A. EWING, F.R.S.

(*Continued from page 664.*)

§ 186. **Effects of Repetition of Magnetic Processes.**—Space may be found here to refer shortly to one or two of the minor phenomena of magnetisation, which the molecular theory goes far to make intelligible.

A consequence of the irreversible displacements which the molecular magnets suffer, together with the fact that the stability of each molecule depends on the configuration assumed by many molecules in its neighbourhood, is that in general a magnetising process has to be repeated more than once before its effects become strictly cyclic. In some cases a progressive change may be traced even during many repetitions of the process.

For instance, let a magnetising force be applied to a piece of soft iron, the strength of the field being regulated so that it brings the metal into what we have called the second stage of the magnetising process, when many of those molecules which are not already upset are on the verge of being upset. Let the force then be removed and reapplied. The configuration of the group during this re-application is by no means the same it was during the first application, and accordingly we may expect that some of the molecules which were just able to stand in the first instance yield in the second owing to the changes which have meanwhile taken place in the grouping of their neighbours. The re-application of the magnetising force may therefore be expected to produce a somewhat stronger magnetisation than was produced when the force was first applied. To a less degree, a third application of the force should make the magnetisation rise a little higher still, and so on.

Similarly, the second removal of the force should leave more residual magnetism than is left after the first removal. But we may expect that the limits between which the magnetism changes when the magnetising force is applied and removed will come to be closer in each repetition of the process; the molecular "accommodation" which goes on as one after another of the doubtful molecules is upset has the effect of narrowing the range through which the magnetism alters in succeeding cycles.

That these anticipations are in accord with the results of experiment will be seen from the following paragraphs, mainly extracted from a Paper which was written without reference to the light which the molecular theory throws upon the matter.†

When a magnetising force is first applied, then removed, and then re-applied, whether suddenly or gradually, the resulting value of I is somewhat higher than that reached by the first application. A third application gives a somewhat higher value, and so on, the effects apparently approaching an asympotic limit. This appears to have been first shown by the experiments of Fromme.‡ At each removal of the magnetising force the residual magnetism is also left somewhat greater than before. And this second action (the increase of the residual magnetism) exceeds the increase of the induced magnetism, with the result that the changes of magnetism between residual and induced diminish in range with successive removals and re-applications of the magnetising force.

The following observations (Table XXXIII.) were made by the ballistic method on a long piece of soft annealed iron wire. The readings are given without reduction to absolute measure; they relate to a point which falls early in the steep part of the curve of magnetisation.

Similar results were repeatedly obtained, both with freshly annealed wires and wires from which a previous strong magnetism had been shaken out by tapping. In curves showing the relation of B or I to H the same thing exhibits itself in what may be called the over-closing of loops formed by removing and re-applying a given value of H. A good example of this is furnished by Fig. 44, §78, which shows how much more considerable the action now spoken of is at early than at late stages of the magnetisation.

Table XXXIII.

Magnetising current.	Throw of ballistic galvanometer.	Magnetism. Induced.	Residual.
First made	203	203	...
broken	−53·6	...	149·4
made	+54·2	203·6	...
broken	−47·8	...	155·8
made	+48·7	204·5	...
broken	−45·7	...	158·8
made	+46·6	205·4	...
broken	−44·9	...	160·5
made	+46·1	206·6	...
broken	−44·0	...	162·6
made	+45·6	208·2	
After many makes and breaks—			
broken	−42·6		
made	+43·1		
After many more makes and breaks—			
broken	−39·5		
made	+39·8		

The following experiment (Table XXXIV.) (also on annealed iron) shows that the same kind of action occurred when the current was slowly changed by the liquid rheostat of Fig. 17, §41, and the magnetism was determined by a magnetometer:—

Table XXXIV.

Magnetising current.	H	Magnetometer deflection.	I Induced.	I Residual.
Gradually raised to 70	2·46	93	298	...
,, reduced to 0	0	65	...	208
,, raised to 70	2·46	97	310	...
,, reduced to 0	0	70	...	224
Then 100 sudden makes and breaks—				
Suddenly raised to 70	2·46	103	330	...
,, reduced to 0	0	80	...	256

Incidentally, this experiment illustrates another point—that the amount of magnetisation gained or lost by applying or removing a given magnetising force is greater when the change of force is sudden than when it is gradual. Other instances of the same thing will be found in the experiment quoted below.

Table XXXV.

Magnetising current.	Magnetometer deflection.	Remarks.
0	0	
Gradually raised to .....+190	+146	Here there is gradual diminution of range. This part of the operation is shown in Fig. 154.
,, reversed to .....−190	−141	
,, ,, ,, ...+190	+127	
,, ,, ,, ...−190	−133	
,, ,, ,, ...+190	+120	
,, ,, ,, ...−190	−132	
Suddenly ,, ,, ...+190	+124	Here there is an increase of range due to the suddenness of these reversals.
,, ,, ,, ...−190	−136	
,, ,, ,, ...+190	+123	
Fifty double reversals, then—		But after repeating the sudden reversals often enough the range becomes smaller than ever.
Suddenly reversed to .....+190	+111	
,, ,, ,, ...−190	−127	
Then gradually ,, ...+190	+108	And a *gradual* repetition of the cycle causes still a further reduction of range.
,, ,, ,, ...−190	−126	

When a magnetising force is applied and then repeatedly *reversed*, the changes of magnetism, instead of being strictly cyclic, form what may be termed unclosed loops. An instance of this is given by Fig. 52, § 82, which shows a series of these unclosed loops in the magnetisation of steel wire. The result

is, as in the case of repeated removals and reapplications of magnetising force, that successive repetitions of the process give a gradually diminishing range of magnetic change. This action, like the one just described, occurs most conspicuously at points in the early part of the curve of magnetisation. The observations in Table XXXV. were made specially to exhibit it, on a piece of annealed iron wire, 400 diameters long, by the magnetometric method.

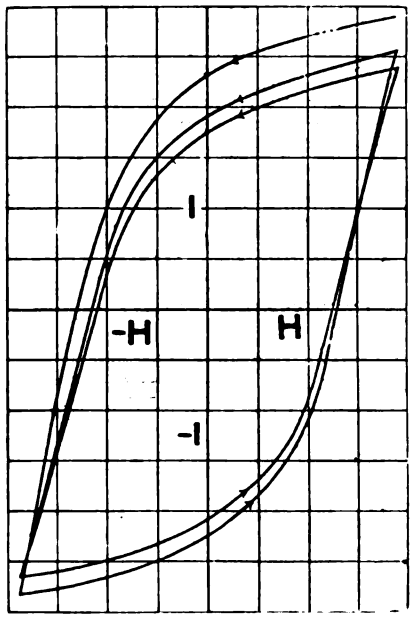

Fig. 154.—Repetition of Magnetic Cycles in Annealed Iron Wire.

In the first part of the above operations, during the five gradual reversals of magnetising force, intermediate readings were taken, which enabled the curves shown in Fig. 154 to be drawn. These show at a glance the manner in which the range of magnetic change diminishes. Sudden reversals, following on these, cause at first an increase of range, thus illustrating the comparative effects of gradual and sudden change of H, but on being repeated many times they reduce the range to a lower value than before.

demagnetised by reversals. It shows that the changes of magnetism are now cyclic. The same result was given by other specimens, which when freshly annealed gave much diminution of range, but when demagnetised by reversals after the magnetising force had been raised to a high value, were found to have lost this property. In this respect, then, a wire demagnetised by reversals differs from the same wire in its primitive annealed

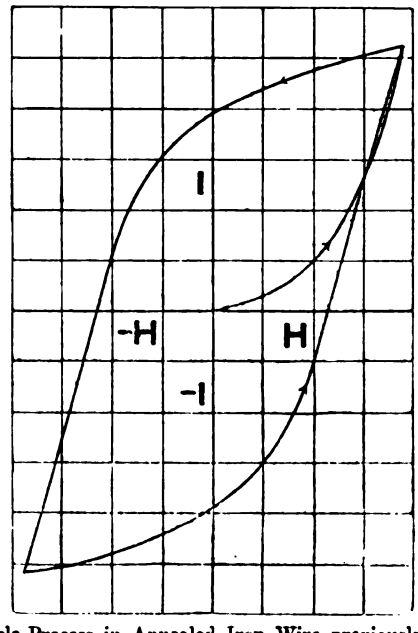

Fig 155.—Cycle Process in Annealed Iron Wire previously demagnetised by reversals.

state. It will be seen, too, by comparing figures 154 and 155, that the unsymmetrical susceptibility with respect to forces of opposite signs which exists in the annealed wire has given place to a very perfect symmetry after demagnetisation by reversals. Re-annealing the wire restored all the characteristics of the primitive state.

The following observations (Table XXXVI.), made with another piece of annealed iron wire at a part of the curve very sensitive to the actions now spoken of, show well the reduction of

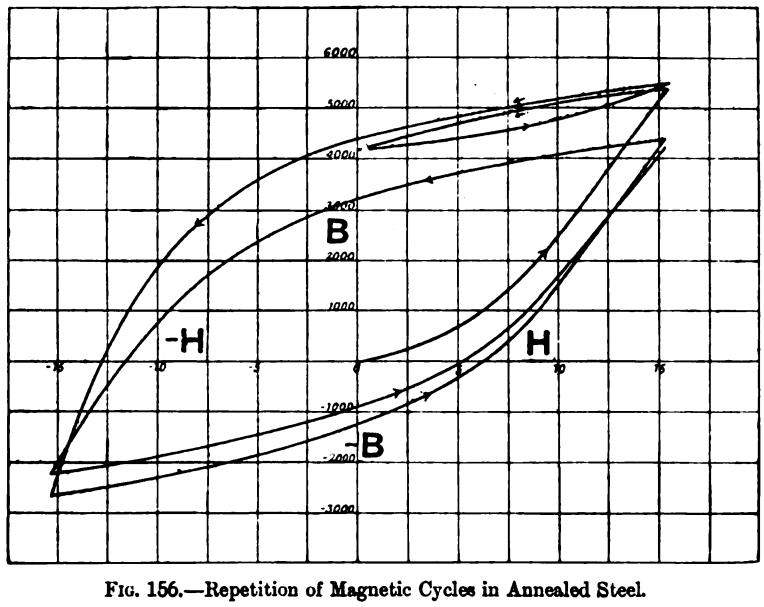

Fig. 156.—Repetition of Magnetic Cycles in Annealed Steel.

The same piece of wire was next subjected to a magnetising force about five times greater than the above, and was then demagnetised by reversals. Experiments similar to the above were then made on it, when it was found that *the tendency to a diminution of range with repetition of a cyclic alteration of magnetising force had disappeared.* The diagram, Fig. 155, shows the effect of applying, reversing, and re-applying the same magnetising force as in the former case, after the wire had been

range by reversals and then the rise of magnetism, induced and residual, which is produced by successive removals and re-applications of H. This last occurs in a very marked way after the range of magnetic change has been reduced by reversals of H. The two directions of the current will for brevity be distinguished as A and B. The changes were sudden, and the magnetism was determined by the direct magnetometric method. A want of symmetry is very noticeable here between the positive mag-

Digitized by Google

netisation due to the current A, which is first applied, and the subsequent negative magnetisation due to the equal and opposite current B.

Table XXXVI.

Magnetising Current.	Magneto-meter deflection.	Remarks.
Made A	+232	
,, B	−110	Diminution of range by reversals.
,, A	+180	
,, B	−101	
,, A	+172	
,, B	−100	
Twenty reversals, then—		
Made B	− 95

Made A	+206	
Broke A	+201	
Twenty makes and breaks, then—		
Broke A	+205	
Made A	+209	
Then reversals again—		The diminution of range by reversals is again conspicuous.
Made B	−105	
,, A	+178	
Forty reversals then—		
Made A	+163	
,, B	−105	
Broke and remade B	−136	
Ditto twenty times	−175	

The magnetisation of steel exhibits, even more than that of iron, reduction of range with successive reversals of H, and want of symmetry between the values of I induced by successively applied + and − values of H. Fig. 156 shows the changes of magnetism which were undergone by an annealed steel wire when a magnetising force of 15 C.-G.-S. units was applied, removed, re-applied, reversed, and re-reversed twice. The want of symmetry between the positive and negative values of the magnetism is very marked in this example: the steel acquires a strong magnetic *set* towards the side of the first magnetisation.

(To be continued.)

THE ELECTRICAL EFFICIENCY OF A SMALL TRANSFORMER.

BY H. CUTHBERT HALL.

The subject of the efficiency of transformers is one which has received a good deal of attention of late, and, at the discussion at the Institution of Electrical Engineers last session on Mr. Swinburne's Paper, the need of more conclusive tests of transformer efficiencies was much emphasised.

Of the three methods commonly adopted for the determination of the efficiency of transformers, the Blakesley split-dynamometer method is perhaps the most convenient, calorimeter tests requiring many observations and almost innumerable corrections, and determinations, involving the measurement of coal and water consumption and engine-efficiency, being only applicable to cases where large numbers of transformers are at the disposal of the experimenter.

The method of testing transformers by measuring the watts required to drive a direct-current motor, driving an alternator to which transformers are attached, is one to which few theoretical objections can be made, and which offers, comparatively speaking, but trifling practical difficulties.

The advantages of this method, as pointed out by a recent correspondent to one of the electrical papers, are that the energy absorbed can be measured in direct current units, and that an approximately accurate test can be made of a transformer of low power.

The results of some tests made on some ·75 kilowatt transformers by this method may, perhaps, prove not uninteresting. The transformers with which the experiments were made were of a well-known closed-circuit type, and the precaution was observed of testing several transformers of the same horse-power (·75 of a kilowatt), in order that any defect in the workmanship of any particular transformer might not prevent a correct decision from being arrived at with regard to the general efficiency of the class of transformers to which the one under test belonged. The sequel, however, proved that this precaution was unnecessary, as the results of the tests were so nearly identical that it has not been thought necessary to publish more than one typical case.

The author had not at his disposal a high-tension alternating-current dynamo of a suitable size; accordingly, a low-tension alternator was used, and the device of transforming up, and down again was resorted to. Therefore, in computing the loss of energy in one transformer, the figures obtained for the total loss had to be divided by two.

The accompanying diagram shows the general arrangement of the direct-current motor, alternating-current dynamo, transformers, and measuring instruments.

A is the direct current motor, B the alternating-current dynamo, C and C_1 the transformers, D the lamps, E the switch between the second transformer and the lamps, G the voltmeter on the secondary of the second transformer, K the ampere-meter in the lamp circuit, and M the voltmeter on the terminals of the alternator B. N is the battery of secondary cells, driving the direct-current motor, and H and J are the direct-current instruments (ammeter and voltmeter) on the battery-motor circuit. The cells which were used for exciting the field-magnets of the alternator B are represented by the letter O. An ampere-meter and a regulating resistance were inserted in the field-magnet circuit, in which the current was thus kept constant throughout the tests. F represents the ampere-meter, and R the regulating resistance.

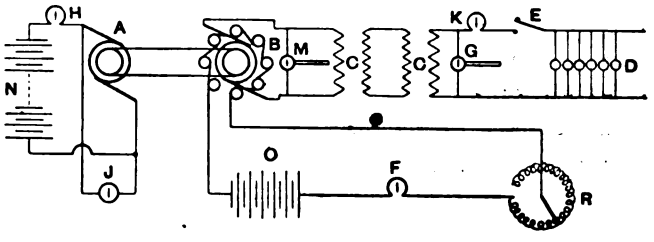

Diagram of Arrangement of Motor, Dynamo, and Transformers.

All the instruments were very carefully calibrated and were placed in positions as far from any disturbing influences as possible. Hot wire voltmeters were used on the alternating circuit, and Evershed's ampere-meters. A Schückert voltmeter was employed to measure the potential difference of the batteries driving the direct-current motor.

The insulation resistance between the primary and secondary coils of each transformer, and between the primary and secondary coils and the core, was carefully measured both before and after the load had been put on, and in every instance the insulation resistance exceeded 60,000 megohms. The insulation tests were made with an Elliott reflecting galvanometer and a battery having an electromotive force of 200 volts.

The speed of the alternator was kept constant, and regulated to give a frequency of 67, that being the frequency for which the transformers were designed.

The transformers were designed to give ·75 of a kilowatt on full load, and to transform from 2,000 volts on the primary circuit to 100 volts on the secondary.

The watts required to drive the motor with various loads on the secondary of the second transformer were as given in the table below:—

No. of lamps on C_1.	Watts driving direct-current motor.
3	1997·5
6	2220·4
8	2364·25
9	2437·5
12	2772·0

Digitized by Google

The efficiency of the motor alternator combination varied slightly with different loads, and had to be determined by putting various numbers of lamps direct on to the alternator.

The alternator was loaded with lamps direct until the direct-current motor watts were as nearly as possible 1997·5. The combined efficiency of the motor and alternator was then calculated from the number of lamps on the alternator and from the direct-current watts, and was found to be 30·33 per cent. The numbers of lamps which the alternator would carry when the direct-current motor was receiving respectively about 2220, 2364, 2437, and 2772 watts were also observed, and the combined efficiency of the motor and alternator calculated at these loads. The results obtained are given in the table below:—

No. of lamps on alternator.	Calculated lamp-watts.	Voltage of lamps.	Watts to motor.	Combined efficiency of motor and alternator.
15	900	100	2843·4	31·65
13	780	100	2470·7	31·57
12	720	100	2285·7	31·50
11	660	100	2170·3	30·41
10	600	100	1978·2	30·33

It will be seen that the efficiency of the motor-alternator arrangement varied very little for loads corresponding to those which were on the motor when transformer C_1 had 3, 6, 8, 9, or 12 lamps attached to its secondary, the lamps forming but a small part of the total load on the motor. Therefore, in calculating the efficiencies of the transformers at various loads, it would have been approximately correct to have considered the efficiency of the motor-alternator combination as 31 per cent.; but, in order to achieve greater accuracy, the actual values given above have been taken in each case.

The efficiency of the motor-alternator arrangement having been determined, the efficiency of one transformer at various loads could be calculated from the data supplied in the table given below:—

No. of lamps on C_1.	Voltage of lamps.	Calculated lamp-watts.	Watts to motor.
12	100·5	727·2	2772
9	102	551·8	2437·5
8	102	499·4	2364·25
6	105	396·9	2220·375
3	107	206·0	1997·5

The watts required to drive the motor when twelve lamps were on the secondary of C_1 were 2,772, and the combined efficiency of the motor-alternator arrangement at this load is 31·65 per cent.; therefore, 68·35 per cent. of the total energy supplied to the motor is lost in the motor and alternator, the remaining 877·33 watts being supplied to transformer C. The watts delivered to the lamps are 727·2; therefore, the efficiency of the two transformers is 82·8 per cent.; and therefore 17·2 watts per cent. are lost in the two transformers, and 8·6 watts per cent. in one transformer. Therefore the efficiency of one transformer at full load is 91·4 per cent.

For nine lamps the watts required to drive the motor are 2437·5, and the efficiency, of the motor-alternator combination is 31·57 per cent.; therefore, the efficiency of the two transformers is 73 per cent., and of one transformer 86·5 per cent. For eight lamps the watts to the motor are 2364·25, and the efficiency of the motor-alternator combination at this load is 31·5 per cent.; therefore, the efficiency of one transformer is 83·8 per cent. With six lamps and three lamps on C_1, it will be seen that the efficiency works out at 79·35 and 67 per cent. respectively.

The watts required to drive the direct-current motor when transformer C_1 was on open circuit were 1792·5. Taking the combined efficiency of the motor and alternator at 30 per cent., the watts lost in the two transformers are 537·75, and in one transformer 268·875, which is 35·8 per cent. of the power of the transformer at full load.

The results for the efficiency of the transformer at various loads are for convenience tabulated below.

No. of lamps on C_1.	Voltage of lamps.	Calculated lamp-watts.	Efficiency of transformer.
12	100	727·2	91·4 per cent.
9	102	561·8	86·5 „
8	102	499·4	83·8 „
6	105	396·9	79·35 „
3	107	206·0	67·0 „
0	...	...	35·8 per cent. of the power of the transformer at full load lost.

THE FRANKFORT EXHIBITION.—XIV.

(FROM OUR SPECIAL CORRESPONDENT.)

Several electric trams have been running during the past five months between the Exhibition and the Opera Place. It was arranged that the line should be constructed and equipped by Siemens and Halske, and this firm arranged with the Frankfort Tramway Company to lend and lay down the rails, while they themselves undertook the remainder of the work.

The line is 1,440 yards long, and is fairly level, there being only one sharp curve of about 13 yards radius. The overhead wire system is employed, the wires being carried on iron poles 18ft. high. The current is supplied at a pressure of 800 volts from the Machinery Hall by two cables of 70 sq. mm. cross-section (·11 sq. in. nearly). One of these is attached to the rails at the Exhibition end, and wherever two rails join they are connected electrically by a copper wire sunk beneath the surface.

The other cable runs by the side of the line close to the posts, 1ft. 8in. below the surface for a distance of 650 yards. Through every alternate post an 18 sq. mm. (·028 sq. in.) sectional wire is drawn, one end being connected with the cable, and the other with the trolley wire. The far end of this underground cable is brought out and connected with a 50 sq. mm. (·08 sq. in.) bare cable, which runs from here along the top of the insulators of the poles on the left side of the line to the end. At every pole this cable is electrically connected with the long working wire. The idea of using both underground and overhead cables is to show that the firm can supply either. There are three sidings on the line, dividing the line up into five fairly equal parts. The points shut automatically by means of springs, no pointsmen being required, the wheels wedging the points apart or being led by them to the siding, where the tram has to wait till the one coming in the opposite direction has passed.

Means are provided by which the driver can communicate with the engineer, and summon help in the event of a breakdown. Both the long working wire and the wires which support it are of galvanised iron, and are 6 sq. mm. (·01 sq. in.) in cross-section.

The chief feature about the line is undoubtedly the simple and convenient system hit upon for making the contact with the overhead wires. Contact is made by means of a steel arm of T shape. The breadth of the arm is about the same as that of the tram, and the arrangement has a very neat appearance. The tram runs with the upper part of the arm lagging a little behind and pressing up on to the wire. When the tram reaches a terminus, the arm will therefore be leaning towards the direction in which the tram is going next; and at starting, the friction against the wire tends to keep the arm back, and the car gliding under the arm, forces the wire upwards for a moment until the arm is in the right direction for the return journey. The arm is kept pressed against the wire by the action of two spiral springs fixed on the axis of the T piece, and also by the weight of the rod frame, the centre of gravity of which is below the horizontal axis. The arm occasionally jumps for an instant away from the wire at the joints. But, as the greatest current used is not more than 40 amperes, the sparking is not very formidable, and could have been cured

Digitized by Google

almost entirely by the use of two arms such as were used on the cars made by this firm for the tramway at Lichterfelde, an illustration of one of which is here given (Fig. 1). The arms in this case, however, though similar in principle, are of a different and perhaps less elegant form.

It may possibly be thought that the contact cross bar of the arm here described would soon wear away; but this has not been found to be the case. It is found that sidings do not offer the least trouble as far as the overhead contact is concerned.

age speed of $8\frac{2}{11}$ miles an hour; the car is, however, always slowed down at sidings and at the sharp curve.

In addition to the two cars working with the current from overhead, there is also a larger car driven by accumulators. This is built to carry 40 passengers, including three standing on either platform. The car is provided with two motors of 10 H.P. each.

The accumulator battery consists of 162 cells of the Tudor type. Hardened india-rubber boxes are used. Whilst being

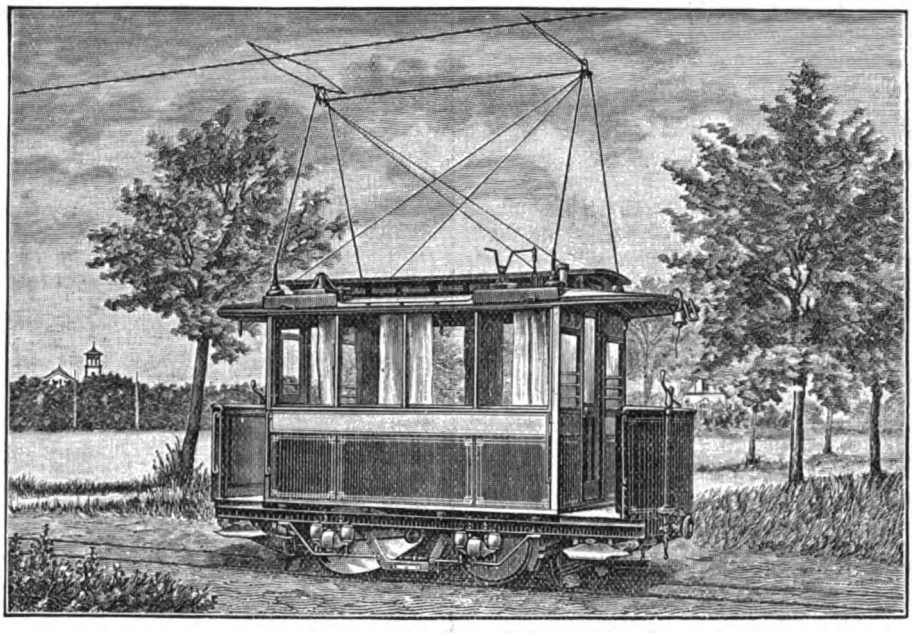

FIG. 1.—Siemens and Halske's System of Overhead Wire Electric Cars. (Lichterfelde line.)

The motor used is a 16 H.P. series wound drum machine; it drives one of the wheel axes by means of endless chains and toothed wheels (Fig. 2). The case containing the motor rests entirely on bearings on the two axes. There are two bearings for the motor on the driven axis, so that this cannot turn in a horizontal direction without carrying the motor with it; on the other axis, however, there is only one bearing for the motor, but that allows the axis to turn in all directions with the motor, and therefore with the other axis, thus allowing

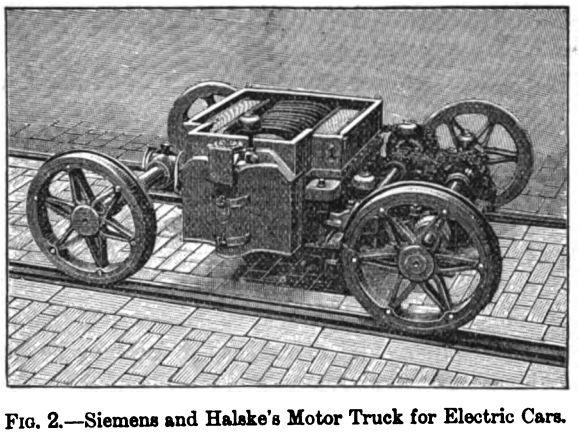

FIG. 2.—Siemens and Halske's Motor Truck for Electric Cars.

the car to round sharp curves. The motor and chains are cased in to keep out the dust and dirt, but the commutator and oil cups are easily accessible. The brushes used are dense coppered carbons, and are pressed perpendicularly against the commutator by spiral springs. The commutator has steel segments. The brushes are very broad, and a little thicker than the usual copper brushes, and require changing about every three days.

Resistance coils, to allow of the current being gradually switched on and off, are provided. The total weight of each of the cars is about 3 tons 3 cwt., and they will carry 30 persons. The 1,440 yards journey occupies about six minutes, an aver-

charged the cells are arranged in frames, which can be raised to any height required, and the substitution of the discharged for the charged cells is accomplished in a very short space of time. The speed is regulated by varying the grouping of the cells. At the station there is a turntable driven by an electric motor. The flywheel from the motor transmits the power on

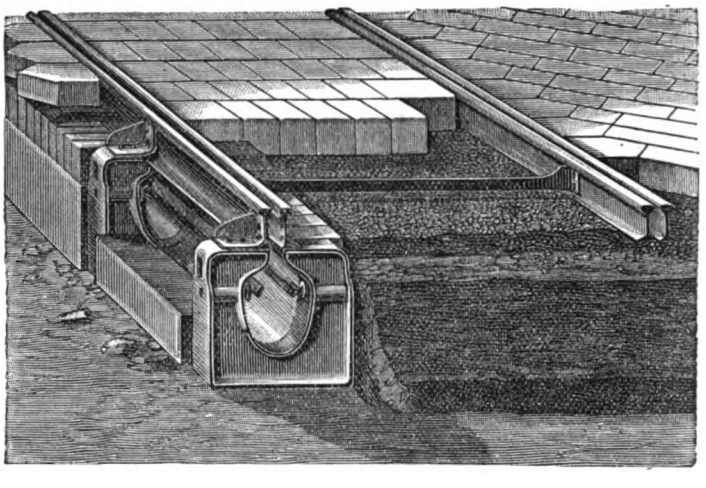

FIG. 3.—Type of Track laid down at Budapest.

to a friction wheel placed at right angles to it, and thence to the turntable wheels, or to a rope, to pull the car on to the turntable according to the wish of the driver.

The firm of Siemens and Halske, in addition to the overhead wire and accumulator traction exhibits, also show 25 yards of the type of track used for the street railway at Budapest. Fig. (3) shows the trench for the two insulated cables. This line was begun in 1889, and the projected length is 24 miles, of which nearly six miles are in operation at the present time. The number of cars running is 29, with eight as reserve. It may be mentioned that the total distance run by the trams on this line from Jan. 1st to Oct. 31, 1890, slightly exceeded 365,000 miles.

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

Advertisement Rates, &c., forwarded on application as above.

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday. Renewals of expiring advertisement orders and alterations to standing advertisements should be in Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday.*

SMALL PREPAID ADVERTISEMENTS *accepted up to 4 p.m. Thursday.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, 1891, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with well-written Biographical Notices of leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1891 should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Prospectuses free.

ELECTRICAL BOOKS AND PUBLICATIONS

All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad*

"THE ELECTRICIAN" *Series at present consists of—*

THE ALTERNATE CURRENT TRANSFORMER IN THEORY AND PRACTICE. By Dr. J. A. FLEMING. Vol I. Price 7s. 6d., post free.

THE ART OF ELECTROLYTIC SEPARATION OF METALS (Theoretical and Practical). By Dr. GEORGE GORE. Price 10s. 6d., post free.

PIONEERS OF SCIENCE.

It seems to us scarcely less than providential that, lying ready at hand for those whose minds must by the unfortunate necessity of existing, perforce be in daily contact with the dry facts of physical science and modern engineering, there should be an inexhaustible stock of subjects which may be discussed at any length and at any moment in the appropriate technical journals, without drawing too largely upon cerebral reserves and with the pleasing certainty that no inconvenient fact can be brought forward to upset a pet theory. Without this mental safety-valve we feel sure that psychology, psychography, psychomancy, and similar heterodoxies, would prove even more fascinating to those of the orthodox fold than is at present the case. A few months ago the readers of *The Electrician* enjoyed an intellectual treat of this description. A discussion, which with a little judicious encouragement might well have been still raging, was started in these columns, the subject-matter being the mode in which energy is transferred in the case of an electric circuit. There was a

Digitized by Google

doughty champion for the longitudinal transfer, and an equally formidable one for the lateral transfer; but as there was admittedly nothing conclusive on either side in the nature of experimental proof or disproof each disputant emerged from the fray confident that he had "smashed, pulverised, and destroyed" his opponent. Like all similar discussions, this particular one probably convinced nobody who was not convinced already; but, at any rate, it may possibly have caused many who take their beliefs ready-made to pause, and may have determined others to hunt down the *experimentum crucis* which shall prove beyond all reasonable doubt the truth of the present orthodox creed. We are afraid, however, that the same moderate claim for utility cannot be made good for the discussion which periodically breaks out as to the relative merits of the theoretical and practical man, nor for those vain but ever-recurring attempts to find the equation for the average market value of the mathematician. It is, therefore, with a more than usually overwhelming sense of the responsibility incurred that we put forth a few discursive remarks as to who may and who may not be deemed entitled to the honourable appellation of "pioneer."

In this as in things more serious the different meanings which different persons attach to the same word is responsible for most of the apparent difference of opinion. No fair-minded scientist, certainly no "sound and reliable journal," would willingly and wittingly belittle a pioneer. But there have been pioneers and pioneers; and in the case of electrical engineering the word has unfortunately gained a decidedly sinister meaning when used in connection with electric lighting, so that those who wish well to the industry might be forgiven if they still exhibit a little dislike of the name and a little distrust of pioneering enterprises of all sorts and descriptions. However, be that as it may, there can be no two opinions as to the value of and praise due to a scientific or engineering pioneer when we take the word in its plain-English dictionary sense of "one who goes before to prepare or clear the way, or remove obstructions for another." All honour to the man who without hope of fee or reward quietly devotes his life to the elucidation of some obscure phenomenon, leaving it to others to reduce his results to practice, content himself to have added one rung to the ladder of human knowledge. Honour in almost equal degree also to the practical engineer, who, often with but faint hope of pecuniary recompense, undertakes to evolve a science out of a chaos of empirical formulæ or to revolutionize existing methods and machinery.

The intellectual and physical equipment of a successful pioneer of science must obviously be of no mean order. It is not everyone who is capable of marching in the van of science, clearing the way. A would-be pioneer must have an objective point, and a tolerably clear idea of the general trend of the path towards it. Blind groping after indefinite objects is not pioneering, and leads to mere confusion in the mind of the unhappy wanderer himself, and, if he be of some scientific repute, to the piling up of obstructions in the face of those who come after him which it requires a genuine pioneer to remove. Many investigators, especially in the past, appear to have taken a malicious delight in rendering their results difficult to decipher, some even going so far as to deliberately hide them from the public gaze. The faculty of stating a problem concisely, of describing experiments clearly, and of drawing correct deductions, may be deemed the second *sine quâ non* of the pioneer. Some men are, moreover, peculiarly happy both in the time and mode of publishing their results. While one seizes the psychological moment and falls quite naturally into the current style, another makes known the valuable outcome of his labours when interest in the subject has flagged, and in a manner calculated to arouse antagonism. A scientific mind, a scientific imagination, a scientific scepticism are one and all essentials. Indeed, the bare enumeration of the qualifications necessary for the part would result in a list longer than the one that includes all the arts and sciences which no self-respecting electrical engineer can afford to neglect.

Last, but by no means least, the pioneer will be all the better equipped for his task if he be of the order Pachydermata. "It were good, therefore," says Bacon, "that men in their innovations would follow the example of time itself; which, indeed, innovateth greatly but quietly, and by degrees scarce to be perceived." Now, this is plainly the course which should be pursued by the ideal pioneer; but it is naturally one which does not, as a rule, commend itself to that gentleman in the flesh, hence he not unfrequently gathers unto himself the usual harvest of those who devise or discover "new things that piece not so well; though they help by their utility, yet they trouble by their inconformity." The attitude of doubt and caution usually encountered acts, it must not be forgotten, as an active deterrent to impostors, and is sometimes fatal to wild-cat schemes; and provided it be honest it may be taken as coming in the regular day's work of the pioneer.

THE DETERMINATION OF CURRENTS IN ABSOLUTE ELECTRO-MAGNETIC MEASURE.

BY G. F. C. SEARLE, M.A.

(*Continued from page 628.*)

§ 21. **Equivalence of a Current and a Magnetic Shell.**—It has been found by experiment (first in 1820 by H. C. Oersted, of Copenhagen) that an electric current possesses magnetic properties. Thus a small magnet placed close to a wire carrying a current tends to place itself at right angles to the wire. The question at once arose as to whether a current would be acted on by a magnet, and whether one current would exert a force upon another. These questions were settled by the experiments of Ampère. He found that a magnet acts on the current, and that the direction of these actions was consistent with the principle of the equality of action and reaction. Ampère also discovered the action of one current upon another. We may conclude, therefore, that the space surrounding an electric current is a field of magnetic force just as much as the space round a magnetised body.

It follows alike from the fundamental experiments of Ampère and the elaborate researches of Weber that a current flowing in a small plane closed circuit acts and is acted on magnetically, exactly like a small magnet placed perpendicular to its plane, with its centre at some point within it, the magnet having a suitable magnetic moment, and having its axis pointing one way or the other, according to the direction of the current. A "small" magnet or circuit means one whose greatest dimensions are very small compared with the distances of magnets, or of other circuits from the one considered. The positive direction of the current is taken to be from the copper to the zinc in the external circuit of a Daniell's cell. We can now specify the proper direction of the magnet. The direction of South pole to North pole of the magnet is related to the direction of the current round the circuit, in the same way as the motions of translation and rotation in the case of a right-handed screw working in a fixed nut. Ampère also found that equal currents flowing very close together, and in opposite directions, exactly neutralise each other's magnetic effect.

§ 22. Consider now any finite linear conductor A B C (Fig. 22) carrying a current. Is it possible to replace it, as far as its magnetic effects are concerned, by a purely magnetic system,

Digitized by Google

and if so, what is the character of that system? The following line of argument, due to Ampère, will lead to a decision on both of these points. Construct *any* unclosed surface having A B C for its bounding edge, and on this surface draw a network of lines dividing it into meshes, as *a b c d*, so small that they may be considered plane. This condition will be satisfied when the dimensions of any mesh are very small compared with the two principal radii of curvature of the surface in the neighbourhood of the mesh. Suppose that currents all of equal strength circulate in all the meshes in the same direction, A B C. The current in each of these meshes may be replaced, as far as its magnetic effect is concerned, by a "small" magnet of proper magnetic moment placed with its axis perpendicular to the plane of the mesh, and with its centre at some point within it (*see* § 21). But in all the lines of the network, except those which form parts of the actual conductor, A B C, there flow equal and opposite currents. Hence, by the experiment of Ampère, mentioned in § 21, it follows that the magnetic effect of all the currents in the subsidiary circuits is zero, so that the magnetic effect of the whole hypothetical system is reduced to that due to the current in the actual conductor, A B C. We see now that the magnetic action of the current in A B C can be mimicked by studding any unclosed surface bounded by A B C with a very large number of "small" magnets, all with their axes perpendicular to the surface, their magnetic moments and method of distribution being as yet undetermined. For any given surface the magnetic force produced by the two systems is exactly the same at all points, which are at a distance from the surface great compared with the

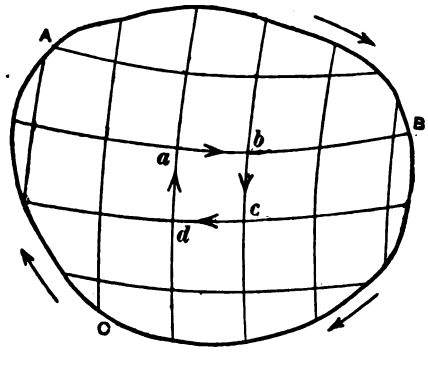

Fig. 22.

dimensions of the magnets. We shall, however, be able to get rid of this difficulty. We have now answered the first part of our question in the affirmative. Applying the same artifice as above to any "small" plane circuit carrying a current, it is easily seen that the magnetic moment of the magnet, by which for a given strength of current it can be replaced, is proportional to the area of the circuit. For, suppose that the circuit is fitted with a diaphragm of paper divided into very small squares, such as "millimetre paper;" a very large number of the squares will be included, and there will be besides a number of partly curvilinear figures where the rulings meet the bounding curve. Let currents all of the same strength circulate in the same direction in all the meshes so formed. The whole diaphragm being "small," the magnetic effect of each square at any distant point is the same, and all the squares can be replaced by magnets of equal moments. The number of squares being proportional to the area of the circuit, it follows that the magnetic moment of a "small" plane circuit for a current of given strength is proportional to its area. We have left out of account the effect of the small curvilinear figures; but when the distance between successive rulings is very small compared with the dimensions of the circuit, the number of such figures is very small compared with the number of the squares, and their effect may be neglected in comparison with that of the squares. Any difficulties which arise on this point belong purely to the Differential Calculus. Returning now to the first part of this paragraph, we see that the magnetic moment of any of the small magnets must be proportional to the area of the mesh which it is to replace. But in a uniform magnetic shell the magnetic moment of any portion is proportional to the area of that portion, so that if we make the surface, by which we filled in the conducting circuit A B C, become a uniform magnetic shell of suitable strength, we shall have obtained a magnetic system which will produce the same magnetic effects as the electric current at all points exterior to the magnetic shell itself. But as the magnetic shell may be supposed infinitely thin, practically no part of the space in the neighbourhood of the current is excluded by this proviso.

Thus a current flowing in a linear circuit of any form can, as far as its magnetic effects are concerned, be replaced by a uniform magnetic shell, of suitable strength, bounded by the circuit, but otherwise of any shape whatever, the direction in which the North side faces being related to the direction of the current in the same way as the translation and rotation of a right-handed screw. This is a most remarkable result on account of its great generality. There is scarcely any other theorem in the whole of physics which depends less upon the shape of the pieces of matter involved than does this present one. This theorem, when properly interpreted (see § 24 below), constitutes one of the two fundamental laws of electro-magnetism, the other being the theorem which expresses Faraday's discovery of the induction of currents. We shall make use of the result of this paragraph to give the electro-magnetic definition of the strength of a current. In doing so we must bear in mind the choice we made in § 3, that we would work upon a system involving the smallest possible number of numerical factors.

§ 23. **The Strength of an Electric Current** is equal to the strength, or magnetic moment per square centimetre, of the magnetic shell by which it can be replaced. Thus the unit current is such that it can be replaced by a magnetic shell of unit strength, having the conducting circuit for its boundary. This is the proper definition of strength of current in electro-magnetic measure. A definition of the strength of a current is often given in terms which involve the action of an element of current (*i.e.*, a short piece of the current having a beginning and an end); but since we can know nothing for certain concerning the properties which an element of a current completely separated from a circuit would possess (all currents in nature flowing in closed circuits), it is much better to define the strength of a current in terms of the properties of a closed circuit. We shall show later how the definition involving an element of current may be derived from the present definition. For the future, we shall consider that all the currents we are dealing with are measured in terms of the electro-magnetic unit as defined above. Partly because the electro-magnetic unit is rather large, and partly on account of the magnitudes of the ohm and the volt, it has been found to be convenient to take as the *practical unit* of current the ampere which is defined to be one-tenth of the electro-magnetic unit. The ampere is NOT, at least in theory, the current which deposits so many grammes of copper or silver per hour in an electrolytic cell. The idea that the electrolytic method is the proper way of defining current strength is rather surprisingly prevalent among students. The ideas involved in the measurement of a current by electrolysis are, no doubt, very much easier than those depending upon magnetic shells, solid angles, 4π, and other recondite matters, but nevertheless they are not theoretically accurate. Another class of people fall into an error very much worse than the one above, and state that an ampere is the current which an E.M.F. of one volt will send through one ohm. This has no doubt arisen from the widespread use of resistance boxes, and of batteries whose E.M.F.'s are given in tables as so many volts. These people forget entirely the methods which have been employed in the determination of the values of the ohm and the volt; in fact, the electro-magnetic definition of the ampere is employed in the evaluation of both the ohm and the volt.

§ 24. **Magnetic Potential due to a Current.**—Being now able to replace a current by a magnetic shell of the same strength we can at once write down the magnetic potential at any point P due to a current of strength i flowing in any circuit. It is simply $V = i\,\Omega$, where Ω is the solid angle subtended at P by the circuit, Ω being taken with the proper sign. The sign may be determined by the specification given in § 21, or by means of the following, which is easily seen to be equivalent to it. The solid angle is to be reckoned positive

Digitized by Google

when the current, as seen from P, appears to circulate in the opposite direction to that of the hands of a watch looked at from the front.

Return now to § 19. Take any closed curve P A B Q, Fig. 23, P and Q being indefinitely close together. We proved that the work done by external agencies in taking a unit pole from P to Q by the path P A B Q was zero when there was no part of the magnetic shell between P and Q, *i.e.*, when the path P A B Q could be continuously transformed into the straight line P Q without cutting through the edge of the shell. But if a part of the shell were between P and Q so that the path PABQ could not be transformed into the straight line P Q without cutting through the edge of the shell, then the work done was $-4\pi i$ where i is the strength of the shell. In the same way, if we draw any curve not linked with an electric current, then the work done in taking a unit pole from any point on the curve all round the curve and back to the starting-point is zero. If the curve *is linked* with the electric current then taking two very near points on it and drawing the equivalent shell so as to pass between them, the work done in the path P A B Q is $-4\pi i$, P being on the North side of the equivalent shell. In the case of the magnetic shell the work done in taking the pole along the straight line Q P is $+4\pi i$, but in the case of the current is zero, since there is now no peculiarity about the short path Q P, as in the case of the shell. Thus, when a unit pole is taken completely round a closed curve which is linked with the current, $4\pi i$ ergs of work are done. By referring back to §§ 19, 21, we can see that the work spent on the magnetic pole by external agencies is positive when the relation between its motion round the

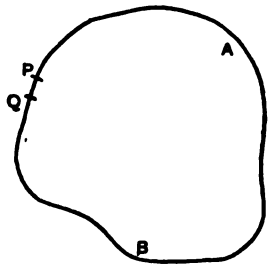

Fig. 23.

curve, and the direction of the current with which the curve is linked is the opposite to that between the rotation and translation of a right-handed screw.

It must be carefully noticed that there is an important distinction between the magnetic potential due to any system of magnets and that due to a current. The potential due to the system of magnets is single-valued, *i.e*, by whatever path we bring the unit testing pole from any fixed starting point to any given point, the work spent upon the pole is always the same. But in the case of the current the potential is many-valued, and for a single linear circuit should strictly be written $V = i\Omega + 4\pi n i$, where n may be any integer, and is the number of times that the path of the moving pole has twined itself round the electric current. See also § 13.

On account of the extreme importance of the result of § 22, and of this present article, it is not surprising that attempts have been made to obtain this result, or results equivalent to it, by different lines of reasoning. Thus M. H. Poincarè in his recent work "Électricité et Optique," Ch. VII., gives a method which depends upon some of Ampère's experiments and upon the *assumption* that the magnetic force at any point near a current can be derived from a magnetic potential just as in the case of a magnet. The method is one of considerable elegance. Again, in the treatise of Mascart and Joubert, Vol. I., Part IV., Ch. I., a method is given, based upon the "law of Biot and Savart," that the magnetic force due to a very long straight current is inversely proportional to the distance from the current. The method is ingenious, but unfortunately in § 447 (English edition) an *assumption* is made which appears justifiable only on the ground that it brings out the correct result.

(To be continued.)

POST-OFFICE TELEGRAPHIC COMMUNICATION WITH THE CONTINENT.

Last week the transfer of the telegraphic communication with the Continent from the offices of the old Submarine Company to the General Post Office was completed ; the premises in Throgmorton-avenue have been vacated, and more than two hundred operators have been added to the large staff at St. Martin's-le-Grand. For the last two and a-half years the work has been under the control of the Post Office, and a number of new cables have been laid and many important through connections have been established.

Fifty-two distinct lines are connected to the large hall, which has been devoted to foreign cable work, besides the four lines of the Paris-telephone cable, which can, if required, be used for telegraph purposes. Hughes' printing instruments are employed, since these are in general use on the Continent. Improvements will probably be introduced, such as an electrical arrangement for driving, in place of the pedal for winding up the weight, and experiments are being made in duplexing. The Hughes' instrument is not a slow one, as is generally imagined, for 700 messages have been sent in the day direct to Vienna, and as many as 80 have been sent in an hour.

One side of the hall is occupied by instruments working on the French cables, and the other by the German, Dutch, and Belgian lines. The through line to Vienna takes the messages for Austria, Hungary, Bulgaria, &c., while the traffic for Constantinople passes through Rome. These direct lines effect a very important saving in time and accuracy of transmission. Another valuable improvement which has recently been arranged is the direct communication between Liverpool and the Continent. Near the entrance to the hall is a table with relays, allowing communication between Liverpool and Havre, but the translating instruments on an adjoining table for Liverpool and Amsterdam were not being used on the occasion of our visit, the lines being connected through on the terminal board, messages being sent at about 100 per hour by this route. Five distinct wires go to Berlin, the instruments being all grouped together.

A double lift nearer the middle of the hall is in communication with the pneumatic despatch service, and the incoming and outgoing messages pass through the hands of clerks at neighbouring tables, where they are distributed to or received from the instruments. A special pneumatic service is laid on direct to this hall from the Stock Exchange, thus avoiding even the short delay caused by the use of the lift. The new land lines and the new cable to Germany are fully occupied ; and these, together with many improvements in working, have enabled the Post Office to keep pace with the large increase of traffic which has been brought about by the reduction in charges for foreign telegrams.

LITHANODE BATTERIES.

Lithanode is familiar by name to many of our readers, but although it has been talked about on various occasions for several years past little attempt has been made until lately to place it on the market. We recently visited the works of the Mining and General Electric Lamp Company at Millbank and Westminster, where various forms of plates and portable lamps are manufactured.

It is generally known that lithanode plates are composed of a compressed powder, and since they consist mainly of peroxide of lead it has been assumed that this material is used in their manufacture. This is, however, not the case, for a plate made by compressing peroxide of lead with however great force will disintegrate when it is wetted. The process which we saw in operation is very simple. A weighed quantity of litharge is mixed on a slab with a measured quantity of sulphate of ammonia in solution. The paste is well kneaded, and, having been placed in a metal gauge, between pieces of canvas, is subjected to a heavy pressure by hydraulic presses. Seven or eight of these presses are employed in the mixing room. The plates thus made vary

Digitized by Google

in size from 3½in. by 3⅛in. up to 7in. by 4in., and the thickness varies from ⅛in. to $\frac{3}{16}$in. On leaving the moulds the plates are allowed to dry very slowly for about a week, during which period they "set." They are then "formed" in a bath of sulphate of magnesia, a current being passed through them to peroxidize the lead. The process is conducted at a low-current density, and is completed in about two days. They are then dried again in a warm drying-room fitted with racks, where a considerable number of plates are stored. A dense plate of peroxide is thus produced, thoroughly homogeneous, very hard, and having a ring when struck. Softer and porous qualities are made for purposes where a rapid discharge is required.

At first, some difficulty was experienced in avoiding local action, for while the lithanode plate itself is quite free from any trouble of this kind a connection of some kind has to be made with the terminals, and it is necessary that the contact should be good, the resistance low, and that no oxidization should take place. Platinum was used at first, but now a strip of gilded lead is used, which gives an excellent contact, and is not attacked during work or while the battery is standing.

Another common misconception has been that lithanode plates are intended only for use in primary batteries. It is true that a lithanode-zinc couple will give nearly 2·5 volts, but, as is usual in nearly all primary batteries, it runs down on discharge, though there is no consumption when the circuit is open. A high-resistance lithanode-zinc cell is made for telephones, bells, &c., and a low-resistance pattern for running small lamps for telescopic and microscopic use, and for illuminating the sights of guns or clock dials. When used as a secondary battery in conjunction with spongy lead, it gives two volts. The electrolyte used is sulphuric acid, diluted to a density of 1·220. The battery should not be run down below 1·8 volt, and it will be found to maintain its voltage as steadily as a good secondary battery. A "capacity" of one ampere hour per ounce avoirdupois of lithanode may be obtained. Several patterns of hand lamps are made, and an order for 600 miners' lamps is being executed for a French colliery. The miner's lamp consists of a two-cell battery mounted in a sheet steel case, and wedged therein by india-rubber blocks. Safety devices are arranged to prevent short-circuiting of the terminals. Portable reading lamps and very compact testing cells, weighing 3oz. and yielding one ampere hour, are among the many patterns which have been made up.

THE GÜLCHER THERMOPILE.

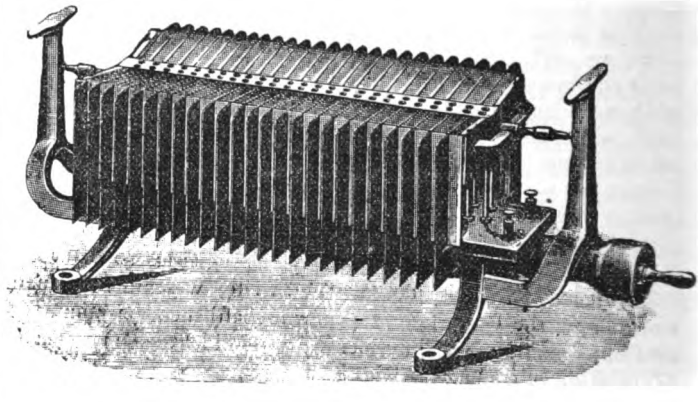
The Gülcher thermopile attracted a good deal of attention at the Frankfort Exhibition, and not only have contradictory figures been given as to its performance but conflicting views are held as to the theoretical efficiency. The practical value of the present form of thermopile may be judged from the figures given, but comparison with a dynamo is unnecessarily severe, and we only make it because the inventor invites such comparison. It seems very probable that well-constructed thermopiles may be used in many cases in place of primary batteries. The range of application of primary batteries is well known to electrical engineers, and, as far as electric light is concerned, they are of little practical use on a larger scale than the running of a five candle-power lamp.

The following account of the thermopile is abstracted from the official journal of the Frankfort Exhibition :—

This thermopile presents a new solution of the interesting but difficult problem of producing electric energy directly from heat. As hitherto constructed these apparatus have never been found of any practical use, owing partly to their short life and partly to their very low efficiency. Herr Gülcher's lately patented thermopile, however, not only does away with these defects, but appears to be capable of competing with the dynamo.

The piles exhibited are constructed for heating by gas, and are so arranged that overheating is rendered impossible, and, consequently, the pressure regulator (up to now a necessary appendage) is done away with. For comparison with the new type an old form of the apparatus is also shown. In the latter, six small gas flames burn outside each negative electrode (formed of a nickel tube) ; in the new form only one flame is used for each electrode, and this is placed inside the tube. If the pressure in the gas mains is increased, the only result is that these Bunsen flames become longer, and the extra length being beyond the extremities of the tubes the effect, so far as heating the latter is concerned, remains unaltered. As soon as the flames are lighted the apparatus requires no further attention. After about seven to ten minutes it is fully heated, and from that time the E.M.F. remains constant, however the gas pressure may vary. The accompanying illustration shows the larger of the two forms in which the apparatus is manufactured for burning gas by Messrs. J. Pintsch and Co., of Berlin. The figure is one-sixth of the full size. The weight is about 10 kilogrammes, and the number of elements 50 : these are placed in two parallel rows on a slate bed, which forms the top of the gasholder. Each element, as already mentioned, consists of a small nickel tube, in which is placed a "one-hole" soapstone burner. A connecting piece of nickel is soldered to this tube, and is connected to the prism-shaped positive electrode, formed of an infusible antimony alloy. In order to prevent any mechanical change, such as fissures, occurring in this alloy, and so changing the internal resistance, two steel rings are placed round the connecting tube. At the outer extremities of the positive electrodes are placed cooling pieces of copper, which also serve to form the connections. The elements are insulated from one another by means of asbestos. The larger of the two forms gives 4 volts. The internal resistance being 0·4 ohm, the pile is capable of giving a current of 5 amperes on a circuit possessing the same resistance. The smaller pile contains 25 elements, and supplies the same current at half the volts. The consumptions of gas are 200 and 100 litres per hour respectively, the cost being about ·36 and ·18 of a penny.

It will thus be seen that these piles are well adapted for the electro-deposition of metals, and also for charging accumulators arranged in parallel. With the help of the latter they are very useful for telegraphic purposes, and can also be applied to running small electric light installations.



In reply to our enquiries, we have received a letter from Herr Gülcher, of which the following is an extract. :—

"I mention that the results obtained from the thermopiles vary slightly, owing to some little differences in the composition of the alloy of antimony employed for the positive electrodes, the casting of which offers some difficulties. The figures given in the report are the average results of a number of thermopiles lately constructed.

"In order to show you how the results have been obtained I will give you an example from my test-book.

"*Date, October* 9, 1891.—Pile No. 98 ; number of elements in the pile, 50 ; gas consumed per hour during the test, 190 litres ; E.M.F. measured by a Siemens torsion-galvanometer of a resistance of 1,000 ohms, 3·8 volts ; difference of potential at the terminals with an external resistance of 0·5 ohm, 2·11 volts. Current during the last test, 4·22 amperes. Calculated from these figures you obtain : The internal resistance of the pile when hot and on full load, $(3{\cdot}80 - 2{\cdot}11)/4{\cdot}22 = 0{\cdot}41$ ohm. The current in an external circuit of equal resistance (0·41 ohm), $3{\cdot}8/2 \times {\cdot}41 = 4{\cdot}634$ amperes. Therefore, the total power of the pile $= 4{\cdot}634 \times 3{\cdot}8 = 17{\cdot}61$ watts with 190 litres or 92·7 watts per 1 cubic metre of gas ; and the maximum available effective power of the pile = 8·805 watts with 190 litres or 46·34 watts per 1 cubic metre of gas.

"There are now three sizes of these small piles being constructed, which differ only in the number of elements according to their purpose, viz., 26, 50 and 66 elements. The latter is especially constructed for charging accumulators, and has an E.M.F. of 4·6 to 5·2 volts, so that during charging it will work

with its full effective power at a difference of potential of 2·3 to 2·6 volts.

The experiments with the large piles, which are to be heated by coke burned in a "generator" stove, have not yet been concluded. The figures given in the report refer to a pile of 16 rows of 80 elements each—that is, 1,280 elements together. In the first four or six rows (nearest to the source of heat) the E.M.F. of each element was about 0·08 volt, whereas in the last row (the farthest from the source of heat) it was only 0·04 to 0·045 volt; the latter elements, however, were of double the height of the first ones, so that their internal resistance was only half the one of the elements in the first rows, and, therefore, all the elements, the first as well as the last, gave the same current, viz., about 10 amperes.

From the measurement taken at that first pile, which has been tested for three months, I place the following ones of two single elements of the first and last row at your disposal:—

Date of measurement, October 20, 1890:—I. An element of the first row: E.M.F. with an external resistance of 100 ohms (a Siemens torsion galvanometer), ·078 volt; difference of potential with an external resistance of ·003 ohm, ·034 volt; intensity of current during the last test, 11·33 amperes. Therefore, internal resistance of the element = (·078 − ·034)/11·33 = ·0039 ohm; and the current for the maximum effective power, ·078/2 × ·0039 = 10 amperes. II. An element of the last row:—E.M.F. with an external resistance of 100 ohms (Siemens torsion galvanometer), ·044 volt; difference of potential, with an external resistance of ·002 ohm, ·021 volt; current during the last test, 10·5 amperes. Therefore, internal resistance of the element = (·044 − ·021)/10·5 = ·0022 ohm; and the current for the maximum effective power ·044/2 × ·0022 = 10 amperes.

The theoretical reasons you mention lead to discouraging results only when based on the old principles of thermo-electric piles. If, however, my present improvements and the still further probable developments thereon be taken into consideration, we arrive at quite different results. In fact, if the price of a thermopile had not to be considered in competing favourably with other generators of electricity, I should already be able, with the present improvements, to construct a thermopile of the same efficiency as that of a dynamo-electric machine driven by a steam engine, calculating this efficiency from the energy stored in coal."

In the concluding portion of this extract Herr Gülcher desires to draw a comparison between his thermopile and a steam engine consuming coal; but we have no information as to the coal required for working the thermopile. As we pointed out on a recent occasion, the cost of gas for a gas engine, and of coal for a steam engine of the same power, differ but very little when the consumption per day or per year is taken, although the cost of fuel per horse-power hour by a gas engine is about five times that of a steam engine. We are inclined to base our estimate rather on the cost of the fuel than on the theoretical quantity of energy contained therein. A steam engine, we know, only returns about one-thirteenth of the energy of the coal, and most of the loss occurs on the boiler side of the slide valve. A far larger proportion of energy is yielded by a gas engine; but if the cost of making the gas from the coal is taken into account, there is little to choose between them, when the load factor is no better than that of most electric supply stations. Herr Gülcher makes a comparison at first on the assumption that *gas* is used for heating the apparatus. Now, 23 cubic feet of gas will yield one horse-power hour in a gas engine; and taking the low combined efficiency of 75 per cent., we have to consume about 40 cubic feet for one kilowatt hour, say 1·2 cubic metres. But the thermopile exhibited at Frankfort consumes 21·6 cubic metres, or about eighteen times as much as a gas engine and dynamo.

The difficulties which have to be encountered by a thermopile are numerous. A small current density must be employed, or the C^2 R will warm the cool junctions. The elements must be metallic, and even if some other substances could be found, they must be good conductors of current, and therefore good conductors of heat. But this makes it difficult to maintain a considerable difference of temperature, and if the cooling by water be attempted a new difficulty of a mechanical nature arises. Severe stresses are set up, and thermo-electric metals being generally brittle, the pile will pull itself to pieces, while there is at the same time a temptation to push the temperature of the hot junctions to a degree not far from their melting point. Solder cannot then be relied upon, and mere screwed up joints are sure to offer considerable resistance under these unfavourable conditions.

For these reasons, and for the economy of heat, a thermopile will only work satisfactorily on a good load factor. It should be applied to continuous work, and will probably suffer far more wear and tear during warming up and cooling down than during a long run of work. The waste of heat in firing up may be compared to that of a boiler or a blast furnace.

The very current which it generates acts antagonistically to the heat of the furnace in virtue of the Peltier effect, which tends to cool the hot junction. But on closer examination this need not constitute a defect, but may be compared to the back-electromotive force of a motor. A good thermopile when it is working will strongly tend to cool the heated junctions and to heat the cooled. It ought to be quite safe to subject a thermopile when at work to temperatures that would ruin it if it were left on open circuit, there being a very close analogy with a motor, which can not only stand, but efficiently utilise a voltage which would burn out the armature coils if it could not run. From one point of view, the back volts of a motor are the essence of its efficiency, since if they were non-existent, a large current would pass. The practical issue of this point is well enough understood, however curiously the problem may be stated, and such as it is it applies by analogy to the cooling of the heated junctions. But it is essential that the cool junctions be kept cool; and here are three causes tending to warm them, conduction, C^2 R, and the Peltier effect. It is not therefore clear why, according to some authorities, the Peltier effect is advantageous rather than otherwise.

The little Clamond piles for laboratory purposes, with an output equivalent to a Leclanché cell, are seldom worth working, but the Hughes instruments of the Submarine Company were thus supplied with current for the lines between London and Paris for some time. A number of ingenious uses have been suggested; it has been proposed to use the cooling Peltier effect for refrigeration, by the continual abstraction of heat. We heard a proposition a few days ago for helping up the pressure at the end of a long feeder. It was suggested that a thermopile should be put in series with the feeder, and warmed up by a shunt coil, but it need hardly be said that the suggestion was not a serious one.

One of the best primary batteries on the market might under very favourable circumstances give an electrical unit for 1s. 6d., but at a great trouble and nuisance in the handling of many gallons of chemicals. A price of about 3s. or 4s. a unit may be taken for ordinary batteries, and this agrees very well with the price per 1,000 "joulads" given in Mr. J. T. Sprague's "Electricity." The cost of gas per electrical unit comes to about 1½d. with an engine and dynamo, and eighteen times this is 2s. 3d. It appears, then, that although no satisfactory comparison can be made with the dynamo, the Gülcher thermopile competes well with batteries, and offers the very important advantage in that there are no chemicals to handle, jars to clean, &c.

ELECTRIC LIGHTING IN THE ITALIAN NAVY.*

BY LIEUT. A. POUCHAIN.

Ever since the year 1875 attempts have been made in the Royal Italian Navy to turn the then recent electrical discoveries to a practical use as a means of obtaining search lights. The plant first tried, *i.e.* the early Siemens and Brush dynamos, the lenticular projectors of Serrin, Siemens, and others, the apparatus of Gramme, Mangin, Reynier, Jablochkoff, and Wordermann, were found neither to satisfy the requirements nor to be of a practical nature. Meanwhile the new features introduced into naval construction, and the new machinery, daily made the

*Abstracted from the *Rivista Marittima*.

Digitized by Google

want more felt of an improved system, which would include at the same time the running of search lights, the direction of artillery, and the efficient interior lighting of engine, ammunition, and other rooms, for which oil or gas was insufficient, unhealthy, or even dangerous.

At first one or two search-lights were considered sufficient for the safety of the ship, and therefore only two high-speed engines coupled direct to the independent generating dynamos were required. A Pacinotti Gramme dynamo, driven by a Brotherhood engine, thus served very well for the occasional use to which they were subjected, in spite of the low efficiency and high consumption of steam. But when the ships in course of time were much modified and enlarged and fitted with smaller and more numerous guns, the torpedo boats on the other hand being greatly improved and becoming more dangerous, the necessity of having several search-lights at various parts of the vessel became more apparent.

The problems to be solved were the following:—(1) to fit every ship with the smallest number of dynamos compatible with efficiency of service; (2) to choose a plant easy of control and supervision, and, above all things, durable; (3) to utilise the old material as far as possible.

In order to comply with the first condition, the Royal Navy was classified according to structure and the strategetical importance of the ships. The current required for each search-light was settled at 50 amperes; a certain number of lights was allotted to each ship, in proportion to the number of its guns, so as to ensure an alternative supply for each lamp. To the current required for this purpose was added that necessary for lighting the engine-rooms, &c.

One or more supplementary dynamos were devoted to the lighting during the day-time of the following eight ships: "Re Umberto," "Sicilia," "Sardegna," "Italia," "Lepanto," "Duilio," "Dandolo," "Lauria," "Morosini," and "Doria," on account of the numerous dark rooms existing on board these ships, owing to their special construction. The electric plant was divided into four categories, viz., dynamos of 300 amperes, 200 amperes, 150 amperes, and 100 amperes, capable of supplying simultaneously six, four, three, and two search-lights respectively, and two dynamos were considered to ensure a perfectly reliable and regular service of light during times of peace. A standard potential of 65 volts was then fixed upon for the machines.

The solution of the second problem was based upon the following considerations. Indirect-transmission engines were excluded as being too cumbersome; high-speed engines, owing to their want of economy and delicacy; and direct-coupled horizontal engines, on account of the amount of room they take up. The vertical type of engine consequently had to be adopted, and of these it was considered advisable to reject compound engines in order to be able to make use of steam from the ship's boilers, the pressure in which did not exceed 45lbs. per square inch.

As regards dynamos the continuous-current system was preferred. Pacinotti-Gramme ring armatures were rejected on account of the powerful reactions occurring in them; and drum armatures were objected to on account of the difficulty of ventilating them, a most important point in view of the high temperatures in the rooms on board the ships. The flat Schuckert-Mordey ring was therefore adopted; and finally, to avoid the use of large polar masses, the four-pole system was chosen. These, with an engine of one or two cylinders, thus formed the plant adopted. The dynamos were compounded to give a constant potential of 65 volts.

In order to satisfy the third condition and utilise the old plant, consisting of Pacinotti-Gramme machines and Brotherhood engines, the fields of the dynamos were re-arranged, so that they could be excited at will either by shunt or series coils, giving, in the first case, 30 amperes at 65 volts for interior lighting, and in the second, 50 amperes at 50 volts for working the search lights, and these generators were assigned to ships of minor importance. The selection of engines and dynamos was a great step towards the completion of the task; but projectors, lamps, and fittings had still to be decided upon, and the choice of these gave rise to a second series of experiments.

Search-light Service.—The best projecting apparatus was agreed upon without difficulty, the Mangin projector having been proved by many years' experience to be the most efficient of all lenticular and parabolic apparatus. The choice of a lamp was by no means so easy to decide upon, and it was only after many unsatisfactory experiments with various types that the head electrician of the navy, Prof. Pasqualini, succeeded in bringing out a good lamp which was at once adopted.

Incandescent Lamps.—The lighting of the small rooms on board by arcs was not to be thought of, and it was decided to provide incandescent lamps which should fulfil the following conditions:—(1) Adaptability to the special features of a man-of-war; (2) sufficient lighting capacity.

Having tried the lamps of Edison, Swan, Brush, Bernstein, Khotinsky, and Cruto, in turn, and weighed the merits and demerits of each, it was decided to select Cruto's latest system with Edison's holders, and for the lamps near the large guns a special spring-holder similar to that of Pieper. The choice of this apparatus was especially happy, as it allowed all the material to be purchased in Italy.

As regards the lighting power of the lamps that of 12 candle-power was finally agreed upon as being the most suitable under the existing circumstances. Where more light than one of these gave was required, several of them were grouped together so as to preserve as far as possible one single type of lamp throughout, an arrangement which is almost essential to a satisfactory system of lighting.

Leads and Insulation.—For the sake of security, the idea of using a single circuit for all purposes was entirely put aside. Separate circuits, therefore, varying in number in different ships, were assigned to the objects of lighting, (1) machine rooms, (2) the guns and ammunition rooms, (3) the gangways and other parts of the ship which had to be illuminated in ordinary daily life, (4) the cabins, and (5) the signalling apparatus. These circuits were distinguished by characteristic numerals for those relating to internal lighting, and by letters for those devoted to running the search-lights, &c.

Finally, it was decided to exclude the use of the vessel as a return lead, both on account of the danger of getting short circuits, and because of interfering with the ships' compasses. It was also considered unnecessary to adopt the multiple wire system on account of the comparatively short length of the circuits, and the ordinary two-wire method of laying the mains was therefore settled upon. The next question to be decided was as to the use of lead-covered cables. On the "Duilio" it was found that contacts between the copper and the lead sheath were of somewhat frequent occurrence, especially at points where branches were taken off the mains. Moreover, it was found that the lead-covered cable had to be used at a lower current density owing to the increased difficulty of radiating the heat. At the same time this form of cable could be much more easily laid down than the other, and accordingly it was adopted for leads which were specially exposed to the weather, the bulk of the conductors, however, being of the ordinary kind without metallic covering, enclosed in wood casing. The sizes of cable used were calculated so as to give a maximum fall of 3 per cent., or two volts on a 65-volt circuit, at the lamps. The dynamos were insulated by being placed on teak beds, and it was found that the total insulation resistance varied between ½ and 1 megohm, a result which, if it could hardly be called good, at any rate was satisfactory taking the circumstances into account.

Safety Apparatus.—Cut-outs on mechanical principles were discarded in favour of a form of fuse adapted to use on iron ships. These fuses were divided into two classes, the first to be used for mains and suited to heavy currents, and made in two sizes, and the second for branches and small currents, made in four sizes. Both classes were used as direct fuses, as being simpler and more secure than those to work in shunt. The larger fuse wires were 50mm. in length and the smaller class 20mm. The automatic interrupters for the protection of the dynamos were adjusted so as to break the circuit if the current rose over 50 per cent. above that which any dynamo was supposed to give as a maximum output.

Distribution.—A good and simple arrangement for distribution of the current conduces in no small degree to the success

Digitized by Google

of any installation. The number of accessory apparatus was brought down as low as possible, and all circuits were brought to a single distributing board. It was made impossible for more than one dynamo to be connected on to a single circuit by using of distributing bars of special design.

The apparatus included an ammeter and a voltmeter; the necessary lamps for testing the circuits; an automatic interrupter for each machine; a Buss tachimeter for each engine; and the regulating resistances for the search-lights. The choice of satisfactory instruments was exceedingly difficult. Most of the commercial instruments in use depend for their action either on permanent magnets or on gravity, or on both. On an iron ship at sea it is clear that neither of these actions could safely be relied on. After a very long series of tests the Déprez-Carpentier instruments were provisionally adopted, but experiments are still being carried on with the view of finding something more suitable.

Engines and Dynamos.—The electric generators adopted for use in the Italian navy included four types, viz.:—(1) an F_2 Victoria dynamo of 300 amperes, compounded to give a constant potential of 65 volts at a speed of 250 revolutions per minute, coupled by means of a Raworth coupling to a vertical two-cylinder engine, provided with an Acme governor and a Buss tachimeter; (2) an E_2 Victoria dynamo giving 200 amperes at the same pressure, the speed being 300 revolutions per minute; (3) an E_2 (bis) Victoria dynamo, giving 150 amperes at the same pressure, the speed being 300 revolutions per minute. Both these dynamos (2 and 3) were coupled in the same way as the F_2 machine to two cylinder vertical engines, and were also provided with the same governors and tachimeters; (4) a D_2 Victoria dynamo, giving 100 amperes at 65 volts at a speed of 300 revolutions. This was coupled to a single cylinder engine, the coupling, governors and tachimeters being the same as before. A single bed plate in all cases served for both engine and dynamo.

The existing plant that was utilised consisted of a Pacinotti-Gramme machine, the fields being rewound so as to be capable of being excited either as a shunt or in series at will. These machines were connected by key couplings to Brotherhood engines, and furnished with Brotherhood governors and Buss tachimeters. These generators were placed on vessels of secondary importance, and were intended to be superseded by the above-described types as soon as they were worn out.

The engines were intended to be run at pressures of 45lb. and 70lb. per square inch. The chief points of interest in connection with the engines were the Raworth coupling and the governors used. Both of these, however, are so well known as to require no description. The same is also true of the 4-pole flat ring Victoria dynamos.

(To be concluded.)

ELECTRIC MINING-MACHINERY, WITH SPECIAL REFERENCE TO THE APPLICATION OF ELECTRICITY TO COAL-CUTTING, PUMPING, AND ROCK-DRILLING.*

BY LLEWELYN B. ATKINSON AND CLAUDE W. ATKINSON, ASSOC. MM. INST. C.E.

(Concluded from page 668.)

DISCUSSION *(concluded).*

Mr. FREDERICK HURD thought the question of danger had been very much overrated. He spoke from practical experience. It was no uncommon thing for him to spend a sixteen-hours' shift in a mine day after day. He had seen machines at work and giving off sparks that would amaze some persons, in places where they had been most particularly requested to be careful; and he was quite sure that it was not possible for these sparks to cause explosions in the way referred to. In the north of England, in Cardiff, and all over the country, such machines were used; also in France, Belgium, Austria, Hungary, America, New Zealand, India, and China, in places where large volumes of gas were supposed to be constantly given off. It was impossible for the cutters to come in contact with the grit and pyrites in the coal without giving off some sparks, and there was more danger to be anticipated from the cutter than from the dynamo. Reference had been made to what might be accomplished with compressed air, but even if they could get cent. per cent. the advantages obtained would not compare with the facilities that would be procured by the introduction of wire. The large pipes necessary to convey compressed air were a source of great expense.

Mr. E. R. DOLBY remarked that various speakers had alluded to the danger of sparking in fiery mines, and Mr. Crompton had stated that he thought the risk from the sparks produced by pick-axes was almost as great as that from the sparks on the commutator of a motor. After the disastrous explosion at St. Etienne, in France, a sub-commission was appointed, consisting of three well-known gentlemen, Messrs. Mallard, Le Chatelier, and Chesneau. They had prepared fire-damp, pure C_2H_4, and let it into a wooden box from a Bunsen burner. In that way they had produced a mixture of different percentages of fire-damp and air. They then placed pieces of sandstone and porphyry near the box, and struck them with pick-axes in such a way as to cause sparks to fall into the box. The mixtures were made so that a naked light ignited them. They found that a mixture of ordinary illuminating gas and air could be ignited by sparks so produced. They then proceeded to experiment upon the fire-damp mixed with air, and they found that it could not in any case be ignited with the sparks. The pick-axes were made of mild steel with removable points, such as were used at St. Etienne, and also of iron such as were employed at the Anzin mines. Besides these they tried picks of steel with 13 per cent. of manganese, and also of aluminium bronze with 2 per cent. of silicon. The aluminium bronze picks produced no sparks, and in the whole series of experiments they never succeeded in igniting any mixture of fire-damp and air. That, he thought, was exceedingly satisfactory. It had been said that the sparks produced on the commutator never caused an explosion, and he thought it was clear from the experiments he had mentioned that sparks from pick-axes would not do so.

Mr. HOWARD D. PEARSALL said, in compressing air by water-power on the principle to which he referred, he had obtained an efficiency of 85 per cent., and if that was multiplied, as before, by the efficiency of transmission and of the secondary motors, the net efficiency to be realised at a distance of three miles was 67 per cent. Those facts were (1) that 40 per cent. efficiency could be and was attained even with no cooling, as in Paris; (2) that the absence of cooling caused a loss of 40 per cent. of the gross power; (3) that a quantity of cold water, a thousand times the weight of the air, could be used so as to produce a nearly perfect cooling. Hence 40 per cent. waste was saved.

Mr. A. P. TROTTER remarked that his only excuse for speaking was that the first two of the machines in question were among the last which he had made before withdrawing from his manufacturing business. Many arguments had been put forward against the use of the machines in coal mines, but the only experiments which had been adduced (besides those that had just been mentioned, and which were not electrical) were those of Mr. Snell, and he did not succeed in igniting a mixture of coal-gas and air by means of sparks from a machine until the commutator got seriously hot. But where the only reason for the ignition of a mixture of air and gas was the fact that the commutator got hot, it seemed that carbon brushes would not be suitable. Those who had spoken of fire-damp igniting at the machine appeared to have lost sight of the fact that with the carefully-protected cases used in the motors, the fire-damp could not suddenly produce an explosive mixture. It must leak in by degrees, and, as the authors had stated—though this had evidently escaped the attention of Prof. Forbes and others—before it could become an explosive mixture the gas would burn, if it could be ignited at all by the spark, in the same way as in a miner's lamp. When the fire-damp got into the lamp it did not suddenly become an explosive mixture; it gave warning, and when the miners retired, they need not let the coal-cutting machine continue to run; the current might be cut off at the spot, or when they came back to the main switch. It was rather disappointing that the discussion which directly challenged air-compressing engineers, had not brought out a few more figures. He had hoped that at Birmingham they had attained something better than 44 per cent. It was difficult to know, with regard to the Paris installation, how to distinguish between what they were doing and what they might do. At all events, the 44 per cent., or even 50 per cent., was an enormous encouragement to electrical engineers, for there were few cases in which they need go as low as that. The loss by transmission in cables might be put at 10 per cent. or 20 per cent., leaving an ample margin for losses in dynamos and motors. Evidently air must do a great deal more than it had yet done if it was to compete with transmission by electricity in mines or elsewhere. One interesting feature of the Paper was the application of electricity to mechanical engineering. They had all seen what terrible blunders had been made in tramway work by persons who knew something of motors and very little of tramways. The inventors of these machines had, after learning electrical engineering, studied the details of the art of coal-cutting, and adapted their motors to it. The only criticisms that had been made, from a mechanical point of view, had been upon the Ingersoll drill. Not a single word had been said as to the electrical driving. It had been stated in the discussion that the wheel-cutting machine was better than the bar-cutter; but the amount bared with the bar-cutter was, if anything, rather more than with the wheel. He believed that the first machine, which used to tear both itself and the coal-face to pieces, and to throw itself off the rails, and hang on by the cutter-bar, travelled at the rate of about a yard a minute. The authors had stated that they were going to try a reciprocating machine. That was one of the most difficult problems that an electrical engineer could have to deal with. To produce anything on the reciprocating principle larger than the electric bell, and make it work with fair economy, seemed exceedingly difficult.

* Abstract of discussion on the Paper read before the Institution of Civil Engineers.

Mr. H. W. RAVENSHAW observed that series-wound motors were always used for high voltage because they required comparatively few turns on the magnets, whereas shunt windings for high voltage required a large number of turns, and there was a great liability to failure of the insulation if the shunt-circuit was broken. The only difficulty with a series-wound motor was, that when working on a constant-potential circuit, if the load was taken off the machine was liable to run away at a very high speed. He had been working on the subject for some time, and had found that by using iron or steel having a great amount of hysteresis, *i.e.*, retaining the magnetism induced in it, he could make a motor which would not race. Employing Dr. Hopkinson's curve for hard mild steel, he came to the conclusion that, in the case of a machine he was building, which was intended to run at 600 revolutions, if he used soft iron magnets it would make on open circuit about 2,400 revolutions per minute, which would mean the destruction of something in connection with it. With mild-steel magnets, the maximum speed would be only 1,800 revolutions, a reduction of 25 per cent. But, by employing an automatic switch so arranged that when working at full load the two halves of the magnets would be connected in parallel circuit, and when below half load they would be connected in series, he found that with steel magnets the maximum difference would be from 600 revolutions at full load to 780 revolutions with light load. That would be an allowable variation in any case where great regularity was not required, and between full-load and quarter-load the speed would not exceed 680 revolutions per minute.

Mr. C. W. ATKINSON, in reply, explained the method of working the cutter-bar. Disk-cutters might be employed where the roof was very strong, and where there was little danger from jamming; but in most cases there was this risk, and consequently the bar-cutter was more generally useful. Several speakers had stated that the wear and tear of the compressed-air machines was much less than that of electric motor. He did not think that was the case. The whole machine shown in the diagrams was completely enclosed in dirt-tight cases, the gearing itself running in oil, the only revolving part visible being the cutter-bar, and that formed a dirt-tight joint at the gear-box cover, so that after many months' running, when the lid was taken off, the oil was perfectly clean. The consequence was that whereas in air-machinery they considered it a fairly good record if a pair of brasses wore two or three months, the wear of the brasses in the electric-machines was so small that after some months it was hardly perceptible. He thought, therefore, that the mechanical wear was less in the electrical than in the compressed-air coal-cutting machine. In reference to electrical wear they had never found any difficulty. The armatures were very strongly constructed, the repair required was only on the commutator, and in their experience that had been extremely small. Several machines had been running for years without requiring anything more than an occasional turning up of the commutator.

Mr. LL. B. ATKINSON said that exception had been taken to the authors having used the results of figures published originally in 1874; but it would appear from the remarks of Professor Lupton, that the only improvement he was able to record since that date was one of 25 per cent., and he appeared to have fallen into the error of believing that he could add this to the 31 per cent. efficiency, making it up to 56 per cent. It was, however, only 25 per cent. of 31, or about 6 per cent. more. Prof. Robinson had referred to the experiments at Birmingham, but he did not say whether he took the brake horse-power of the generating engine and of the motor, or whether he took the indicated horse-power. The authors had been careful to state that they took the brake horse-power of the engine and of the motor. It had been stated that the Paris figures might be very much improved. Possibly they might; all that the authors had ventured to do was to deal with the figures which had been actually obtained, in working with the electricity and with compressed air. They had given the figures obtained from working tests of the motors; the only remaining element being the loss in the cable, and that, in the present stage of electrical science, was a mere matter of arithmetic, and not a question involving any theory. Another important point upon which special stress had been laid was the question of the safety of electricity in fiery coal mines. Prof. Lupton and Prof. Forbes had contested the authors' statement, that the arrangement of covers designed by them afforded a safe means of employing electricity in mines. The authors had stated that all experiments went to show that there was very little danger of ignition, but that if there was any, the proposed arrangements obviated it. Prof. Forbes said that the casings looked very nice in the drawings, but as a matter of fact would not exclude the gases. Mr. Brain thought if they could prove their case and keep the gas out for two hours mining engineers would be satisfied. In order to settle that point they had one of the boxed-up motors placed inside a large box filled with coal-gas, or coal-gas and air. After five hours they drew out, by means of a pipe, some of the gas inside the cover surrounding the armature. This was passed through the eudiometer, and they endeavoured to explode it with an electrical spark, but were unable to do so either when it was mixed with equal volumes of air, or with four volumes of air, or taken as it was from the interior. As a check they ascertained by experiment that they could explode a mixture as weak as 1 in 14. For the purpose of measuring the actual proportion of gas inside the covers, Mr. Pitkin had kindly lent them one of his gas detectors, which were very sensitive. The result showed that after five hours, in an atmosphere with very much more gas than would be found in any coal mine in existence, only 0·5 per cent. of gas could be detected in the chamber. He thought that that answered both Prof. Forbes' theoretical objection and also the remark of Mr. Brain. He might mention that the motor was stationary, but that was rather a disadvantage, as it was found that the chief leakage was through the bearings. When the motor was running the oil was evenly distributed on the bearings, and there was no tendency to leakage. Prof. Forbes has dwelt at great length on the danger of using motors, and afterwards called their attention to the Tesla motor. They had heard of that machine for two or three years, and it had always been going to take them by storm, and do many wonderful things. The last time he made inquiries about it, nearly a year ago, he found that it was still unpurchasable even from the manufacturers in America. He thought, therefore, that they ought not to wait until the motors had been perfected before attempting to do mining by electricity. Prof. Forbes had admitted that there was a difficulty about starting the Tesla motor, and if so that would be a fatal objection to the employment of it for coal-cutting. Sometimes, after a stoppage or a fall of the roof, the cutter-bar became jammed so tightly that a man might pull as hard as he could on a long lever placed between the bolts of the coupling and not be able to move it. By suddenly switching on a current to a motor that would take 25 amperes, with an engine with a heavy fly-wheel, they might get 100 or 150 amperes for a second or two, and that would pull the motor clear almost of any stoppage. The Tesla motor was difficult to get to start at all, and could not possibly move the machine in a case of that kind. The great advantage of electricity in coal-cutting was the enormous power of starting where there was a block. It was surprising to see how a machine weighing 1½ tons would lift itself up off the rails at starting if the cutter was jammed. With reference to the question of the relative merits of the bar-cutter and the disc-cutter, two or three speakers had stated that they believed the latter would do the most work, but unfortunately they had given no data and no reason for the supposition. He knew that the makers of disc-cutters were very particular to choose soft materials to work in, and would not try them in hard. The authors, on the other hand, had considered that they ought to cut in what the manager of the pit thought was stuff that he could best afford to waste, and the cutters they had designed were used in material which disc-cutters would probably not work in at all. He believed that Mr. Frederick Hurd, who had had a great deal more experience than any one present of disc-cutters, looked favourably on the form of cutter given in the Paper, after having considered the relative merits of both. Prof. Lupton's argument that they ought not to attempt to use electricity in coal mines because there was a remote possibility of an explosion, might be applied to almost every class of machinery. There were boiler explosions and railway collisions, and cables were occasionally overwound with serious results; still they did not say that those mechanical contrivances ought not to be used because accidents might possibly happen. The proper way of approaching the subject was to inquire if the thing was worth doing. Prof. Lupton said that it was, if the tables of efficiencies given in the Paper were correct, and he did not seriously confute them; Mr. Atkinson therefore concluded that it was worth attempting, and the Paper was the record of what they had done in that direction. Reference had been made to the firing of gas by sparks from a pickaxe or from any steel instruments striking against a hard material. Mr. Atkinson had recently read a report of the Prussian Fire-damp Commission, in which he found that the Prussian Commission decided to investigate this question, but afterwards renounced it on account of the experiments of Messrs. Willner and Lehmann at Aix-la-Chapelle, on the inflammability of mixtures of fire-damp by incandescent metallic wires and electric sparks, which proved that even violent sparks from rupture of the current, accompanied with the explosion of fragments of iron in a state of combustion, had no effect on the inflammation of fire-damp. The results, therefore, of experiments so far had been to prove that the danger had been very much over-rated, whilst the system adopted by the authors practically excluded the gas from the point of danger. Mr. Snell had supported the view which the authors put forward, that under normal conditions a motor would be unlikely to ignite gas; but admitted also the advantage of arranging it, so that even under abnormal conditions no danger would arise. Mr. Snell had also upheld the opinion of the authors, that the whole armature ought to be protected, and not the commutator only. In the course of his remarks, Prof. Lupton had severely criticised the use of electricity in mines where gas was present, on the ground that, unless certain precautions were taken, danger was to be anticipated, and, therefore, advised the use of compressed air, unless it could be shown that electricity offered great advantages; but Prof. Lupton would lead his hearers to suppose that this advantage did not exist, and that, as the figures given by the authors in some cases related to machinery made and tested a good many years ago, they were no longer to be relied upon, owing to the great improvements which had been made since. Prof. Lupton had suggested further, that there should be a competition between electrical and compressed-air plants transmitting 10 H.P. to a distance of 10,000 yards. Table V., which the authors had calculated, showed what results might be anticipated of such a trial, taking Prof. Kennedy's experiments in Paris, and well authenticated trials of dynamos and motors as the basis of the calculations. He omitted to give any tables or details of trials to prove his contention, and in the absence of these data, and in the face of the fact that all existing records supported the authors' figures,

Table V.—Compressed Air *v.* Electricity.

Prof. Lupton's suggestion ought not to be entertained. In criticising Table II., Prof. Lupton referred to an installation running at the Trafalgar Collieries, in which the distance was the same, and although a cable of nineteen wires was used instead of seven, as described in Table II., there was a loss of 20 per cent., whereas in the Table, a loss of 10 per cent. only was shown. Prof. Lupton pointed out that the voltage used at the Trafalgar Collieries was one-half of that proposed to be used by the authors, and this statement accounted for the whole difference, for by doubling the volts, and keeping the size of the conductor unaltered, the loss would be reduced to one quarter, so that the cable might be halved in size, and the loss still be one-half of that with the lower volts. This corresponded with the Table in every respect. Prof. Lupton stated that a 3in. pipe would be ample for a 10 H.P. engine working with compressed air: but every maker of compressed-air machinery to whom the authors had mentioned the point, had selected a 4in. pipe for the work, when working at an ordinary pressure of about 50lb. to the square inch. Prof. Lupton's alterations, therefore, to the figures and prices were incorrect. He also asked what was the price of the machine, compared with that of a compressed-air engine; these costs were given in Table II., the price of both electric and compressed-air machinery being taken as an average market price. Professor Lupton's remarks as to the apparently contradictory advice given by persons whom he had consulted as to the proper voltage to use in transmitting power were capable of an easy explanation. Small motors of ½ H.P. to 1 H.P. were difficult to wind for more than 150 volts; if, therefore, it was desired to run them from mains supplying large motors, at, say, 300 to 500 volts, it was better to work either two or three of them in series, or to insert resistance, and although by this means the efficiency might be reduced by 50 per cent., yet the useful work obtained was greater than would be got from a compressed-air motor of the same size, and to which power was being transmitted for an equal distance. The question as to the best voltage to use was one which an engineer in laying out a plant would carefully consider, in order to get the best results; but criticisms concerning the efficiency of motors as small as ½ H.P. running off transmission systems, involving, perhaps, 200 or 300 H.P., were not very vital to the question. The authors regretted that considerable bias in favour of a particular system, and apparently want of practical experience of any other, had led Professor Forbes to condemn the arrangements described by them in unmeasured terms. He appeared to be under the impression that most coal mines were normally filled with an explosive mixture, and that the working face was the most dangerous place in the mine; whilst, as a matter of fact, it was generally a part where the air was purer and more free from gas, owing to the thorough ventilation, than in almost any other. It was perfectly true that, if the authors' motors were left for, say, a week, in an explosive mixture, it would be possible to imagine an explosion occurring from their use; at the same time, such a condition was not in any way likely to occur, and the supposition of the authors, that an electric motor would not be worked continuously in such a mixture for a longer period than two or three hours, was one that allowed an ample margin for every practical case. In reply to the suggestion of Prof. Forbes that the words used in the Paper were intended to produce the impression that this machinery had been employed in fiery mines, although such had not been the case, the authors might point to a pumping plant, working with one of these enclosed motors, which had been in use in the Murton Colliery of the South Hetton Coal Company for seven or eight months, and which had been approved both by the mining inspectors and by the engineers of the colliery, and which had led to no fires or explosions. Prof. Forbes had pointed out the danger of using electric cables at all; but the experience of all colliery owners and managers who had tried them had shown that, if they were properly put down in the first instance, and had reasonable supervision, difficulties of the kind suggested did not occur in practice. With regard to the Tesla motor—although machines of this class undoubtedly had a future before them, the authors thought that no engineer practically acquainted with the requirements of coal-cutting machinery would recommend a motor where, with the latest improvements, the torque exerted at a standstill is considerably less than when running; and although in that motor no commutator is used, nevertheless it would be equally desirable to enclose the armatures, to prevent sparking in the event of a wire being broken. The remarks of Prof. H. Robinson called for attention, he being the only speaker who endeavoured to support the contention that compressed air was as efficient, or more efficient, than electricity, by any show of figures. But the authors could only assume that the results given as *efficiency* represented the ratio between the indicated horse-power of the engine and the indicated horse-power of the motor, in which case, as bearing on the present discussion, they were not comparable with those in the Paper. But if the results given by Prof. Robinson could be maintained by publication of figures or records, this should certainly be done, as they were considerably in advance of what the authors had seen. In reply to Mr. Pearsall's criticisms, the figures in Table II. were estimated or calculated, and were placed side by side for the purpose of comparison. The data on which these figures were calculated were as follows:—In the electric transmission the loss in the cables was accurately known, while the efficiency of the electric motor had been determined by careful experiments to be 85 per cent. The brake horse-power of the steam-engine was also arrived at by a knowledge of the efficiency of the dynamo, gained by careful experiments. In the case of compressed air, the efficiencies of the compressing plant and of the air motor were taken from the figures in Prof. Kennedy's Paper before the British Association on the "Popp" system in Paris, the prices in each case being those given by leading makers. Mr. Pearsall gave a considerable number of figures, and ended by saying that compressed air, with an efficiency of 85 per cent., was an accomplished fact, which could be seen any day; the authors only regretted that he did not indicate where it could be seen, as they were quite sure that a large number of engineers would be interested in a result which was certainly unique.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *October* 10, 1891.

The New York Electric Light Subways.—The subway wail has broken out again, and with full force; this time it is in the form of a desperate protest on the part of the East River Electric Light Company against the extortion of the Subway Company. Not only does the latter organisation demand $1,000 yearly rent per duct, but charges extortionate prices—from $3 to $6 per cubic yard—for excavating, and is alleged to furnish the necessary pipes to the Electric Light Company at 60 or 70 per cent. above cost. The state of things is, in fact, so bad that the electric light companies cannot run their wires in thinly populated districts, for they have only a few customers per duct and still have to pay $1,000 rental. The whole history of the Subway Company has been one of crooked business methods and bad service; but there appears to be no way of escape.

Regulator Socket for Incandescent Lamps.—One of the interesting small novelties recently brought out is a regulating socket for incandescent lamps manufactured by the Reis Electric Specialty Company; it is intended for use only on alternating circuits, and consists of a small coil of variable impedance enclosed in a somewhat enlarged lamp socket. More or less of the windings on this coil are utilised according to the different positions in which the ordinary key of the socket is turned, thus varying the light of the lamp. It is possible by this apparatus to turn the lamp down to a dull red or allow it to glow at its full brilliancy. There is, of course, a slight amount of energy loss in hysteresis and heating, but not considerable, and where the electrical supply is furnished by meter the use of this socket will produce a saving.

Edison and Electrical Traction.—Mr. Edison is again promising wonderful things in the electric street railway line. His apparatus appears to be some arrangement by which electric current at low potential is to be supplied through the ordinary rails. This is a subject that Edison has been pursuing off and on for several years, the intention being to use a voltage so low that the leakage from the rails, even when the ground is wet, will not rise to a prohibitive amount. It will be interesting to learn how he proposes to effect his distribution, possibly by means of supplying individual sections of the line from continuous current transformers. From what he says an important factor of the invention consists in a device enabling him to take up current from the rails even in muddy weather. He also says that he is building a large electrical locomotive to be used in connection with some of Mr. Villard's plans, and expresses himself in favour of taking current from stations about 20 miles apart, and perhaps replacing steam, not all at once but gradually.

The New York Rapid Transit Committee.—The plan apparently favoured by the New York Rapid Transit Committee is the one almost forced upon them by Mr. Worthen, their consulting engineer. It is a modification of the old arcade scheme of a four-track road under the surface of Broadway, and it involves the construction of a tunnel 44 feet in width, wide enough to accommodate the cars, and supporting the entire mass of superincumbent earth. The top of the tunnel is intended to be nine feet below the surface, leaving room for the somewhat complicated system of pipes that occupies our streets above it. It goes without saying that such a plan will be enormously costly, and it is very doubtful indeed whether private capital could be secured for it. It would be a very difficult matter to earn reasonable dividends on a sum of more than $50,000,000, particularly in the face of the active opposition that would be offered by the present elevated roads. The plan could probably be carried out successfully by the city at a sufficient expenditure, but whether a company could be organised to do the work is doubtful.

EASTERN TELEGRAPH COMPANY (LIMITED).—This Company announce the payment by warrants, on November 2nd next, of interest for the half-year ending October 31st, on their Four per Cent. Mortgage Debenture Stock. The transfer books will be closed from October 28th to November 2nd, both days inclusive.

CORRESPONDENCE.

WHY BELITTLE PIONEERS?

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Your leader on multiphase currents puzzles me. Can it be that *The Electrician*, that sound and reliable journal, has for once discarded its guiding principle and given us irresponsible opinions instead of solid scientific facts? Or can it be that you have mistaken one for the other? In this leader you say, "Meanwhile it is our duty to watch the new developments, to understand them if we can, and to keep our readers posted as to what is being done with them." A most excellent sentiment; but do you carry it into practice? A person who knows nothing of multiphase currents, and takes up *The Electrician* hoping to get some instruction from your leader on this subject, will naturally come to the conclusion which you so tersely express at the end, namely, that "the whirling of the armature at Frankfort is in more senses than one a *tour de force*." In plain English this means—"Yes, it is true the motor runs; but after all this is merely an experiment made at great cost and under conditions which do not occur in practice, and therefore the whole thing has no practical importance." It is a curious commentary on your concluding sentence that an hour after reading your article I received a letter from one of the Directors of the Oerlikon Works, in which the writer tells me that they had just started their three-phaser, and were now driving their works by three-phase current. Is this also a *tour de force*?

At the last British Association meeting a learned professor went to the trouble of reading a paper in which it was stated that there was really nothing in this Lauffen experiment, that an ordinary alternating current would answer equally well, and that, in fact, ever so much better work had already been done in America. This opinion was given before the Lauffen transmission plant had been started; and although now the engineers of this undertaking can afford to smile at the prediction of failure, at the time it must have caused them some anxiety; for remember, that practical engineers, even if they go their own way, do look up to professors. Why, then, should the professor dishearten them at a time when they most want support and when moreover it is too late for them to follow any advice, good or bad? To judge from the attitude of some English scientists and newspapers one would be led to think that Tesla, Bradley, Dobrowolsky, Brown, and the rest of the multiphase contingent, were a band of electrical miscreants, having some dark design against the industry, instead of pioneers striving to open up new fields for it. But it has always been so. How did the old-fashioned electrical engineers (that is, the majority of us) sneer at Gaulard and Gibbs even after the taint of perpetual motion which disfigured their patent had been duly discounted, and Dr. Hopkinson had shown that a high efficiency of transformation could be obtained? Or, to come nearer our own time, was not Ferranti attacked from many quarters for his 10,000-volt scheme; and was he not told over and over again that it would be a failure? What strikes me as so incongruous about all this is that men who in the ordinary way of business would refuse to give scientific advice, except for the consideration of a substantial fee (and quite right, for consulting engineers cannot, any more than other men, afford to work gratuitously), are so often ready to give discouraging advice to the pioneers, and that even without having been asked for advice or offered a fee. As long as private persons show their philanthropy in this manner no one has a right to interfere. In this free country everybody is at liberty to belittle everybody else as much as he pleases; but when scientific journals begin to give this gratuitous advice of a negative character, then their readers have a right to complain. I am quite aware that in taking up this position I lay myself open to the retort that you are convinced that the multiphase current is of little practical use, and that therefore you take it to be your duty to warn your readers against over-estimating its advantages. If this is the case, that is, if you really have got to the bottom of this intricate subject, then I pray you let us have a series of very exhaustive articles on it in *The Electrician*; and I promise you that not only outsiders like myself, but even the Haselwanders, Teslas, and Dolivos will read these articles with the greatest interest and benefit.

But perhaps I have misunderstood you altogether. Your leader was really based on an article in *Industries*; and my quarrel is, therefore, rather with that paper than with *The Electrician*. Then you might ask, "Why not send this letter to *Industries*?" Well, the reason is that *Industries* did not publish a leader on this subject, and you did. Now it is one thing to publish an article plentifully diluted with "if's," and "when's," and "let us suppose," and "say," and "assume," this, that, and the other, to get a basis for a theory; and it is quite another thing to publish a leader in which these qualifying things have been omitted, and the unfavourable conclusion of the article is put forth with all the weight of an editorial pronunciamento.

I will not here enter into the question whether the Lauffen installation could have been equally well carried out with ordinary synchronising machines and a single-phase alternating current. The learned professor and the learned gentleman who wrote the articles in *Industries* evidently think that it could; but against these opinions there is the broad fact that it has not been so carried out, and that, in fact, nothing even approaching such a transmission plant has ever been made with any kind of current. From your remarks it would seem as if you regarded the use of the simple alternating current for transmission of power as a kind of revelation brought to light by Mr. Mordey's experiments. I do not know to what experiments you refer, but it may interest your readers to learn that electric transmission of power by ordinary alternating currents is no longer an experiment, but has become an established fact. I personally know at least of one such power transmission, in which four of my ordinary 100 H.P. alternators are used. This has been at work for the lighting of Cassel since the spring of this year. The plant was supplied by the Oerlikon Works; and it is therefore obvious that this firm when deciding on the Lauffen work knew perfectly well what could be done with the simple alternating current. Yet they elected to use the three-phase current. Is that not a better proof of its suitability to this particular kind of power transmission than the opinion of the writer in *Industries*? Of course, the great merit of the system is the starting power. You hint rather than assert that this is not particularly great. Mr. Ravenshaw, your correspondent, has observed that some time elapses between the moment when the motor is started and the water appears on the top of the artificial fall. Considering that the main must be nearly 100 ft. long, and that centrifugal pumps require a certain minimum speed depending on $\sqrt{2gh}$ before they give any water at all, the lag of the water behind the motion is not very surprising; yet it would be a fallacy to suppose that there is no load on the motor when starting. There is friction and inertia to be overcome, the latter being that due not only to the weight of the revolving part of the motor, but also the disc of the pump and the water in it. The question of maximum torque at starting is so important that at the last meeting of the Testing Commission which I was able to attend, it has been decided to make special tests in this direction. When these and all the other tests will be published we shall be in a position to correctly judge the merits or otherwise of multiphase currents; but meanwhile do not let us belittle its pioneers. The German and American electricians have always been ready to give their English colleagues and rivals credit for their work: why should we be less just and courteous on our side?—Yours, &c.,

GISBERT KAPP.

Wimbledon, October 17, 1891.

MULTIPHASE CURRENTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your article on "multiphase currents" I find that you are overlooking some of Tesla's patents. This inventor describes quite clearly in his patents from '87 to '88 the three-phase current as applied at Frankfort; and the only novelties

Digitized by Google

which this Exhibition brings to light are important constructive improvements in its application.

The general reports upon the Lauffen-Frankfort transmission give the impression that to the application of the three-phase current is due the favourable issue of the experiment. I wish, however, to call your attention to the fact that the principal object of the experiment was to prove the possibility of transmitting high-tension currents over long distances by naked wires, and with such a degree of security against danger and such a small amount of leakage as to demonstrate that this mode has the right to exist commercially. The adoption of the three-phase current only increased the difficulties to be met, since the generator, the transformers, switches and controlling appliances, as also the conductors—a most important disadvantage—became more complicated than they would otherwise have been had the usual alternating current been chosen.

The only reason justifying the choice of the three-phase current was to demonstrate its advantages when applied to several small motors at the same time.

As the line at Frankfort has not been tried up to the present with more than 20,000 volts, I think it a little over-hasty to say that the insulators are unable to stand the pressure of 30,000 volts. I only wish to point out that considering the employment of ordinary insulators on two-thirds of the line, the result must be looked at as an exceedingly satisfactory one. I quite agree that as soon as a practical single-phase motor is produced we shall not hear much about multiphase currents, except in some special cases, as for distribution of power in a big workshop where we need no transformation, and perhaps, also, for mining purposes.—I am, &c.,

C. E. L. Brown.

TEMPERATURE CO-EFFICIENTS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: It is with great pleasure I have read Mr. Weaver's letter in to-day's *Electrician*. It is some years since I have tested Willoughby Smith's core; but as all the gutta-percha core made by the best known manufacturers has practically the same temperature co-efficient, my remarks will equally apply to Mr. Weaver's tests. The tables of co-efficients found in all text books are merely approximations, and must be taken as such. Instead of $(1 + \alpha)^t$, the true formula is probably something like this—$(1+\alpha)^t - m^t$, where α = co-efficient for 1°, m is a constant, and t = the difference between standard and observed temperatures.

Last year I took a series of tests on six coils of gutta-percha core at various temperatures with a view of ascertaining their correct co-efficient; which tests proved conclusively that the co-efficients did not vary simply as the log of the difference of temperature, but increased more rapidly as the temperature decreased. My values I found, however, could not be taken as being absolutely correct, owing to the fact of the core being of recent manufacture, and therefore its insulation was not stable; and I venture to suggest that this probably accounts for the majority of Mr. Weaver's tests at the same temperature being higher in Table No. 2 than in Table No. 1.

It would considerably facilitate the corrections for temperature being made if companies would only stipulate in their specifications to contractors that all insulation tests of the cable should be reduced to a temperature of 60°F., the core having been previously tested at that temperature, instead of still adhering to the 75°F. temperature. I am aware manufacturers of electric light lead have already adopted 60°F. as their standard temperature; this has, however, probably been done entirely from a business point of view. Practically under no circumstances will the temperature of a submarine cable have a greater variation than between the limits of 34°F. and 86°F.; so by making the standard 60°F. the greatest correction it would be necessary to apply would be for difference of temperature of 25°F., and whatever error existed in our co-efficient would only be multiplied by that number instead of, as at present, by either 41° or 11°; and as by far the greater number of tests are taken nearer a temperature of 60° than of 75°, there would be a decided advantage.

I have found cables vary considerably when corrected for large differences of temperature, some of them correcting fairly well with the ordinary log formula; where, however, there is a great difference between the result obtained by correction for a low temperature and that obtained when the core was tested at the standard temperature it points to a slight weakness in the core itself. This is practically either due to bad joints or the conductor in places not being quite central.

These weaknesses being unaffected by temperature are more apparent at low temperatures where the resultant fault is small. This, again, is another reason for making the standard lower, as it thus gives the contractor a better opportunity of localising any small fault in the core before sheathing.

Apologising for trespassing so much on your valuable space, —I am, &c.,

J. Leslie Fuller.

Westcombe-park, October 17th.

[Errata.—An over-zealous printer expanded the abbreviation K^t. into kilowatts in Mr. Weaver's letter in our last issue. The tables, of course, refer to megohms per knot.]

THE INTERNATIONAL OKONITE COMPANY.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I notice in your report of the meeting of our Company a statement which is incorrect. In explaining some causes which have led to less demand for our goods, I stated that the shipping orders we had received the year before from Messrs. Mather and Platt had fallen off 50 per cent. in the current year. Your report implies that the orders of Mather and Platt had fallen off 50 per cent. As I know this to be the reverse of the truth, I could not have made such a statement, and beg you, therefore, to allow me to correct the report upon this point which appeared in your journal of October 16th.—I am, &c.,

John Shaw, Commercial Manager
International Okonite Company, Ltd.
100, Queen Victoria Street, London, E.C.,
October 21, 1891.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

Tenders Invited.—The Minister of Public Works of Egypt announces in our advertisement columns that he is desirous of receiving tenders for the installation of the electric light at the Abdin Palace, Cairo. The work to be done includes the supply and fixing of the generating plant and all the necessary apparatus, except the brackets, pendants, &c.; and the installation is to include about 3,000 incandescent lamps and 25 arc lamps. Conditions, plans and schedules may be obtained at the offices of the Administrative Service of the Minister of Public Works; and tenders are to be delivered before noon on December 1, 1891.

———Tenders are invited by the Municipal Chamber of Braga, Portugal, for the public and private lighting of the city, either by means of gas or electricity. Official forms of tender may be obtained from the Municipal Offices. The basis of tendering will be about £3. 15s. per lamp.

Tenders Accepted.—The Town Council of Bradford have decided to accept the tender of Messrs. Andrews and Preece (Limited) for the providing and fixing of fittings required in the lighting by electricity of rooms in the municipal buildings, for the sum of £898, exclusive of fittings to be provided by the Corporation, at an estimated cost of £450.

——— The tender of the Brush Electrical Engineering Company has been accepted for lighting the Bilston Market Hall.

Christiania.—The tenders sent in for the Christiania Central Station were opened on October 12th, and the result will be made known in about a month. The tenders for equipping the entire station were from Messrs. Crompton and Co. (Limited), Messrs. Siemens Brothers and Co. (Limited), the Electric Construction Corporation (Limited), Messrs. Sharp and Kent, Messrs. Woodhouse and Rawson United (Limited), Messrs. Siemens and Halske, the Edison General Electric Company, New York, Messrs. Schuckert and Co., the Thomson-Houston International Electric Company, Hamburg, the Helios Company, Compagnie Centrale Edison, Messrs. O. L. Kummer and Co., and the Actiengesellschaft für Chromakkumulatoren,

Digitized by Google

Berlin. For supplying the boilers, tenders were received from the Düsseldorf-Ratinger Röhrenkessel Fabrik, Ratingen ; the Babcock-Wilcox Company (Limited), the Gohrig und Leuchs Kesselfabrik, Darmstadt ; and the Steinmüller Röhren-Dampfkessel Fabrik, Gummersbach. Callender's Bitumen, Telegraph and Waterproof Company (Limited), were the only tenderers for supplying the cables ; Messrs. T. and A. Jenssen and Dahl, of Christiania, alone tendered for supplying the steam engines ; and Messrs. Mather and Platt were the only tenderers for supplying the dynamos and instruments.

Sales by Auction.—Messrs. Wheatley Kirk, Price, and Goulty, in conjunction with Messrs. Edwards, Son, and Bigwood, of Birmingham, are instructed by Arthur Henry Gibson, Esq., the receiver and manager of Taunton, Delmard, Lane, and Co. (Limited), in liquidation, Star Tube Works, Heneage-street, Birmingham, to sell by public auction, at an early date, on the premises, the entire contents of the above well-known works. The catalogue will include beam, vertical, and horizontal steam engines, single and coupled ; "Root's" patent high-pressure tubular boilers, with from 100 to 388 tubes ; Cornish, vertical, and egg-ended boilers ; and a quantity of tube rolling and drawing machinery, loose plant and effects, &c. Further particulars will be found in our advertisement columns, and catalogues may shortly be obtained of the auctioneers.

Messrs. W. T. Glover and Co.— This firm report a very busy summer, necessitating the laying down of additional plant to meet the increasing demand for their manufactures. They have recently registered a new telegraphic address—"Glovers Salford." Mr. Henry Edmunds, who has been attending the Electrical Congress at Frankfort, has now returned to the Company's London offices, 39, Victoria-street, Westminster, S.W.

Messrs. Ernest Scott and Mountain (Limited).—The new works recently erected by Messrs. Arthur and Co. at William-street, Anderston, are lighted throughout by electricity, the installation having been carried out by the above firm, under the superintendence and to the specification of Mr. W. A. Bryson, consulting electrical engineer, Glasgow. The plant consists of two Tyne compound-wound dynamos, each machine being capable of giving an output of 25,200 watts when running at a speed of 670 revolutions per minute. The current from the dynamos is taken to a very massive switchboard, consisting of two large enamelled slate bases, placed one above the other. On the lower slate base two coupling switches are placed, arranged so that the dynamos can be coupled parallel or run singly if required. On the upper enamelled slate base five double-pole main switches are fixed together with automatic cut-outs. These switches control the five floors of the building by separate circuits, so that any floor can be switched off from the dynamo room. There are altogether 600 16 c.p. incandescent lamps, suspended from the ceiling by flexible pendants, each pendant being fitted with a china ceiling rose containing a fusible cut-out. We understand that Messrs. Ernest Scott and Mountain (Limited) are extremely busy at the present time in their electrical department.

Messrs. Drake and Gorham.—Shendish, the residence of Mr. A. Longman, has recently been fitted with the electric light by Messrs. Drake and Gorham, the power being obtained from a gas engine which also does the pumping for the house. The installation consists of an accumulator capable of discharging up to 50 amperes and about 100 lights.

Brush Electrical Engineering Company (Limited). — The secretarial and managerial offices of this Company have been removed to Albert-buildings, 49, Queen Victoria-street, E.C.; the offices of the chief engineer will remain at 112, Belvedere-road, S.E.

Dissolution of Partnership.—Mr. John Ferguson and Mr. John M'Kay have retired from the firm of M'Whirter, Ferguson, and Co., electrical engineers, Faraday Electric Light Works, Campbell-street, Govan, Glasgow ; and the business will in future be carried on under the same name by Mr. William M'Whirter, who will pay all debts incurred by the old firm.

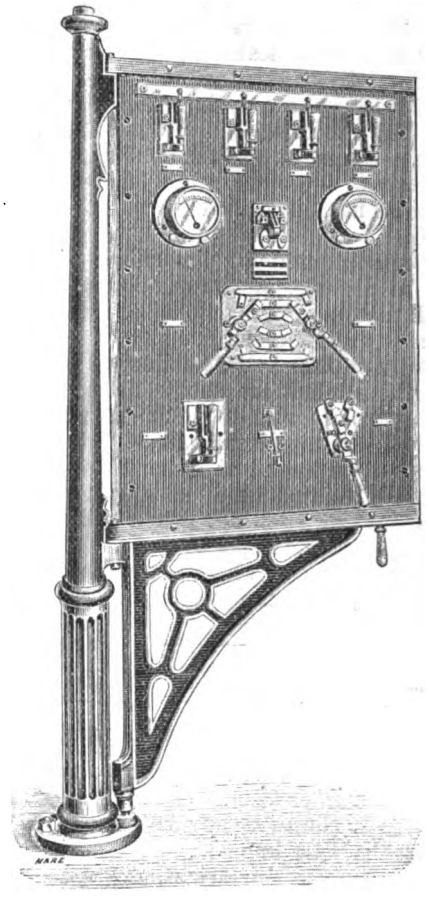
Cadogan Electric Light Company (Limited).—A petition for the compulsory winding up of this Company has been presented by Mr. Henry Lowenfeld, of 31, Lowndes-square, and is down for hearing before Mr. Justice Kekewich on October 31st.

Bankrupts.—At a meeting of the creditors of Hugh A. Fergusson, Berkeley Lodge, Upper Berkeley-street, held on Thursday at the London Bankruptcy Court, before Mr. H. Brougham (Official Receiver), it was resolved to wind up the estate in bankruptcy, and appoint Mr. C. J. Singleton, Staple Inn, trustee, to act with the assistance of a committee of inspection.

——— A receiving order has been made against Victor Silberberg, who is described as of 47, Oxford-street, electrical fittings manufacturer, trading as the Electrical Fittings Manufacturing Company. The act of bankruptcy is a deed of assignment to creditors. No particulars transpired at the meeting.

Lamps and Lamp Shades.—The *Observer* of Sunday last contains an interesting article on the above subject. The remarks of the *Observer* correspondent apply chiefly to gas lamps and shades, but many of the fancy designs referred to are of equal service in electric lighting displays.

A Swinging Switchboard.—Messrs. Newton and Hawkins, of Taunton, make a switchboard arranged with hinges, these hinges being attached to hangers on the wall, or to a cast-iron pedestal



bolted to the floor. This allows connections to be got at, and alterations to be made with great facility, enough slack being left in the wires to allow the whole board to be opened like the door of a cupboard.

COMPANIES' MEETINGS & REPORTS.

Eastern Extension, Australasia, and China Telegraph Company (Limited).

The thirty-sixth ordinary general meeting of this Company was held on Wednesday last ; Sir John Pender, K.C.M.G., presiding.

The SECRETARY (Mr. F. E. Hesse) read the notice convening the meeting and the minutes of the last meeting, which were approved by the present meeting and signed by the Chairman as correct. The report of the Directors was taken as read.

The CHAIRMAN : Before asking you to approve of the report I will, as has been my custom, first make some few remarks upon it. The gross receipts for the half-year under review amounted to £264,878, against £254,856 for the corresponding period of 1890, showing the substantial increase of £10,022, and this would have been even greater but for the fact that the accounts include two months' receipts at the reduced rates to Australia, to which I shall more particularly refer later on. The working expenses have been £71,476, against £76,670 for the corresponding half-year, showing a decrease of £5,194, which is accounted for by the ships' expenses having been lighter during the past six months than in the corresponding half-year of 1890. The net revenue has amounted to £155,165, against £136,675, for the corresponding period of 1890, showing an increase of £18,490, due to the causes already explained. Two interim dividends at the rate of 5 per cent. per annum have been distributed for the half-year under review, amounting to £62,500, and the balance of £92,665 is carried forward. The conversion of the Six per Cent. Debentures into Four per Cent. Debenture Stock has been satisfactorily completed during the past half-year, and it is gratifying to find that the new stock is quoted in the market at a substantial premium—6 to 8 premium. This stock was distributed among the shareholders at par. With regard to cable operations, further renewals have been made to the Tonquin-Hongkong section, about 140 knots of cable having been

Digitized by Google

inserted since the last meeting, and the cable is now in good working order. Total length of cable, 469 miles. By degrees we shall practically renew this cable. Several small interruptions have occurred during the past half-year, but the traffic has been practically unaffected, owing to its transmission by the duplicate line. Since the close of the half-year the Madras-Penang (original) Cable has broken a short distance from where the renewal work carried out last year terminated; but the duplicate cable laid last year is carrying the whole of the traffic without the least delay, and no inconvenience has therefore been experienced. Fine weather is now reported to have set in in the Bay of Bengal, and as the s.s. "Recorder" will be in the vicinity of the break in a few days, it is anticipated that communication will be restored very shortly. The Company's station at Elephant Point at the mouth of the Rangoon River, which, as I mentioned at a previous meeting, was endangered by the rapid encroachment of the sea, has, by arrangement with the Indian Government, been closed, and a considerable portion of the cable between Elephant Point and Penang picked up and used elsewhere. An arrangement has also been entered into with the Dutch Government for extending the Company's system to Sumatra by laying a submarine cable from Penang to Deli, the centre of the tobacco district of Sumatra, from which an additional source of traffic is expected. The length of this cable is 166 knots. The cable will moreover open up an alternative route to Java and other portions of Netherlands India, and as it will be provided from the stock at Singapore, the work will be carried out at a comparatively small cost. It is with deep regret that I have to announce the death of our colleague, Sir Thomas Fairbairn. He was one of our Directors from the early days of the Company, and, though during the past few years he had suffered from bad health, still his mind was clear to the very last. We do not propose to fill up his seat at the Board at the present time, as the number remaining is sufficiently large to efficiently conduct the Company's affairs; but we shall always make it a point at our Board whenever an active member falls out to replace him by someone who will be useful to the Company. I have now given you some particulars of the work we have been doing during the last six months; and I will just supplement those remarks by saying that I am satisfied that you will be pleased with the accounts which we have put before you to-day. Very few companies indeed can carry forward the amount we have carried forward. It is only twelve months ago that I announced to you that we were negotiating for an alteration in our tariffs with the Australian Colonies. Six months ago I told you that we had completed those negotiations to our satisfaction; and to-day I am able to tell you, after some little experience, though a short experience, of the working at the reduced tariff, from 9s. 4d. to 4s., that I believe the Companies will not eventually lose in any way by the arrangement, and that the general telegraphing public will benefit very largely indeed. In saying this, however, I must also make this remark—that we have been dealing with English-speaking people—people who know the value of telegraphy—people who use it for commercial purposes; and as they find that the more they use it, the more trade grows, that is our hope in the future. We cannot calculate on the same results in countries where the English element is comparatively small to the population, such as India and China. We have made reductions there, but we have not got the same return. I make these remarks with the view of their coming before the English merchants in India and China, and I trust that they will think twice before they allow themselves to go back in the commercial race. I believe that submarine telegraphy has established such a connection between this country and commercial interests all over the world, that it is impossible to carry on business without using the cables. That is a bold statement; but I make it because I know something of commercial life, and I know where energy is applied and where strong will is exercised, they will find that the more closely they keep in touch with the mother country the more prosperous will their relations be. I cannot say so much of the local traffic; but in dealing with the Japanese and the Chinese we have got people who are very keen, painstaking, and persevering, and I think it likely that any good example set by the English community will be eventually followed by those who see that what benefits the English should benefit them also. The next time I meet you I hope to be able to tell you that the reduction in the tariff from 9s. 4d. to 4s. has been a practical success, and that it is likely to be a permanent institution. I cannot leave this subject about the reduction of tariffs without expressing my thanks, as I did last year, to the agents-general of our colonies who took part in the bringing about of this arrangement. Two of them are returning to their colonies. Sir Dillon Bell has already left, and Sir Graham Berry is shortly to leave. Sir Dillon Bell took an active part in the negotiations, and was very much disappointed to find that the state of things in his colony did not admit of their taking a share in the guarantee. But I believe his influence will be used in New Zealand to further the arrangement which I believe will be crowned with success, and that he will try and bring New Zealand into it, so that she may share in its advantages. Sir Graham Berry, who has throughout taken a most active part in this matter, is returning to Victoria, and I know that we shall have in him an intelligent supporter of any system that will bring into closer relations the Colony which he has so ably represented with the mother country. I know he believes that the more they can work together the more successfully will their respective interests be promoted. When just before coming here I looked through the speech that I made to you six months ago, I found that it was so full of details in regard to the questions of which I have been speaking to-day, that to go further into them now would only be repetition. Six months hence I hope I shall be able to congratulate you, the Directors, and the Colonies, upon the success of this grand experiment, which I feel sure is likely to prove satisfactory. When we see everything progressing well, and we can pay you good and steady dividends, adding to the reserve fund, and strengthening ourselves in every possible way, I think we ought not to forget the fact that a great Company like this has now attained a position when it should think of those who have been more or less identified in bringing about such great results—I refer to our staff generally. We are anxious that a fund should be established and promoted for the purpose of giving pensions to those who are in our service. This service is a peculiar one. It is one that requires intelligence, honesty, and a good deal of self-reliance. We have to send out young men to our different stations all over the world, and nothing pleases me so much as from time to time to find that when our stations have been visited by distinguished men from this country, we receive reports stating that our young men are a credit to the country and the Company they represent. Perfectly knowing the value of our staff, the important position they hold, and that they have to live like gentlemen, we want them when the time comes when they must retire to have something to look forward to on their taking that step; and I think that the Company in its days of prosperity can justly contribute to the fund required for enabling that to be carried out. It is proposed that the Company should contribute to a Pension Fund something like 5 per cent. per annum on the staff salaries, and the staff contribute 2½ per cent.; but the details of this proposal will be settled later on by competent actuaries. All that I ask you to-day is to approve generally what I have foreshadowed. Some years ago you agreed to contribute towards an Assurance Fund, and we are going now to practically merge that fund into the Pension Fund. The Company's 5 per cent. will amount to a little over £2,000 a year in addition to the £1,500 already authorised for the Assurance Fund, and we hope in a few years' time to accumulate such a fund as will enable us to make an allowance upon retirement that will place a man in more or less comfortable circumstances. I have now given you a general idea of what we want to do, and I feel confident that in the midst of our prosperity you will not forget that something is due to those who have helped to build up our success. I shall put no formal resolution to you to-day on the subject, as the details must first be thoroughly worked out, but six months hence I hope to be able to bring this matter before you in a more explicit and formal manner. I now beg to propose—

"That the report and accounts of the Directors, now submitted, be received and adopted."

The Most Hon. the MARQUIS of TWEEDDALE: I beg to second the resolution.

The CHAIRMAN: If any gentleman wishes to put any question to me regarding any point that I may have omitted, I will answer him with much pleasure to the best of my ability.

Mr. JOHN NEWTON: I do not think that a resolution of this kind should be passed without something being said from this side regarding the proposed pension fund. At a time like this, when we all see a profit on our investment in the Company, I feel convinced that there is not a shareholder who will not heartily endorse what you have said; and we are very glad to find that, although rather late in the day, you are proposing this arrangement in connection with our staff. I think it should have been proposed years ago. The shareholders are greatly indebted to the Directors for their successful management, and to the staff for the assistance which they have rendered. The staff have not the Directors about them; and you may depend, therefore, that we have splendid representatives when such reports are made about them as those to which the Chairman has referred. Another point which I think the shareholders have to congratulate you upon is the reduction of the tariff from 9s. 4d. to 4s., and I am very glad to see that that measure has been attended, so far, with success. I think that the Directors and the staff may be congratulated upon the successful result now shown, and I believe, as I have already said, that we shall all heartily support the proposed pension fund.

Captain LEWIS: If you will allow me, I should like to add my congratulations to the Directors for taking this subject into consideration I have served in many of the climates where our young men are, and I can speak well of their acts and doings. Every person who has travelled in China, Batavia, and the Eastern Archipelago, must know the diseases to which they are subject—dysentery and fevers of all kinds; and surely when a man has broken down in the service, he has some claim on a great and rich Company like this, just as in the case of the army, the navy and the civil service.

The CHAIRMAN: Before I ask you to pass the resolution, I wish to thank Mr. Newton and Captain Lewis for the remarks which they have made, as I believe, when they are printed and sent abroad, they will convey even more gratification to our young men than any remarks I might make. They are aware that I know all about them, and am interested in them; but when they find that the views held by the Chairman and Directors are approved by the shareholders it will be a double satisfaction to them. I am, therefore, quite sure that the remarks which you have made to-day will be just as much appreciated by them as they have been by ourselves. It has been the desire of this Board to make this Company strong in every sense of the word—strong in the support they have from their staff, strong in commanding the confidence of the shareholders, and, above all, strong in having the unanimous support and approval of the great body of people who use the telegraph system. With these remarks I beg to put the motion. He then put the resolution in the usual way, and declared it carried unanimously. Continuing, he said: Gentlemen, that closes the business of the meeting; and just let me add that I should have liked to see more shareholders here to-day. The Directors like encouragement as well as the staff, and, although we like the people who are away to repose confidence in us, at the same time it is far more satisfactory to the Directors to see the shareholders come to the meeting.

Mr. GRIFFITH: May I be permitted to propose a vote of thanks to our able Chairman and his colleagues? I think that the absence of our fellow-shareholders is an argument in favour of their confidence in the Directors. If they take this report in their hands they can certainly

Digitized by Google

have no objection to offer to the management. I think that the remarks that have been made by the Chairman tend to encourage those who are here in regard to our prospects. It is most satisfactory to find that so bold an attempt to promote the interests of the commercial world as reducing the tariff from 9s. 4d. to 4s. has been satisfactory as far as it has gone. I am glad to find such progress, but, on the other hand, I regret that our Indian and China fellow subjects are not quite so ready to avail themselves of the great advantages offered to them by the Company. I think it is only by telegraphy that we can maintain our position in banking and commerce. You have heard the interesting speech which has been delivered by the Chairman, and you have the Directors' report; and I think that you will all agree that our thanks ought to be tendered to Sir John Pender and his colleagues.

Captain LEWIS: I have much pleasure in seconding the motion, and I am glad to see the Chairman looking so well.

The resolution was carried unanimously.

The CHAIRMAN: I am very much obliged to you on behalf of my colleagues and myself for this renewed expression of your confidence in us. I can only say this, that as long as we continue to be in such perfect touch with our shareholders—such a united body—I think we cannot fail to command success. At all events, if success can be gained by good intentions, your Board will be sure of achieving it.

The proceedings then terminated.

The Brazilian Submarine Telegraph Company (Limited).

The thirty sixth ordinary general meeting of the shareholders of this Company was held at Winchester House, Old Broad-street, on Wednesday last, under the presidency of Sir James Anderson.

The SECRETARY (Mr. Richard Collett) read the notice convening the meeting and the minutes of the last meeting, and the report was taken as read.

The CHAIRMAN: In the remarks I am about to make I do not know whether you will regard them as discouraging or otherwise, but I felt at our meeting six months ago that I ought to call your attention to an active competition which was being created, and now I feel that I must not keep back anything you ought to know, or give a colouring, good or bad, to the facts of our position. I shall therefore read the remarks I have prepared, conscious of my responsibility in view of what may be a turning point in our history. I need only call your attention to a few leading items in the report and balance-sheet. We have increased our agencies by establishing agencies, especially at Buenos Ayres—a most important agency, which accounts for the greater part of the increase of £500 under this head, Abstract B, as compared with the corresponding period of 1890, and I anticipate we shall yet be compelled to add to this amount for other agencies. The salaries are £218 more, necessitated by the increase of work; and we must further add to this amount when we establish duplex, a few weeks hence. For laying on water to our Madeira station we have had to pay £187. Travelling expenses, stationery, and sundry items are larger in consequence of dealing with an increased and abnormal revenue. But as a set off there has been some saving in the expenditure, as follows:—The electrical expenses show a decrease of £361. The Sanatorium at St. Vincent, which cost £600 last year, does not appear again, and the cost of repairs to buildings has been £395 less, showing altogether a reduction in the expenditure of £1,350, so that there is in the aggregate a decrease of £83 upon the working expenses; while there has been an increase in the revenue of £33,920, and the gross revenue for the half-year is £158,000. In the report we have properly stated that this revenue is exceptional, and largely due to disturbances in South America with which we are all familiar; and I may here call your attention to the fact that the current half-year will have to bear the cost of a repair near Pernambuco, referred to in paragraph 6 of our report, amounting probably to at least £10,000, and the cost of duplexing our cables about £6,000. This will explain the wisdom of carrying forward so large a sum. There is also in the balance-sheet under review a sum of £11,200 which has been long in dispute. We cannot of course look forward to the recurrence of such an item in our favour. Neither can we hope, and we ought not to hope, for a recurrence of such a series of disastrous revolutions as have augmented our receipts abnormally for the last twelve months. We must, in fact, be prepared to anticipate a period in which the cry for economy and retrenchment both in political and commercial circles will be such as must reduce our revenue. Nor is this all that can and has already come upon us. You may remember that when I had the honour of presiding at your last meeting I pointed out upon the map the various opposing lines which were being promoted. Since then one line—the French Antilles cable, up to the present extending from Hayti to the vicinity of Para, a short distance from the terminal station of the lines of our partners, the Western and Brazilian Company—has been completed and opened for traffic. Up to the present time this rival line has not done us much harm, but they will no doubt learn to take some traffic. I do not know if they intend to lower the tariff, and we do not yet see that it is our policy or in your interests that we should initiate a war of tariffs. The termination of the civil war in Chili has again brought into active rivalry and competition for traffic what is called the Central American Telegraph Company. We have had to count with this active competition for a good number of years, and we did not suffer much. As to the amount of injury they can do us in the future, a great deal depends upon the question of their adopting an unremunerative tariff, and extending their cables to the east coast. There is still another rival cable from Senegal to Pernambuco, which we are assured will be laid in about six months, and which I pointed out to you on the map at our last meeting. The main injury this rival line will do us will also depend upon the tariff they adopt. This, however, we can say with certainty, that whatever tariff any of these lines may adopt, we shall adopt the same, or lower; and beyond all controversy each and all of our rivals will regret a war of rates more than we shall. We have no right to complain that promoters and contractors should engage in such enterprises if their judgment cannot see anything better for the exercise of their energies and the expenditure of their money than following where we have led, and for a good many years struggled on without any increase of revenue, bearing what is commonly called the heat and burden of the day; paying only 5 per cent., with an insufficient reserve for at least five years. It is a common saying that imitation is the sincerest form of flattery; and if we were vain we might take credit for far-seeing sagacity and ability in projecting the first cable to Brazil; but as it will do no good to your interests, and we are not vain, we shall not ask any consideration upon that score. We must let sentiment alone. We have seen the possibility of these lines coming into existence for years. There was no way of staving them off otherwise than by paying very large sums for concessions, and laying unnecessary cables, which would have depleted your reserve years ago, with no profitable result whatever. We have left to others to try this experiment, and we have kept our money, and you have had your dividends averaging for the 17 years a trifle over 6 per cent., and now we must look on and see how far this lavish expenditure has been judicious, and study how far we can best meet the competition. We adopted the policy of increasing your reserve and laying another cable out of that reserve, thereby increasing our carrying capacity without increasing our capital; so that with a large carrying capacity and a moderate capital we are in the position of carrying a large traffic which a reduced tariff may happily develope. This Company has duplicate cables throughout. Our partners, the Western and Brazilian, have duplicated their system over their most important sections, and both Companies are establishing duplex over every section of their cables. We think these provisions, with our experience, should give us a service that will secure us a large share of the traffic. Then I may here say that we are not without resources to carry our energies into the pastures of our rivals; but I must not be too explicit upon this point at present. You may be sure that your Directors are not neglecting any and every feature which bears upon united and harmonious working with our partners, and extending our efforts whenever we can usefully do so. Of course I have something in my mind when I say that, but I shall not say anything more explicit about it now. I know I am speaking rather vaguely—you must trust us. The duplex will cost us money—we shall need a larger staff; everything we now do, even to hold our own, will cost us money, and I personally should be willing to do something that will cost us some pecuniary sacrifice to carry out extensions; but we have reached a stage in our existence when we cannot halt, we need not lead, and run away we shall not. I congratulate you, therefore, that, besides paying you on this occasion a good dividend and a large bonus, we are carrying a good sum to our reserve, not too much, however, when you consider that we have the maintenance and the life of two cables about 7,365 miles in length to provide for. The first duty of your Directors is to secure the maintenance of your property, and I am glad that the duplication of our cable is complete. Your reserve is a substantial amount, and we are as ready for the fray, if fray it must be, as any of our rivals, who have, so far, only single cables. I am not going to boast—there is an old saying, and you know where it is written, "Let not him that girdeth on his harness boast himself as he that putteth it off." We have for years seen the probability of this competition, and I think it only fair to warn you that we must not expect the continuance of an 8 per cent. dividend. We must spend money to meet negotiations which are daily engaging our attention. We must be prepared for a falling off in our revenues, whether the threatened tariff is inaugurated or not; and we must, in short, keep all the money we can in our reserve. It is altogether in your best interests that this should be done. At the same time we do not stand alone. The Globe Telegraph Company, our partners, the Western and Brazilian, and the Eastern Telegraph Company, and some others, are deeply interested in our success. Now, gentlemen, this is the second time I have told you this story. The use of the telegraph is progressing; every year seems to show a moderate increase over the general system of international telegraphy, not always on every section, but sometimes in one direction, sometimes in another, alternating and gradually pervading the whole system. This rivalry may prove to be a blessing in disguise; but, without pretending to prophecy, some of our rivals, in my opinion, will have to wait longer for their share of the blessing than we shall. I do not take a desponding view of our future, but it would be wrong on my part not to tell you as fully as I may the nature of our immediate prospects. The more I reflect upon it the more am I convinced we were right in not expending large sums of your money upon acquiring concessions and laying cables years before they were needed, neither do I dread a reduced tariff: but whenever it comes it is certain that for some years it must yield a reduced revenue. Since 1876 we have from time to time made reductions varying according to locality and destination from 33 to 57 per cent. of the original tariff, and we should in all probability have again reduced the tariff before this time but for the rival cables that we saw springing up. At present, however, we are, we think, justified in pausing and waiting for our rivals to take the first step if they intend doing so; a reduction of tariff on our part at this moment would be a deliberate throwing away of money, and it would not stop any of our rivals from promoting their schemes. Still further upon the assumption, and it is only an assumption, that a reduction of the tariff, if substantially large, would increase the traffic, and temporarily retard our rivals with their single cables; it is certain that pending this growth of traffic we should be the losers, and that as soon as this growth became apparent our rivals would certainly rush on as they are doing at present. So that we should have borne all the loss of the initiation of a reduced tariff with no doubt some increase of traffic, only to have the increasing traffic shared with competitors. These and

Digitized by Google

other points are subjects of daily consideration with your Directors, and I feel that I ought not to add another word as to our policy or plans at this meeting. I now move—

"*That the report of the Directors and the accounts to June 30, 1891, now submitted, be approved and adopted, and that a dividend be now declared of 1s. per share (making, with the interim dividends already paid, a total dividend of 6 per cent. for the year ended June 30, 1891), and also a bonus of 4s. per share in respect of the profits for the year ended June 30, 1891, the said dividend and bonus to be respectively free of income tax.*"

Mr. FREDERICK YOULE seconded the motion.

Dr. TREWHELLA asked when the Company's monopoly ceased.

The CHAIRMAN replied that it would cease next year, but although they had protested the Brazilian Government had given another concession.

Dr. TREWHELLA: But it cannot come into operation, I presume?

The CHAIRMAN: Oh, yes, whenever they like. What do Governments care for us? We are merchants, and we shall have to fight our competitors. He then put the resolution, which was carried unanimously.

On the motion of the CHAIRMAN, seconded by Mr. J. DENISON PENDER, the Hon. W. St. John F. Brodrick, M.P., was re-elected to his seat at the Board, as was also Lord Sackville A. Cecil, on the motion of the CHAIRMAN, seconded by Mr. THOMAS FULLER (tho Managing Director).

Dr. TREWHELLA then proposed the re-election of the auditors, Mr. Henry Dever and Mr. John Gane.

Mr. HAWKES seconded the motion, which was unanimously adopted.

Dr. TREWHELLA then proposed a cordial vote of thanks to the Chairman and the Directors for their vigilant watchfulness of the shareholders' interests. He had observed in nearly everything that the Chairman had said a great deal of caution, and he thought that this must commend itself to them all. He had been connected with the Company from the very beginning, having been one of the original allottees, and he thought they were in very excellent hands.

Mr. HAWKES seconded the motion, which was unanimously adopted.

The CHAIRMAN, in acknowledging the vote, assured the shareholders that they were doing all they could to maintain the interests of the Company.

The proceedings then terminated.

The City of London Electric Lighting (Pioneer) Company (Limited).

An extraordinary general meeting of the City of London Electric Lighting (Pioneer) Company (Limited) was held at Winchester House, Old Broad-street, on Tuesday last, under the presidency of the Hon. Alan Charteris, when the subjoined resolution, which was passed at the extraordinary general meeting of the Company held on September 30, was submitted for confirmation as a special resolution—

"*That the Company be wound up voluntarily.*"

Mr. J. C. BULL read the notice calling the meeting and the minutes of the last meeting.

Mr. RONALD H. SAVORY proposed—

"*That the resolution passed at the extraordinary general meeting of the Company held on September 30th, namely, that the Company be wound up voluntarily, be confirmed,*"

which was seconded by Mr. W. H. KEED, and carried.

Mr. RONALD H. SAVORY proposed—

"*That the Hon. Alan Charteris and Mr. J. Cecil Bull be, and are hereby, appointed liquidators of the Company for the purpose of such winding up, at a remuneration of 50 guineas each,*"

which was seconded by Mr. J. A. KELMAN, and carried.

The proceedings then terminated.

NEW COMPANIES, STATUTORY RETURNS, &c.

BRITISH MEXICAN ESTATE COMPANY (LIMITED).—This Company was registered on October 14, 1891, with a capital of £200,000, divided into 39,800 shares of £5 each, and 5,000 shares of 5s. each, by T. Cresswell, Stanmore Villa, Hither Green, Lewisham, S.E. As the name implies, the objects are to acquire and develope estates in Mexico, and to construct, execute, equip, work, and control railways, tramways, docks, electric light, heat, and power works, telephones, telegraphs, &c.

MANCHESTER SHIP CANAL, PONTOONS, AND DRY DOCKS COMPANY (LIMITED).—The above Company was registered on October 14, 1891, with a capital of £300,000 in £10 shares, by C. Doubble, 14, Serjeants'-inn, Temple, E.C., while their main objects are to construct dock and shipbuilding yards on the Manchester Ship Canal. One of the articles in the Memorandum of Association reads, "To carry on business as electrical engineers and suppliers of electricity for the purposes of heat, light, motive power, or otherwise." The first Directors are G. Renwick, T. Bell, J. T. Eltringham, and A. Taylor.

C. MEADOWS AND COMPANY (LIMITED).—This Company was registered on October 16th, 1891, with a capital of £20,000 in £10 shares, by Franklin, Wild and Co., 14 and 15, Broad-street-avenue, E.C. The objects are to acquire and carry on the business of C. Meadows and Co., forgers, roller and steel manufacturers, mechanical and electrical engineers, brassfounders, machinists, &c., at Tinsley Park Works, near Sheffield. The first Directors are C. Meadows, Park-lane, Broomhall Park, Sheffield, and A. Senior, of 7, Parkers'-road, Sheffield, the former being the Chairman and Managing Director. Office: Tinsley Park Works, Tinsley Park-road, Sheffield.

SERPOLLET SYNDICATE (LIMITED).—This Company was registered on the 15th October, 1891, with a capital of £2,000, in £1 shares, by T. F. Wild, 15, Broad-street-avenue, E.C. The objects are to acquire certain patents for the generation of steam and the regulation of the supply thereof to motors, to design and manufacture all kinds of steam boilers, including those of the Serpollet system, and all accessories thereto, and to carry on the business of mechanical and electrical engineers, brassfounders, metalworkers, boilermakers, millwrights, &c. The regulations of Table A mainly apply. Registered office: 15, Broad-street-avenue E.C.

AURORA ELECTRIC LIGHTING AND DISTRIBUTION COMPANY (LTD.).—The statutory return of the above Company, made up to October 12, 1891, was filed on the following day. The Company, which was registered on May 29, 1891, has a nominal capital of £25,000 in £1 shares; 35 shares have been taken up, the full amount called, and all calls paid. The original subscribers are the only shareholders. No agreement has as yet been filed for the taking over of any business. Registered office: 54, New Broad-street, London, E.C.

BOURNEMOUTH AND DISTRICT ELECTRIC SUPPLY COMPANY (LTD.).—The statutory return of the above-named Company, made up to October 10, 1891, was filed on the 15th following. The Company which was registered on June 1, 1891, to take over the businesses of supplying Bournemouth and district with electricity, carried on by the Brush Electrical Engineering Company (Limited), has a nominal capital of £50,000, in £5 shares. 5,725 shares have been taken up, and upon 2,570 £3 per share has been called, and £7,271 out of £7,710 paid. The remaining 3,155 shares have been issued to the Brush Electrical Engineering Company (Limited) as fully paid. Of the 2,570 shares 435 are taken up by the Brush Electrical Engineering Company (Limited), 1,741 by the Electric and General Investment Company (Limited), of 1, Great Winchester-street E.C.; and the remainder taken up locally. Office: Observer-chambers Albert-road, Bournemouth.

MAXIM-WESTON ELECTRIC COMPANY (LIMITED).—At an extraordinary general meeting of the above-named Company, duly convened and held at Winchester House, Old Broad-street, in the City of London, on Thursday, August 7, 1890, the following extraordinary resolution was duly passed:—"That it has been proved to the satisfaction of this meeting that the Company cannot by reason of its liabilities continue its business, and that it is advisable to wind up the same accordingly voluntarily." And at the same meeting John Marks, Esq., of 113, Great Russell-street, Bloomsbury, in the County of Middlesex, auctioneer, and James Hodgson, Esq., of 19, Queenhithe, in the City of London, paper merchant, were appointed joint liquidators for the purposes of such winding-up. (Filed on October 17, 1891).—This Company was registered on January 17, 1889, with a capital of £75,000, divided into 500,000 shares of 3s. each, to acquire the business and property, and to undertake the liabilities of the Maxim-Weston Electric Company (Limited), then in liquidation, the Directors being Messrs. J. Marks, J. G. Couchman, G. H. Hildyard, J. M. Klenck, and L. Swaby. At the time of the statutory return (May 30, 1889), 261,886 shares had been taken up, upon all of which 2s. per share had been considered as paid, while a call of 6d. per share had been made, resulting in the payment of £6,433. 0s. 6d., leaving £114. 2s. 6d. unpaid. At the time of the first annual return (May 23, 1890) 269,696 shares had been taken up, a similar sum being considered as paid, while a call of 1s. per share had been made. Office: 55, Victoria-street, Westminster, S.W.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY (LIMITED).—The traffic receipts for the week ended October 16th were £4,461.

CITY AND SOUTH LONDON RAILWAY COMPANY.—The traffic receipts of this Company for the week ended October 18th amounted to £794; aggregate receipts for half-year to date, £11,205.

COUNCIL BLUFFS (IOWA), U.S.A.—The coupons due November 1st prox. in New York, on Council Bluffs (Iowa), Gas and Electric Light Six per Cent. First Mortgage Gold Bonds, numbered from 1 to 50 inclusive, will be paid by the City Bank (Limited), at the exchange of $4·85 per £, on and after October 20th. The coupons must be left three clears days for examination.

ELECTRIC ARMS AND AMMUNITION SYNDICATE (LIMITED).—The adjourned petition for the winding up of this Company was heard before Mr. Justice Jeune on Wednesday. Mr. Marten, Q.C., and Mr. Smith for the petitioners, submitted that the substratum of the Company was gone, and that it ought to be wound up; but Mr. Justice Jeune, without calling on Mr. Millar, Q.C. and Mr. McLaren said that, having regard to the statement of Dr. Fleming and to the letter of Major Walker, the Chairman of the Company, he did not consider that the Petitioners had made out their case, nor did he consider that the time had yet arrived for winding up the Company, and therefore he dismissed the petition with costs.

Digitized by Google

NATIONAL ELECTRIC SUPPLY COMPANY (LIMITED).—The prospectus of this Company has just been issued. The capital is £100,000, in £5 shares, of which 100 are founders' shares. £20,000 has already been applied for by the Directors and their friends, and the present issue is 12,000 ordinary shares. Applicants for 120 ordinary shares are entitled, on allotment, to one founders' share at par value. The founders' shares are entitled to one-third of the net profit, after payment of 7 per cent. on the ordinary shares, which are entitled to the remaining two-thirds. The Company has obtained a provisional order for lighting by electricity the whole of the municipal borough of Preston, where a temporary installation has been in operation by the Company for the past six months, the success of which has determined the Company to put down a permanent installation. The system adopted is the low tension, and the wires will all be underground. A contract has been entered into with Messrs. Latimer Clark, Muirhead, and Co. (Limited) for carrying out the installation; and a convenient site has been secured for the central station. Mr. C. H. Cobbold is the Chairman of the Board; the Engineer and Manager is Mr. Fred. F. Bennett, M.I.E.E.; and the Secretary (*pro tem.*) is Mr. Titus Thorp, with offices at Victoria-buildings, Preston. The list of subscriptions will close on or before Thursday next, the 29th inst.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended October 16th, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £3,535.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 702.—Vol. XXVII. FRIDAY, OCTOBER 30, 1891. Price Fourpence.

NOTES.

The result of the introduction of the trolley line system of electric traction into this country will be watched with interest by electrical engineers. It is one thing to disfigure the important thoroughfares of a town with the overhead conductor, or, still worse, with the network of suspending wires which are generally required at each corner or sharp curve; and it is another thing to place an outlying suburb in connection with the busy part of a city by a tram line passing through the frequently squalid districts which intervene. Inhabitants of those towns which can boast of greater architectural features than can be found on the route of the new line at Leeds may be thankful that the experiment is being tried there. No one who is familiar with the beautiful country to the north of that town would like to see the complicated insulators and sprawling "frogs" hung up in the sky, as incidents in the foreground of an abbey or a dale. The experiment may be welcomed by our makers of traction machinery, since, if it gives satisfaction, they have only to go forward and erect such lines wherever they may be wanted. If the conditions of this contract are no better than those which were being negotiated a short time ago, no English manufacturer would have cared to undertake it, and thus an opportunity has been afforded them of standing on one side, and seeing the specimen of the American work which this line is an attempt to introduce.

The German electrical instruments which are described by our Frankfort correspondent in the present issue strike the English eye as being in a somewhat undeveloped condition; and yet we are fully aware of the strides which electrical engineering has recently made in that country, the high aim and thoroughness with which it is carried out, and the accuracy which everyone expects to find in German scientific work. The name of Kohlrausch is or should be familiar to all students of physics, many of whom are greatly indebted to the well known book by that author on physical measurements. The Kohlrausch ammeter is of a type which has appeared on several occasions. Prof. Blyth spent a good deal of pains upon it. Profs. Ayrton and Perry reduced the displacement of the core to a minimum; and Mr. A. Miller was working on a core floating in mercury at the time of the Inventions Exhibition, magnifying the motion by the displacement of liquid in a fine glass tube. Thin as the tube of iron may be, we fail to see how the serious errors which are caused by the presence of iron can be avoided. In the best English instruments the iron is reduced to a little morsel of wire, and every effort has been made to correct the errors which even these few grains produce. The cores of some American solenoid instruments run into ounces.

A recording voltmeter is not a very difficult instrument to make, for the range need not be great. The elimination of the friction of the pen is one of the chief difficulties. But a recording ammeter is a very different matter, for it is necessary that it shall go back to a definite zero, besides working correctly throughout its range. The important point, however, is the production of a uniform scale, without which all measurements of areas are impracticable. We observe in the illustration of the Hartmann and Braun instrument (Fig. 3, p. 717), that the scale does not appear to be uniform. It would be easy to criticise the motor-meter and the magnetic cutout, but it is very possible that they give satisfaction, so we only call the attention of English manufacturers to them.

It is fortunate for this country and for its overgrown capital that our progress in other directions has been more rapid than it has been in regard to the telephone. Even if we leave out such apparently phenomenally talkative countries as Sweden, Norway, and Luxembourg, Great Britain figures very badly on a list which will be found in our "Notes" column. In Germany it seems over 100 individuals per 100,000 inhabitants find the telephone within their reach; in Great Britain less than 60 can afford it. In Berlin more than 11 citizens per thousand use the telephone; while in London the figure is 1·5. The telephone may not be an unqualified blessing, but these comparisons show that there is something rotten in this respect in the state of Denmark—or rather England.

Mr. Bayly's letter to *The Times* of Wednesday again draws attention to the pressing need for telegraphic communication around our coast, a subject which the Associated Chambers of Commerce are constantly urging upon the Government, but apparently without much encouragement. This time Mr. Bayly tells a pathetic story of the wreck of the "Marana," one of four ships totally lost during the blizzard storm last March, within a short distance of the Start lighthouse, and the drowning of 25 of her crew, owing to there being no electric connection with the Prawle coastguard station. What is true

Digitized by Google

of that part of the coast is equally true of many other points, and it is scandalous that preventive measures are so long delayed simply because no single department of the State cares to incur the expense. If these lightships, lighthouses, and coast-guard stations belonged to some railway company the obligation to employ them humanely for the saving of life, as well as commercially for the protection of property, would have been sternly enforced long ago. This is distinctly a national question, and the expense of establishing an electric girdle round the British Isles should be a charge upon national revenue.

A few months ago we alluded to some experiments of Mr. F. J. Smith, who had examined a variety of electro-magnets with the special object of finding the form most suitable for use in chronographs. It now appears, from an article contributed by the same investigator to the October number of the *Philosophical Magazine*, that the best kind of electro-magnet for this purpose consists simply of a twisted iron wire used as the core of a long solenoid. It has long been known that under certain circumstances twisted iron wires untwist when magnetised in the direction of their length; but the fact, like a host of others connected with the science of magnetism, has not hitherto been used for any theoretical or practical purpose. It occurred to Mr. Smith that a light pointer attached to one end of the wire could usefully indicate the flow of current in a surrounding solenoid, and on investigation it was found that such a pointer responds to sudden changes of current more rapidly than is the case with any other form of electro-magnet. The motion of the pointer is very slight, but this is no disadvantage in the stylus of a chronograph, where the great thing wanted is exact coincidence in time between the motion of the pointer and the alteration of the current.

The investigation gave rise incidentally to several interesting points. Wiedemann, who first described the phenomenon, examined twisted wires subjected to stress; and found that magnetisation caused them to untwist. Mr. Smith used wires to which he had given a permanent torsional set, but without exposing them to the influence of longitudinal pull. The magnetic forces he employed were much greater than those used by Wiedemann, and under these circumstances the wire, instead of untwisting, increases its twist when magnetised, and the torsion increases with the strength of the magnetic field. A maximum is, however, reached when the field is about 1,000 times as strong as that due to the earth, and after this the wire commences to untwist.

Our attention was recently called to a small point in connection with the law of electric lighting about which a mistake might easily be made. According to Section 4 Sub-Section 1 of the Electric Lighting Act of 1882, no Provisional Order may be granted unless notice of the intention to apply for it has been served on the Local Authority of the district on or before the 1st day of July in the year in which application is made. On the other hand, a hasty perusal of Rule V. of the Board of Trade Rules (August, 1890), relating to the mode of procedure to be adopted by intending applicants for Orders and licences, would lead one to suppose that this all-powerful Government department had over-ridden the Principal Act, and altered the above mentioned date to 1st November. As a matter of fact, however, the rule in question relates only to applications affecting a district in which there are already statutory electric light undertakings. The rule requires notice to be given to all such "undertakers" within the area, whether Local Authorities or otherwise, and this notice is in addition to that required by the Act itself, to be given to the Local Authority of the district.

The Naval Exhibition, which closed on Saturday last, has been an unqualified success as an Exhibition; that is to say, a place of amusement and mild instruction. Neither the music nor the cuisine were as good as were to be found at the German Exhibition; but the toy warfare and fireworks were thoroughly appreciated. A half-pay Admiral of our acquaintance, though nearly 80 years of age, was very desirous of visiting the Exhibition, as he had never seen a naval engagement. The electric lighting was very satisfactory, although the arc lamps needed an occasional stirring up with a pole. The lighthouse was a feature not only of the Exhibition, but of the metropolis. The light was rather variable—3,000,000 c.p. according to the official account, 500,000 c.p. according to yesterday's *Daily Telegraph*, probably 10,000 c.p. on a photometer. The lesson to be learned by electrical engineers was that an engine-room may be laid with oilcloth and kept as clean as the engineer's office, and the lesson has already borne fruit in more than one central station.

At the moment of going to press we learn that the Leeds Tramway was opened sucessfully by the Mayor, the whole six cars crowded with people being run at once.

"Elektrotechnische Rundschau."—The *Elektrotechnische Rundschau*, which is just entering upon its ninth year of publication, is now appearing twice monthly in a considerably enlarged form.

The Electric Lighting of the New Bankruptcy Courts.—We hear that the electric light is being installed in the new Bankruptcy Court, where it will doubtless be as much at home as it was in the old.

A New Electric Railway Subway.—It is stated that the London and South-Western Railway Company intend to apply next Session for powers to construct an electrical railway in a subway from Waterloo to the City.

Projected Electric Railway between Baden and Voslau.—Negotiations are pending with regard to an electric railway between Baden and Voslau, a distance of about 3 miles. The scheme also includes the lighting of both towns, and the estimated cost is £25,000.

Paddington Vestry.—At the last meeting of this Vestry it was decided that the Works Committee be requested to arrange for a public opening of the electric light installation in the Vestry Hall, the expenses to be met by the subscriptions of the members of the Vestry.

Cable Interruption.—The Great Northern Telegraph Company announce that the Japanese land lines between Hiogo and

Digitized by Google

Osaka are interrupted, owing to a severe earthquake which occurred on Wednesday morning last, and which has caused great damage and loss of life.

Lightning.—During the severe thunderstorm last week the lightning struck a blacksmith's shop at Winfarthing (Norfolk). The fire travelled under the thatch, and demolished seven cottages. Two thatched cottages in Little Melton were fired by lightning the same day and gutted.

Alternate Current Curves.—We hear that the apparatus and diagrams illustrating Dr. Fröhlich's beautiful optico-telephonic method of taking periodic curves, which was exhibited by Siemens and Halske at the Frankfort Exhibition, will be shown by Siemens Bros. at the Crystal Palace.

Sheffield.—At the last meeting of the Town Council the sub committee of the Parliamentary Powers Committee recommended that the Corporation should support the application of the Sheffield Telephone Exchange and Electric Lighting Company for a Provisional Order. The recommendation was adopted.

Temperature Coefficients.—Erratum.—Mr. Fuller asks us to make the following corrections in his last week's letter:—$(1+\alpha)^t - m^t$ should read $(1+\alpha)^t + m^t$, where α and m are both constant; also, instead of "but increased more rapidly as the temperature decreased," read, "but *decreased* rapidly with the temperature."

Telephonic Communication with Plymouth Breakwater Fort.—Telephonic communication has now been successfully established between Mount Wise, Devonport, the breakwater fort in Plymouth Sound, and Fort Picklecombe, on the western shore of the harbour. The work has been carried out under great difficulties, owing to the bad weather.

Proposed Electric Tram Line.—The Sedgley, Dudley, and Wolverhampton Tramway Company are about to apply to the Board of Trade and the local authorities for sanction to use electricity in lieu of steam. During the last two years there has been great difficulty in running the engines, owing to the steep gradients at Upper Gornal and Sedgley Hill.

Huddersfield.—At the last meeting of the County Council it was decided to make application to the Local Government Board for permission to borrow the sum of £50,000 for the purpose of electric lighting works, and the Town Clerk was instructed to take the necessary steps in connection with this matter, and also to obtain the approval of the system adopted.

Electric Launches.—The electric launch apparently bids fair to become an indispensable adjunct to every seaside resort, places as wide apart as Paignton, Bray, and Southport each proposing to have a small fleet of them next season. The General Electric Power and Traction Company are, we believe, preparing to place several electric launches on the Manchester Ship Canal.

Glasgow.—At the last quarterly meeting of the Glasgow Chamber of Commerce attention was drawn to the unsatisfactory working of the telephone system on the trunk lines. For a considerable time past, it was said, the service had been giving great dissatisfaction as regarded the working to Edinburgh and Leith, and individual subscribers could get little or no redress.

The Italian Government and the Telephones.—Last year the Italian Government presented a Bill to Parliament for buying up the telephone system of Italy. This Bill was subsequently abandoned, and the Minister of Public Works has since presented to the Chamber of Deputies another one, according to which, if approved, the service of the telephones is to be carried on by private enterprise for twenty-five years.

The City and South London Railway.—The Directors of the City and South London Railway have arranged to issue season tickets. They have further decided to increase the fares from 2d. to 3d. between the hours of 8 and 10 a.m. on and after November 1st. We may remark in this connection that our New York contemporary, the *Electrical World*, has in its issue of October 24th by far the best view we have yet seen of this Company's generating station. The illustration is accompanied by an excellent and critical description of the line by Mr. Carl Hering.

A New Dry Cell.—A new dry cell, brought out by Herr Leo Graef, in Rotterdam, is said to possess a high electromotive force with extremely good recuperative properties. From tests made it appears that a cell on open circuit gives 1·55 volts. On being closed on a 50-ohm circuit for 13 minutes the volts fell to 1·50, but had again risen to 1·54 after four minutes' rest. On external resistances of 10 ω, 5 ω, and 1 ω respectively the volts after 15 minutes fell to 1·41, 1·31, and 0·95; but a four minutes' interval was sufficient in the last case to raise them again to 1·30.

The Telegraph Line to Gilgit (Kashmir).—The wire to Gilgit is to be an underground one. In fact, any system on posts of the ordinary character would, says the *Indian Engineer*, never stand the winter snows. Even supposing that the wire could be sufficiently raised not to be covered by the drifts—and this, we imagine, could only be done by having a staff in the cold weather to watch how and where the snow principally drifted—the posts would not stand the pressure unless they were placed firmly on cairns of stone. It is calculated that two full working seasons will be needed to carry the telegraph to Gilgit. Both labour and time will be required to lay an underground cable across the mountain ranges covered for seven months in the year with snow.

Worcester.—At the last meeting of the Watch Committee, Mr. Swete, electrical engineer, reported that in accordance with the instructions of the Committee he had canvassed the citizens of Worcester for the purpose of ascertaining the amount of electrical energy that would be required by them in the event of electrical works being established. His canvass had proved that a satisfactory demand for electric light and power existed, in that out of only 388 circulars distributed he received 189 replies taking up lamps or motors equivalent to 13,660 incandescent lamps of 10 c.p. He had but little doubt that if the inquiry were extended an equivalent to 16,000 lamps would be wanted. The report was referred to the Sub-Committee to recommend what should be the next step in the matter.

* Not yet repaired.

The Telegraph across the Kistna River.—On the evening of the 7th September, a Madras paper reports that a daring attempt was made to destroy the telegraph crossing the river Kistna at Bezwada. These crossings, says the *Indian Engineer*, are the longest telegraph "spans" in the world, being something like 1,700 yards in length. There are seven of them across the river from hill to hill; and they are all terminated on stout wooden posts fixed in the rock at the top of the Bezwada and Seetanagram hills, and are protected by wooden houses. At about eight p.m. on the above date these terminals were seen to be in flames. On examination it was found that three out of the seven protection houses were completely burnt, and the terminal posts considerably charred. The heat of the flames destroyed the insulators to which the wires were attached, and the latter fell into the river. It was found that attempts had been made to set fire to all the terminals, but fortunately the fire could not be got to burn, owing perhaps to the strong wind. It is stated to be without doubt a clear case of incendiarism, as matches, charcoal, wood-shavings, and kerosene oil were employed.

"Lightning."—A new weekly journal bearing this name is addressed from Faraday House, Charing Cross-road, to "the great reading public," "householders whose residences are fitted up with electric light," "investors," and others. The "others,"

Digitized by Google

by-the-bye, constitute a large proportion of our own readers. Amongst the attractions is a ladies' column, from "Bess" to "My dear May," various prizes, and a City letter, &c. It is difficult to imagine the kind of investor who would give serious attention to advice from such a source. The technical press have regarded descriptions of apparatus from the point of view of the manufacturer and the trade, but *Lightning* will also cater for the "general reader." The attempt does not look more hopeful than the previous ones which have been made to sit between two stools.

The Chicago Exhibition.—A meeting of the Royal Commission was held at the Society of Arts, John-street, Adelphi, on Wednesday afternoon, 21st inst, to receive the report of Mr. James Dredge and Sir Henry Trueman Wood on the result of their visit to Chicago. The report was received, and ordered to be printed, thanks having been voted to the authors. The Commission considered and approved a form of circular to exhibitors, which was ordered to be issued. They decided to appoint the following Committees:—Finance, Fine Arts, Indian, Colonial, Engineering, General Manufactures, Electricity, Agriculture, Mines and Metallurgy, Textile Industries, Science and Education, Transportation; also a committee of ladies to correspond with the ladies' committee at Chicago. They further decided to invite the assistance of Chambers of Commerce as local committees.

The Electric Light at Kimberley.—The Kimberley papers received by the last mail from South Africa record the inauguration of the new electric installation for the lighting of the borough. The installation has been carried out under the direction of the borough electrician, Mr. David A. Bremner, formerly with the Brush Company. The Mayor, who presided at the inaugural ceremony, said that their original installation cost £7,000, and the yearly expense of working it had been £4,500, and yet complaints were constantly arising owing to the erratic nature of the supply of light. At last they were fortunate enough to secure the services of Mr. Bremner, who had come out specially from England to take up the duties of borough electrician. Mr. Bremner's first duty was to report on the state of the installation, and he uncompromisingly condemned the whole thing. This caused them to look on the new electrician as a man of very expensive ideas; but Mr. Bremner carried the day, with the result that they now possessed what was certainly the finest electric lighting plant in the colony. At a meeting of the Borough Council subsequently, a special vote of thanks to Mr. Bremner was passed. The installation consists of 56 arcs.

Lightning Guard for Electric Light Installations.—The latest form of Dr. Lodge's lightning guard, designed for the purpose of filtering lightning out of electric light leads, is being constructed by Messrs. Muirhead and Co., of Cowley-street, Westminster. The current enters at one end of the axis, circulates through two thick wire highly-insulated coils, and leaves by the other end of the axis; but in so doing it has to pass three pairs of brass collars, which clamp between them a square of mica coated with tinfoil, the corners of which come very close to an outer metal case thoroughly connected with the ground. When lightning, therefore, attempts to follow the current, it spits off from one or other of the covers of the first tinfoil to earth, thereby striking a momentary arc, which is destroyed the next instant by the fusion of that cover of tinfoil. The other covers remain ready for a future occasion. We understand that, by the kindness of Major Cardew and Mr. Wimshurst, one of these instruments has been privately tested at the Board of Trade laboratory, and has been found to work exactly as intended. The air gap necessary between the brass collars and the outer case must depend on the voltage of the installation for which it is designed and the length of arc accordingly to be expected. At present it has only been tested up to about 100 volts.

Opening of the Dusseldorf Central Station.—On September 1st Messrs. Schückert and Co., of Nuremberg, completed the municipal electricity works in Düsseldorf, which they had carried out on behalf of the Town Council. Since that day the works have been in regular operation, but it was only on Saturday afternoon last (24th) that the inauguration took place. The Düsseldorf municipality now own the gas, water, and electricity works. There are one principal and three secondary stations. The current from the generating dynamos is used partly to charge the secondary batteries in the sub-stations, and partly to feed the distributing mains simultaneously with the accumulators. The Schückert dynamos give 1,000 amperes at 350 volts. The mains connecting the central with the sub-stations were furnished by Messrs. Felten and Guilleaume, of Mülheim. Two of the sub-stations contain small batteries, whilst in the third two sets of 140 cells, having a total output of 1,000 amperes, are arranged. These storage batteries were provided by the Accumulator Works Company of Hagen, who have undertaken to maintain them for ten years. The generating station has been equipped for the simultaneous supply of 10,000 16-c.p. lamps, and the distributing mains to carry current for 25,000 lamps. Applications equivalent to 15,000 16-c.p. lamps have already been received, and 171 installations, comprising 12,000 lamps, are either already put up or in process of installation.

Telephonic Progress in Europe.—The following are some official statistics as to the number of telephonic subscribers in various European countries at the end of the years 1887 and 1890 respectively:—

	No. of subscribers. 1887.	No. of subscribers. 1890.	No. of subs. per 100,000 inhabitants. 1890.
Sweden	5,705	19,240	400
Switzerland	4,900	9,203	316
Luxembourg	...	653	307
Norway	...	5,110	255
Germany	14,733	49,531	105
Denmark	1,370	1,837	90
Belgium	3,365	5,282	88
Netherlands	2,493	3,363	75
Great Britain	15,114	20,426	58
France	7,175	16,000	41
Spain	594	7,089	40
Italy	8,346	9,183	34
Portugal	350	890	26
Austria-Hungary	3,032	8,153	21
Russia	5,280	6,556	7

The following are some figures relating to the chief European towns:—

	No. of subscribers. 1887.	No. of subscribers. 1890.	No. of subs. per 1,000 inhabitants. 1890.
Luxembourg	291	853	47·4
Geneva	1,376	2,200	30·1

ELECTROMAGNETIC THEORY.—XVIII.

BY OLIVER HEAVISIDE.

(Continued from page 656.)

§ 95. We may now briefly compare some of the more important formulæ in the two systems. Let us denote quantities in rational units as in the preceding (except that when vector relations are not in question we need not employ special type), and the corresponding quantities in irrational units by the same symbols with the suffix $_i$; thus, q and q_i. Also denote $(4\pi)^{\frac{1}{2}}$ by x.

Let q_i be the irrational charge which repels an equal irrational charge at distance r with the *same* force F as a rational charge q repels an equal charge at the same distance. Then,

$$F = \frac{1}{c}\left(\frac{q}{xr}\right)^2 = \frac{1}{c}\left(\frac{q_i}{r}\right)^2, \quad . \quad . \quad . \quad . \quad (9)$$

Therefore

$$q = xq_i. \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

As regards the ratio of the units, it is sufficient merely to observe that the magnitude of the number expressing a quantity varies inversely as the size of the unit. This applies throughout, so that we need not bring in units at all, but keep to the concretes appearing in formulæ.

By (10) we shall have

$$x = \frac{q}{q_i} = \frac{\rho}{\rho_i} = \frac{\sigma}{\sigma_i} = \frac{D}{D_i} = \frac{C}{C_i}, \quad . \quad . \quad . \quad . \quad (11)$$

if ρ is volume-density of electrification, σ surface density, D displacement, C electric current density (or else the total displacement and current).

Since $D = cE$, and $D_i = cE_i/4\pi$, ... (12)

whilst $D = xD_i$ by (11), we have also

$$x = \frac{E_i}{E} = \frac{A_i}{A} = \frac{V_i}{V} = \frac{e_i}{e} = \frac{P_i}{P}, \quad . \quad . \quad . \quad (13)$$

where A is the time-integral of E, V the line-integral of E, or voltage, e impressed electric force, P electric potential or potential difference.

The permittivity c is the same in both systems. So is the ratio c/c_0 of the permittivity to that of ether, or the specific inductive capacity (electric). The permittance of a unit cube condenser is c, and also $c_i/4\pi$. If S is the permittance of any condenser

$$S_i = x^2 S, \quad . \quad . \quad . \quad . \quad . \quad . \quad (14)$$

and its energy is

$$\tfrac{1}{2}VQ = \tfrac{1}{2}V_iQ_i = \tfrac{1}{2}SV^2 = \tfrac{1}{2}S_iV_i^2, \quad . \quad . \quad (15)$$

if Q is its charge and V its voltage. We also have

$$\tfrac{1}{2}ED = \tfrac{1}{2}E_iD_i = \tfrac{1}{2}cE^2 = \tfrac{1}{2}cE_i^2/4\pi, \quad . \quad . \quad (16)$$

$$\tfrac{1}{2}P\rho = \tfrac{1}{2}P_i\rho_i, \quad . \quad . \quad . \quad . \quad . \quad . \quad (17)$$

$$\tfrac{1}{2}AC = \tfrac{1}{2}A_iC_i, \quad . \quad . \quad . \quad . \quad . \quad . \quad (18)$$

the first and second sets relating to electric energy, the third to magnetic energy.

By Ohm's law

$$V = RC, \quad \text{and} \quad V_i = R_iC_i; \quad . \quad . \quad (19)$$

therefore by (11) and (13)

$$x^2 = \frac{R_i}{R} = \frac{r_i}{r}, \quad . \quad . \quad . \quad . \quad . \quad . \quad (20)$$

where r is resistivity, so that

$$EC = E_iC_i = RC^2 = R_iC_i^2. \quad . \quad . \quad . \quad (21)$$

§ 96. If the repulsion between two magnetic poles m and m is F at distance r, and this is also the repulsion between irrational poles m_i and m_i, we have

$$F = \frac{1}{\mu}\left(\frac{m}{xr}\right)^2 = \frac{1}{\mu}\left(\frac{m_i}{r}\right)^2, \quad . \quad . \quad . \quad . \quad (22)$$

where μ is the inductivity of the medium, common to the two systems, as is likewise μ/μ_0 the ratio of μ is that of the ether, or the permeability. So

$$m = xm_i. \quad . \quad . \quad . \quad . \quad . \quad . \quad (23)$$

Here some discrepancies come in. For

$$B = \mu H, \quad \text{and} \quad B_i = \mu H_i; \quad . \quad . \quad (24)$$

so we have $$x = \frac{m}{m_i} = \frac{H_i}{H} = \frac{B_i}{B} = \frac{L_i}{L} = \frac{M_i}{M} = \frac{\Omega_i}{\Omega} = \frac{h_i}{h}, \quad . \quad (25)$$

where L and M are surface integrals of B or inductances, Ω is magnetic potential or gaussage. If I be intrinsic magnetisation (intensity of), then

$$I = \mu h, \quad \text{and} \quad I_i = \mu h_i/x^2, \quad . \quad . \quad . \quad (26)$$

from which, and by (25), we have

$$I = xI_i. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (27)$$

The equation $\mathbf{B} = \mu\mathbf{H}$, in the sense used by me, expands to

$$\mathbf{B} = \mu(\mathbf{h} + \mathbf{F}), \quad . \quad . \quad . \quad . \quad . \quad . \quad (28)$$

where $\mathbf{h}$ is intrinsic, and $\mathbf{F}$ is the magnetic force of the field. Also

$$\mu = \mu_0(1 + \kappa) = \mu_0(1 + 4\pi\kappa_i), \quad . \quad . \quad (29)$$

so we have, by (28) and (26),

$$\mathbf{B} = \mathbf{I} + \mu_0\mathbf{F} + \mu_0\kappa\mathbf{F}, \quad . \quad . \quad . \quad . \quad (30)$$

where $\mu_0\kappa\mathbf{F}$ is the induced magnetisation.

In the common equation,

$$\mathbf{B}_i = \mathbf{F}_i + 4\pi\mathbf{I}_i \quad . \quad . \quad . \quad . \quad . \quad . \quad (31),$$

the intrinsic and induced magnetisations are lumped together for one thing, and it is assumed that $\mu_0 = 1$. The quantity κ is thus essentially a numeric, whilst μ is only a numeric by assumption. But whilst $\mu = \mu_i$, we have $\kappa = x^2\kappa_i$. Although magnetisation, whether intrinsic or induced, are of the same kind as induction, yet the reckoning is discrepant. Compare (27) with (25) for B and B_i. In (27) also, I may be either intrinsic or induced, so far as the ratio x goes.

The common equation, $\text{div.}\mathbf{D}_i = 4\pi\rho_i$, becomes

$$\text{div.}\mathbf{D} = \rho, \quad . \quad . \quad . \quad . \quad . \quad . \quad (32)$$

and the characteristic equation of Poisson becomes

$$\nabla^2 P = -\rho, \quad . \quad . \quad . \quad . \quad . \quad . \quad (33)$$

the 4π going out by the rationalisation. But P itself is given by

$$P = \Sigma\rho/4\pi rc. \quad . \quad . \quad . \quad . \quad . \quad (34)$$

The definition of current density,

$$\text{curl}\,\mathbf{H}_i = 4\pi\mathbf{C}_i,$$

becomes

$$\text{curl}\,\mathbf{H} = \mathbf{C}. \quad . \quad . \quad . \quad . \quad . \quad . \quad (35)$$

Other changes readily follow. But now that I have explicitly stated the relation between my rational formulæ and the ordinary, I leave the irrationals—for good, I hope—and return to the rational and simplified formulæ, which are so much superior.

(To be continued.)

BOILERS.*

The principal types of modern steam boilers may be classified thus :—

Cornish boilers are horizontal cylindrical boilers with flat ends and one internal flue.

Lancashire boilers are similar to Cornish boilers, except that they have two internal flue or flues.

Multitubular boilers (marine type) are horizontal cylindrical boilers with internal flues, or fire tubes.

Multitubular boilers (loco. type) have a fire box at one end from which tubes run through to smoke box.

Water-tube boilers are constructed in various ways, the tubes, unlike multitubular boilers, contain the water, from which the steam is generally evaporated into a receiver at the top.

Vertical boilers are those in which the shell is placed in a vertical position. The internal arrangements of this class are very varied.

In addition to the above there are numerous designs combining two or more of the above in one boiler ; these are sometimes called compound boilers.

Boiler Power.

Nominal Horse-Power—N.H.P.—This term is meaningless and misleading, as the horse-power obtainable by means of a given boiler varies enormously with the engine to which it supplies steam.

As, however, this term is still in use, we give the following definitions of it as proposed by different authorities :—

Watt's formula :—N.H.P. = cubic feet of water evaporated per hour.

Another rule says that for each N.H.P. a boiler requires

1 cubic foot of water per hour,
1 square yard of heating surface,
1 square foot of grate area,
1 cubic yard capacity.

The following formulæ are sometimes used :—

$$\text{Cornish boilers N.H.P.} = \frac{(D+d)\,L}{7}$$

$$\text{Lancashire boilers N.H.P.} = \frac{(D+2\,d)\,L}{8}$$

$$\text{Cylindrical boilers N.H.P.} = \sqrt{H+G};$$

where

D = diameter of shell in feet,
d = diameter of flue in feet,
L = length of shell in feet,
H = heating surface in square yards,
G = grate area in square yards.

The standard adopted for the horse-power at the Centennial Exhibition in the United States was 30lb. of water evaporated per hour at 70lb. pressure.

Inasmuch as the amount of steam per horse-power required by engines of different types as made at the present day varies from 12lb. per hour with the most economical triple expansion engines to 50lb. per hour with small single-cylinder engines, it is useless to specify the boiler by the horse-power required. Indeed, it is not exceptional for boilers to give four times the horse-power as found by the above rules.

Prof. Thurston estimates the water required per hour per horse-power in good engines where

I.H.P. = indicated horse-power,
w = lb. water per I.H.P. per hour,
p = steam pressure,

$$w = \frac{200}{\sqrt{p}};$$

while in the best engines

$$w = \frac{150}{\sqrt{p}}.$$

This gives, with good engines at 100lb. pressure, 20lb. water per I.H.P. per hour.

This gives with best engines at 100lb. pressure, 15lb.

This gives with best engines at 144lb. pressure, 12·5lb.

The best guide as to the evaporative power of boilers is the amount of *effective heating surface*. The quantity of water evaporated per square foot of heating surface varies with the type of boiler, and the conditions under which it is operated. Under ordinary conditions the following table will serve as a rough guide :—

Type of boiler.	Lbs. water evaporated per hour per sq. foot of heating surface.
Horizontal cylindrical	4 to 6
Multitubular	5 to 10*
Water-tube	3 to 5
Vertical	2 to 5

More efficient evaporative results can be obtained at the lower rates of evaporation, while for many other reasons it is advisable to have plenty of boiler power, so as to avoid forcing.

* Such high rates as 10lb. are only obtainable from boilers in locomotion, and this is attributed to the jarring or shaking, which hastens the liberation of the bubbles of steam as they form, together with the strong draught obtained with the exhaust from the engine, as is customary in locomotive practice.

It will be observed that a higher rate of evaporation is obtainable in the horizontal cylindrical boiler, which is attributable to the better circulation as compared with fire-tube or water-tube boilers.

Heating Surface.

The efficiency of the heating surface depends upon the difference of temperature at the inside and outside of the plate, as well as upon the thickness of the plate and nature of the surface. Rankine gives the following formula :—

If H = quantity of heat units transmitted per square foot per hour.
t = temperature of hot gases in flue.
t_1 = temperature of water in boiler.
K = a constant = 160 to 200 for steam boilers, then

$$H = \frac{(t-t_1)^2}{K} \text{ approximately;*}$$

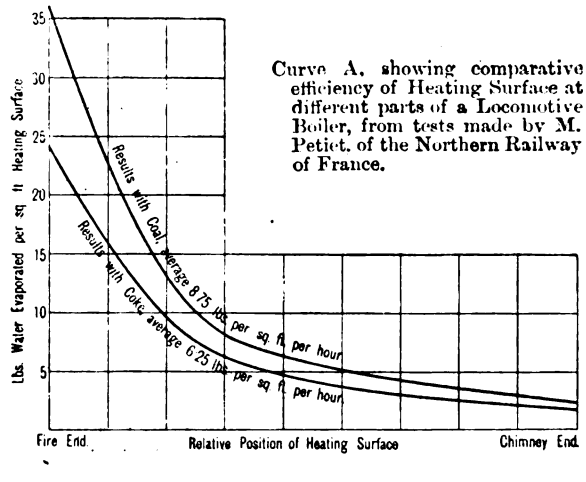
and, according to Peclet,

$$H = (t-t_1)\,A\{1+B(t-t_1)\},$$

where

A for polished metallic surfaces	=	·9
A „ dull „ „	=	1·58
B „ polished „ „	=	·005
B „ dull „ „	=	·0066

The curve A has been plotted from the results of actual experiments made by Havrez upon the evaporative power of



Curve A, showing comparative efficiency of Heating Surface at different parts of a Locomotive Boiler, from tests made by M. Petiet, of the Northern Railway of France.

different sections of a multitubular boiler of the locomotive type, and illustrates the rapid falling off in the efficiency of the heating surface as the distance from the fire increases. The length of the tubes was 12ft. 3in., and the boiler was divided as follows :—1st section, fire-box and 3in. of tubes; and four sections of tubes, each 3ft. long.

The results were as follows :—

Section of boiler.	Heating surface, in square feet.	Lbs. water evaporated per square foot heat surface, per hour in lbs.	
		Coke.	Briquettes.
Fire-box	76·5	24·5	36·9
1st tube section	179	8·72	11·44
2nd „	179	4·42	5·72
3rd „	179	2·52	3·52
4th „	179	1·68	2·31

It will be observed that the evaporation per square foot at the fire-box is fourteen times that at the last section of tubes for coke, and for briquettes sixteen times.

In practice it is probable that, owing to the formation of deposits, &c., a relatively larger duty will be done by the surface at the end of the flue. Sufficient heating surface should be provided for the best fuel and draught ever likely to be used; beyond that extra surface may be detrimental.

* It will be observed from this formula that H varies as the square of the difference of temperature.

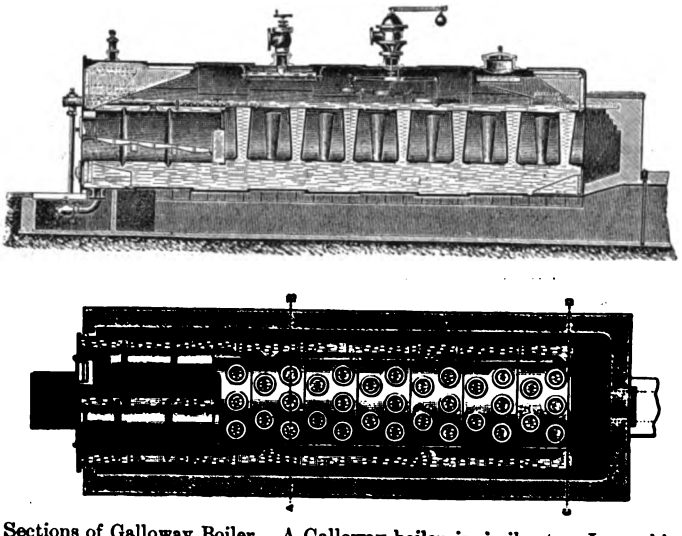
Digitized by Google

Relative Value of Heating Surface.

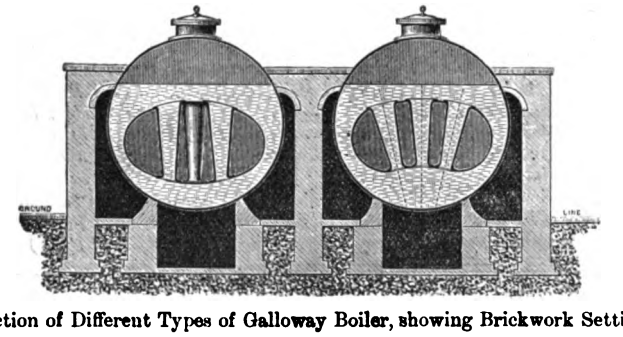
Horizontal surface above the flame = 1
Vertical " " " = ·5
Horizontal " below " = 0
Tubes and flues = $1\frac{1}{4}$ of their diameter.
Convex surfaces above the flame = $1\frac{1}{3}$ diameter.

Effective heating surface varies from $\frac{3}{4}$ to $\frac{5}{6}$ of the *total* heating surface, as the bottoms of internal flues and tubes are not so efficient as the tops and sides.

The effective heating surface of *multitubular boilers* is taken as the upper half of the furnace above the level of the grate bars, the surface of the combustion chamber above the level of the bridges, the actual surface of the back tube plates, together with the surface of the tubes measured externally, *i.e.*, external circumference × length between tube plates. The fire-box and chamber surface are generally stated separately from the tube surface.



Sections of Galloway Boiler. A Galloway boiler is similar to a Lancashire boiler, but with the addition of a number of conical water tubes into the flues.



Section of Different Types of Galloway Boiler, showing Brickwork Setting.

The Admiralty calculate the tube surface by the external circumference of tubes × length over tube plates, omitting the surface of both tube plates.

The front tube plates are always omitted.

In *locomotive boilers* the effective heating surface is given as the whole of the surface of the fire-box above the grate bars, less the aggregate area of the tubes, and the surface of the tubes measured externally and between the tube plates.

Generally speaking, for economy, the heating surface should not be less than one square foot, and not more than two square feet per 5,000 B thermal units to be transmitted per hour.

In torpedo boats one square foot of heat surface is often transmitting 12,000 to 15,000 B. T. units per hour, while in some mills as little as 1,000 B. T. units are absorbed per square foot per hour.

The natural action of water is that heated portions of water, as well as the steam when generated, seek a directly upward means of movement or escape. Colder portions seek the coolest means of descent where it is possible to have this, undisturbed by opposing currents.

THE VARIATION OF THE ELECTROMOTIVE FORCE OF BATTERIES WITH PRESSURE.*

BY HENRI GIBAULT.

By following up the ideas put forward by H. von Helmholtz in his theory on free energy we can deduce the following formula

$$q\frac{dE}{dp} = dv;$$

where E represents the electromotive force of a cell; q is the quantity of electricity developed when the reactions give rise to a variation of volume v, p representing pressure. This formula allows us to estimate the variation in the electromotive force of a battery due to pressure. Now, it is easy to measure this quantity, and thus verify the formula, and consequently the theory. This is what I did, and here give briefly the results.

When working with batteries which did not give off gas, I found that the variation of electromotive force was of the form

$$E_0 - E = ap - bp^2,$$

b being an infinitely small quantity, which only assumes importance at high pressures. Hence, for such batteries at moderate pressures, the variation of electromotive force with pressure is linear, which is in accordance with theory.

In an analogous investigation on batteries evolving gas, experiment showed that the variation of electromotive force could be expressed as a function of the pressure by the formula

$$E_0 - E = A\lambda p + cp,$$

c being again very small, which is equivalent to saying that for moderate pressures the variation of electromotive force follows a Napierian logarithm, as is also shown by the first formula.

The agreement between theory and experiment goes further still, and becomes striking by reason of the similarity exhibited between the numbers indicated by one and by the other, as one can satisfy oneself by the few examples set out in the table below, which shows the variations of the electromotive force of different batteries, expressed in ten-thousandths of a volt, due to a variation of pressure of 100 atmospheres.

Battery.	Calculated variation.	Observed variation.
Daniell (20 % $ZnSO_4$)	+ 5·17	+ 5
" (27·56 % $ZnSO_4$)	+ 2·20	+ 2
Warren de la Rue (1 % ZnCl)	+ 6·62	+ 7
" " (40 % ZnCl)	− 5·04	− 5
Planté Accumulator (8·8 % H_2SO_4).	− 12·70	− 12
Volta	− 586·00	− 600
Bunsen	− 383·00	− 405
Gas battery	+ 865·00	+ 845

I think, therefore, I may conclude that there exists for moderate pressures perfect agreement between the numbers deduced from H. von Helmholtz's theory and those obtained experimentally. In the case of excessively high pressures, variations due to the secondary effects, inevitable under such conditions, are probably added to the normal variations.

FRIDAY, November 6th.

PHYSICAL SOCIETY.

5 p.m. Paper to be read on "Corresponding Temperatures, Pressures, and Volumes." By Prof. Sydney Young.

Digitized by Google

The Electrician.

Published every Friday, Price Fourpence; Post Free, Fourpence Halfpenny
Editorial, Publishing, and Printing Offices:
SALISBURY COURT, FLEET ST., LONDON, E.C.
Telephone No. 2714. Telegrams: "ELECTRICIAN NEWSPAPER, LONDON."

All Letters relating to Subscriptions, Advertisements and other business matters should be addressed to the Publisher, "THE ELECTRICIAN," *Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* "THE ELECTRICIAN" *Printing and Publishing Company, Limited, and be crossed* "Coutts and Co." *All Editorial letters to be addressed to the Editor.*

All letters intended for insertion in "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails.*

"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from Publishing Offices as above.*

New Volumes of "THE ELECTRICIAN" *commence in May and November. Back Numbers and Volumes of* "THE ELECTRICIAN" *are frequently wanted, and offers will be made by the Publisher therefor.*

SUBSCRIPTION RATES.

The rates for Subscriptions to "THE ELECTRICIAN" are as follows:—

	3 months.	6 months.	12 months.
	s. d.	s. d.	s. d.
For the United Kingdom	5 0	10 0	19 6
For Foreign Parts and Colonies:— Within Postal Union	6 6	12 6	24 0
For Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	14 6	28 0

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

Advertisement Rates, &c., forwarded on application as above.

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday. Renewals of expiring advertisement orders and alterations to standing advertisements should be in Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday.*

SMALL PREPAID ADVERTISEMENTS *accepted up to 4 p.m. Thursday.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, 1891, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with well-written Biographical Notices of leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1891 should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Prospectuses free.

ELECTRICAL BOOKS AND PUBLICATIONS

All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

"THE ELECTRICIAN" *Series at present consists of—*

THE ALTERNATE CURRENT TRANSFORMER IN THEORY AND PRACTICE. By Dr. J. A. FLEMING. Vol I. Price 7s. 6d., post free.

THE ART OF ELECTROLYTIC SEPARATION OF METALS (Theoretical and Practical). By Dr. GEORGE GORE. Price 10s. 6d., post free.

PRACTICAL NOTES FOR ELECTRICAL STUDENTS. By A. E. KENNELLY and H. D. WILKINSON. Vol. I. Price 6s. 6d., post free.

THE STEAM ENGINE INDICATOR AND INDICATOR DIAGRAMS. Edited by W. W. BEAUMONT. Price 3s. 6d., post free.

ELECTRO-CHEMISTRY. By Dr. GEORGE GORE. Price 2s., post free.

Several Further Volumes in Active Preparation.

NOW READY, IN TWO VOLUMES.

"THE ELECTRICIAN" PRIMERS.

Fully Illustrated.

Price: Stout paper covers, 2s., post free, 2s. 2d. each; strong cloth, 2s. 6d., post free, 2s 9d. each. Single Primers, 3d., post free, 3½d. Abroad postage extra.

NOTICE.

The present Number of "THE ELECTRICIAN" completes Vol. XXVII. With next week's number will be issued (gratis) the Index to the Volume.

READY NEXT WEEK.

Volume XXVII. of "THE ELECTRICIAN," price 12/6; post free, 13/6.

NOW READY.

Cases for binding Volume XXVII., price 2/0; post free, 2/3.

STEEL-PLATE PORTRAITS

Of W. H. Precoe, F.R.S.; Michael Faraday (out of print); Sir John Pender, K.C.M.G.; Sir William Thomson, F.R.S. (Past-President of the Institution of Electrical Engineers); C. H. B. Patey, C.B. (Late Secretary of Telegraphs, G.P.O.); Dr. John Hopkinson, F.R.S. (Past-President of the Institution of Electrical Engineers); Dr. Oliver J. Lodge, F.R.S.; Prof. William Crookes, F.R.S. (President of the Institution of Electrical Engineers); Willoughby Smith (out of print); and Prof. von Helmholtz, have been issued as Supplements to "THE ELECTRICIAN."

A few Copies of these admirably-executed Steel Engravings can be supplied, price 1s. each, post free on roller, 1s. 2d. Or framed in neat Black Pillar or Brown Ornamental Frames, price, 4s. 6d, carriage paid (U.K.)

THE USE OF SMALL MOTORS.

With a keen sense of disappointment many electrical engineers recognise the fact, which many others ignore with complete indifference, that there is no demand for, and at present but little likelihood of, the extended use of small electric motors for industrial purposes in this country. A number of electrically driven pumps, fans, cranes, and mining machines are in use; but we do not allude to these, or to electric tramways and launches, so much as to the numerous uses to which we have so often been told that motors may be applied. It is still somewhat doubtful whether an appreciable demand for current for motive power would be a boon to or a strain on the resources of supply companies. A better load throughout the day would, of course, be a great advantage, but during the winter months there would be a two-fold demand during the latter part of the afternoon. If this should be large enough to require increased generating plant, it would not only mean that no smaller proportion would stand idle during the winter's day than at present, but a considerably larger propor-

Digitized by Google

tion would so stand in summer. It is not for want of careful consideration of the problem that this state of things is still to be found. The question has received the close attention of several men who could do an excellent business in the sale and erection of motors; and several central station managers, who could deal with a larger load than they have at present, have tried to encourage business in this direction. We know quite enough about transmission of power; there is not a problem, from a dentist's drill to the driving of the largest factory in the country, that could not be taken in hand at once by half-a-dozen manufacturing firms.

The price of labour is so low that for occasional work, hand power which demands no outlay of capital is to be had everywhere, and carpenters and jobbing ironmongers will employ a dozen hands and prefer to utilise manual labour for sawing, drilling and turning, rather than invest in a gas engine or a steam engine. For continuous work the question resolves itself at once into the price. We do not know, and do not expect to know for a few years, the price at which electrical energy can be supplied. The smaller stations in London can hardly hope to go below 5d. per unit and pay a 10 per cent. dividend at that. It is quite possible that when a demand for a million lights is made on the Deptford station, they will be able to supply at 8½d.; and by that time—we do not mean to be ironical—a small alternate-current single-phase motor will probably have been found. But even putting the price of a unit at 5d. and the efficiency of a motor at 85 per cent., the horse-power hour would come to 4·4d. as against about 1d. an hour with a gas engine. The important question to be considered is in what trades or for what purposes can small motors be profitably used. It seems very improbable that any motors running nine hours a day and yielding more than four horse-power can be used, unless under very exceptional circumstances. At 5d. per unit this would cost 18s. a day.

Although the price of a thing is that which it will fetch, the consideration of convenience cannot be estimated in pounds, shillings and pence, because different people will attach different values to it. The convenience of a motor, and, more than this, the convenience of separate motors for driving separate machines, is very great; and it remains to be seen how much the public will care to pay for it. Another convenience is the ease with which a motor can be started and this is of great value in intermittent work. All this is fully recognised by those who have been trying to develope the sale of motors; and the important matter is now to discover situations where these conveniences will make it worth while to use them. Hydraulic supply threatened at one time to be a formidable rival, but the purposes for which it has been used are very few compared with those for which a motor is suitable.

We have said that while some engineers have given much thought to this lack of demand for small motors, others ignore it. A rather striking example of the latter attitude is to be found in the prospectus of the National Electric Supply Company, which has been formed for supplying Preston with electric light and motive power. Electric supply companies have generally kept this question of motive power rather in reserve; but in the prospectus before us it is brought into considerable prominence. A good deal is made of a statement volunteered by Mr. Edison "during his recent visit to London." "The next thing you have to do will be to turn your electric force into motive power. Ah! America's the place for that!" We can understand that confusion between force and power is as common in America as with us; but to turn force into power only means that it must be given room to work. That is just what we want. Our dynamo builders do not need to be told how to build motors, they want to know who requires them. This prospectus contains two paragraphs on this subject, and commences with the truism, "The application of electricity as motive power in this country is yet in its infancy." Of course the prospectus tells us about America, and we are always glad to receive any scientific information from that country, and to pick up practical hints; but when we come to commercial matters and prices we may be thankful that our conditions of life are so widely different that no useful comparison can be drawn. The shrewd people of Lancashire are quite familiar with the renting of power; and they know a thing or two about what Americans can do and what they cannot do, what they try to do and how much it costs them. "The countless purposes to which electricity may be usefully applied as a motive power, especially for driving light and small machinery, only require to be understood to assure a large and general demand for current, especially during the day-time. The Company propose to supply motors at a small rental." How very dull must we be as a nation, in the eyes of the author of this prospectus, that we have not "understood" a few of these "countless purposes;" and it is only fair, if we criticise him, to give the detailed suggestions in full. "Amongst the many trades which could use the current may be mentioned:—Jewellers, for driving lathes; hairdressers, for hair-brushing machinery; cutlers, for grinding and polishing; grocers, for coffee mills; driving fans, for ventilation; tobacconists, for tobacco-cutting machines; turners, in wood or metal work; printers, for printing machines; gas fitters, &c., for drilling; and numerous trades where sewing machines are used." Little motors taking one or two hundred watts might be useful for small lathes for work which cannot be done well by a foot-lathe; but it must be remembered that the employer can only be expected to use them if he can get more or better work to cover the expense. Hair-brushing has already been tried, and is one of those irregular operations for which a motor is very well adapted. We are doubtful about cutlers, grocers, and some of the other trades. When power is wanted by them it is wanted in long spells, and it is worth starting an engine. If the business is not large enough to stand this, it will find a difficulty in paying for electrical energy. If printing could be done with any economy or advantage by electricity we should welcome it; but no one has yet shown where the economy comes in. We should like to see a motor on every sewing machine; and it is possible that, where large numbers are used in one building, power might be transmitted to them electrically more economically than by belts. Small lifts for occasional use could be worked more cheaply by current than by hydraulic power, and we believe an endeavour is being made to push them; there are several at work in London.

The prospectus alluded to gives a list of the number of lamps connected to the mains of the London supply companies, but maintains a discreet silence about the number of motors used. It fails to explain who is to pay the rent for the motors. If a shop were opened in, say, Queen Victoria-street, for the free presentation of motors to anyone who would undertake to make regular use of them in their business we doubt if the demand would be so very great. It is, however, a mistake to suppose that all this is an evil. True, it is not good for electrical trade, but it proves that we can work more cheaply by other means, and that the productive power of this country is therefore greater than if such expensive labour-saving assistance were needed. Encourage by all means the use of small motors, but let us not deceive ourselves or the confiding public.

REVIEWS.

The Practical Telephone Handbook. By JOSEPH POOLE. (London: Whittaker and Co. 1891.)

This essentially practical book is published at an opportune moment, owing to the recent expiration of the Bell and Edison patents that have so long checked the development of the telephone in England. We have already seen a very considerable increase in telephonic activity throughout the country, and there is no doubt a demand for books giving reliable information on the subject.

One cannot help noticing that in Mr. Poole's book a considerable number of the illustrations are old friends, that have already done duty in Mr. Preece's book on the Telephone and in other similar works; and when, as in the case of the illustrations of the Mix and Genest and Berliner transmitters, this is coupled with the fact that the figures do not show the latest form of instrument, at all events as known in this country, it is impossible not to regret that new blocks were not prepared. On the whole, however, Mr. Poole may be congratulated on the discretion that he has shown in his choice of apparatus for description; for, on the one hand, he has kept within reasonable limits the pages devoted to instruments of purely historical or experimental interest, while, on the other hand, his book contains readable accounts of all the best known and most widely used instruments, together with a considerable amount of fresh information not hitherto published in book form.

Commencing with a clearly-written preliminary chapter, dealing with such elementary electrical knowledge as is required for the apprehension of the principles involved in telephony, Mr. Poole proceeds, in a second chapter, to describe such batteries as are commonly employed in telephonic work; next he gives a concise account of the history of the telephone, and goes on in Chapters IV. and V. to describe the receivers and transmitters in common use at the present time. Signalling apparatus and intermediate switches and switchboards are dealt with in the next two chapters, the various details of these and their connections being very clearly illustrated by a number of well-chosen diagrams. Chapter VIII. is devoted to switchboards of the multiple type, and IX. to special exchange systems, such as that used by the British Post Office and those of the National and Mutual Companies at Manchester, together with the system in use at Paris. The descriptions of these several systems are somewhat brief, and one regrets in particular that the novel and interesting arrangements adopted by the Mutual Company at Manchester are not more fully illustrated. There is, however, more information than would perhaps be suspected, considering the small compass.

Test-room appliances, out-door construction, long-distances working, faults and their localisation, underground work, and miscellaneous telephone apparatus and applications, comprise the subject matter of the remaining chapters of the book; and are valuable, giving, as they do, much reliable information of a practical kind rarely to be found in text books. An appendix, describing the new "Collier" and "Mercadier" receivers, and containing an abstract of Mr. Bennett's Paper on "The Telephoning of Great Cities," completes the book. Considering its moderate dimensions, the book is very comprehensive, and, taking it altogether, it may be safely recommended to all who take an interest in practical telephony.

Le Gaz et ses Applications. Par E. DE MONT-SERRAT et E. BRISAC. Bibliothéque des Connaissances utiles. (Paris: J. B. Baillière et Fils.)

This is a small, well-illustrated, and interesting book, treating in a very practical way of the uses and applications of gas. A good elementary account of the manufacture and "canalisation" is given; but all this information can be found elsewhere. The interesting chapters are those which describe numerous kinds of gas burners, and which criticise their performances. These are well worth the attention of electrical engineers, who ought to be fully alive to the great perfection to which gas engineering has been carried. Some very interesting pages are devoted to the subject of illumination, and the geometrical laws which govern it are briefly alluded to. We have found much useful information on units of light and photometry, and will only criticise one of the few statements in which electric light is alluded to. Quoting Brown-Séquard, who has found that the contraction of the pupil of the eye is produced mainly by yellow light, and the experiments of M. A. Charpentier, who has found that the eye is very much more sensitive to feeble rays from the red end of the spectrum than from the blue end, the authors argue that when other illuminants, including glow lamps, are replaced by arc lamps, three or four times as much light is required "if one wishes to obtain analogous effects from the point of view of vision." They adduce as a proof that the yellow rays of the sun are the most intense. Now, while the light of the arc is rich in blue and actinic rays, it is on the whole much more yellow than the sun. It is of a pale primrose colour. No information is given as to how M. Charpentier measured the "quantity of light:" if it was done with a photometer it must have produced a certain amount of illumination. Was this measured against the corresponding amount of illumination of a certain colour that could be got out of the standard source of light used in the photometer? Or was the same "tone" reproduced in different hues? The figures given are 7·4 for extreme red, 17·76 yellow, 362·6 middle green, 1150·25 *bleu franc*, in arbitrary units apparently, and each of these is just sufficient to allow the eye, after 20 minutes' complete rest, "to discern the forms of external objects." The point is of more than merely physiological interest; but if a certain amount of light is produced, how can it be usefully measured except by the eye, and if the eye can see it what more is required? It is easy to understand that one kind of sugar is three times as sweet as another, meaning that one third of the weight will produce the same sweetness; but two measurement are there compared, and here we only have one.

The Gas, Water and Electric Lighting Companies' Directory. Edited by CHARLES W. HASTINGS. (London: Hazell, Watson and Viney.)

This is a handy and clearly printed little Directory of some 200 pages. It is to be regretted, however, that the very item of information so frequently wanted, namely, the price of gas, is omitted here, although contained in the volume on Gas Statistics by the same author. If space is limited perhaps the columns headed "Distance from London" and "Railway" might be abolished to make room for this much-needed heading. The Electric Lighting section is fairly accurate, complete, and up to date.

THE DETERMINATION OF CURRENTS IN ABSOLUTE ELECTRO-MAGNETIC MEASURE.

BY G. F. C. SEARLE, M.A.

(*Continued from page 691.*)

§ 25. **Calculation of some Simple Cases.**—In order that we may begin to see some fruits of our labours we will find the magnetic force produced by a long straight wire and by a long uniform solenoid at points inside it.

Long Straight Wire.—This must, of course, form part of a closed circuit; but we may suppose that the rest of the circuit is so distant that for points near the wire the distribution of magnetic force is symmetrical with respect to the wire. In a plane perpendicular to the wire describe a circle of radius r, having the centre of the wire for its centre (Fig. 24). The magnetic force F will be the same all the way round this circle, and its direction will be everywhere along the circle. In moving the pole completely round the circle in the direction indicated by the arrow an amount of work $-4\pi i$ will be done by external agencies (*see* § 24). The negative sign indicates that the magnetic force due to the current is in the direction of the arrow. The work done by the magnetic force is $2\pi r \times F$. Equating these two expressions for the work done, we have $2\pi r F = 4\pi i$. Hence $F = 2i/r$, or the magnetic force at any point is inversely proportional to the distance of the point from the axis of the wire. The method of proof shows us that the result is equally true if the conductor is a hollow cylinder, whose

Digitized by Google

section is two concentric circles. If the return current flows back by a tube outside the wire, and concentric with it, then, since the total current through any curve drawn so as to embrace the outer cylinder is zero, it follows that the magnetic force everywhere outside the outer cylinder is zero. At all points between the inner and outer cylinder it has the value $2\,i/r$.

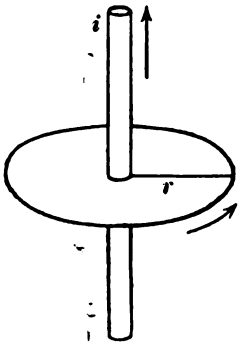

Fig. 24.

Long Uniform Solenoid.—Take a long solenoid (Fig. 25), uniformly round, so that there are n turns of wire per centimetre of its length. Consider a rectangle, A B C D, the side B C being inside the solenoid, parallel to the axis, and one centimetre long. Let the side A D be outside the solenoid. Then, if the solenoid is long, and B C is not near either end, the magnetic force F along B C will be very nearly uniform, and there will be no appreciable magnetic force along A D, A B, or C D. Take a unit magnetic pole round the path A B C D. Its path is linked n times with the current, so that

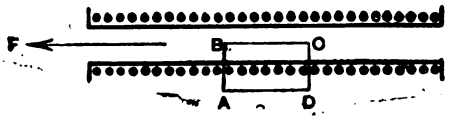

Fig. 25.

the work done is $4\pi n i$ (*see* § 24). But the only part of the path in which any work is done is the part B C. The work done here is F, since B C = 1cm. Hence, equating the two expressions for the work, we have $F = 4\pi n i$, a well-known expression.

§ 26. **Case of a Circular Current.**—The magnetic potential at any point, P, due to a current of strength i is $i\,\Omega$, where Ω is the solid angle subtended by the circuit at P. The magnetic force in any direction, S, is $-i\,d\Omega/d\,S$ in the direction in which S increases. We will now apply this to a circular current. Let A (Fig. 26) = radius of current, x the distance of a point P on the axis from the centre O of the coil.

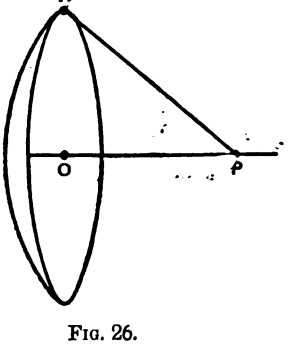

Fig. 26.

We shall have to make use of the following very important result in three-dimensional mensuration. Take a sphere and describe about it a cylinder touching the sphere round the equator (Fig. 27). Draw any two planes A A′ B B′ parallel to the equatorial plane. These will cut off from the cylinder a ring and from the sphere a certain portion of the surface contained between the two proper lines of latitude. Then it can be easily proved that the areas cut off by the two planes from the sphere and the cylinder are equal. Thus if h be the distance apart of the two planes, and r the radius of the sphere, the area of the ring on the sphere is $2\,\pi\,r\,h$. The solid angle subtended at O by the ring is, of course, $2\,\pi\,r\,h/r^2 = 2\,\pi\,h/r$ (*see* § 8). Returning now to the case in hand, we have to calculate the solid

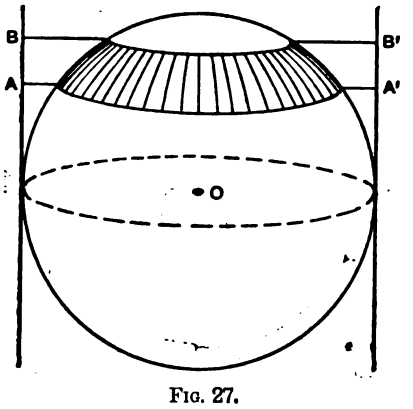

Fig. 27.

angle subtended by the circle at P. About P describe a sphere of radius A P. The plane of the circuit will cut off from the sphere a spherical cap, whose height is A P − O P. Its area is, therefore, $2\,\pi\,A\,P\,(A\,P - O\,P)$, and the solid angle subtended by it at P is

$$\Omega = 2\,\pi\,\frac{A\,P - O\,P}{A\,P},$$

or

$$\Omega = 2\,\pi\left(1 - \frac{x}{\sqrt{x^2 + a^2}}\right).$$

Thus,

$$V = 2\,\pi\,i\left(1 - \frac{x}{\sqrt{x^2 + a^2}}\right).$$

Hence, F = magnetic force in the direction in which x increases

$$= -\,d\,V/d\,x = 2\,\pi\,i\,\frac{a^2}{(x^2 + a^2)^{\frac{3}{2}}}.$$

When $x = 0$, *i.e.*, at the centre of the coil, $F = 2\,\pi\,i/a$.

§ 27. **Tangent Galvanometer.**—A circular coil of radius a is placed with its plane in the magnetic meridian, and a small magnet is hung at the centre. Let H (Fig. 28) be the earth's horizontal magnetic force, F the magnetic force at the centre of the coil due to a current i. H and F are then at right angles, and their resultant makes an angle θ with the magnetic meridian given by $\tan\theta = F/H$. The magnet places itself along the direction of the resultant magnetic field, and indicates a deflection θ. Thus, $2\,\pi\,i/a = H\tan\theta$, or $i = H\,a\tan\theta/2\,\pi$.

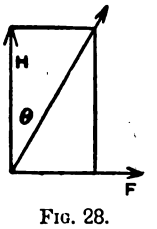

Fig. 28.

If there are n turns of wire close together, and a is the mean radius, we shall have $2\,\pi\,n\,i/a = H\tan\theta$.

or,

$$i = \frac{H\,a\tan\theta}{2\,\pi\,n}.$$

Thus the tangent galvanometer gives us a means of measuring currents when we know the following data. a the mean radius of the coil, H the strength of the earth's horizontal field, and θ the angle of deflection. In order that a may be capable of accurate determination the radius of the coil should be considerable, and if it has more than one turn of wire the turns should be very close together. Since at points not exactly at the centre of the coil the magnetic force is not exactly that

Digitized by Google

given by $F = \frac{2\pi n i}{a}$, the magnet should be as short as possible in order that its ends may be at places where the magnetic force is as nearly as possible equal to its value at the centre. We can easily find the variations of the magnetic force at points on the axis very near the centre, by expanding the complete value of F in ascending powers of x/a.

$$\text{Thus, } F = \frac{2\pi i a^2}{a^3\left(1+\frac{x^2}{a^2}\right)^{\frac{3}{2}}} = \frac{2\pi i}{a}\left(1 - \frac{3}{2}\frac{x^2}{a^2} + \frac{3\cdot 5}{1\cdot 2}\cdot\frac{x^4}{2^2 a^4} + \dots\right)$$

Thus, if $a = 30$ cm. and $x = 1$ cm., the value of F differs from that at the centre by less than one part in 600. To determine the variation in the magnetic force at points in the plane of the coil, very close to the centre, is a rather more difficult matter, and one which we shall not discuss at present.

§ 28. **Galvanometer Constant.**—The value of the magnetic force at the centre of a coil when unit current is flowing through it, is called the galvanometer constant of the coil. As a rule a coil has more than one turn of wire, and the windings occupy a finite space. We shall proceed to calculate the galvanometer constant for a coil whose mean radius is a, the radial depth of the windings being $2h$, and the axial length $2k$ (see Fig. 29). We may, to a very high degree of approximation, replace the current flowing in the n turns by a uniform distribution of current ρ per square cm. of the section. If the value of the current is i we have $ni = 4hk\rho$. Consider a small part of the section at the point whose co-ordinates,

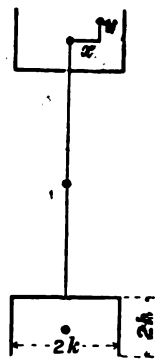

Fig. 29.

referred to the centre of the section, are x, y. If $dx\,dy$ be the small area, the current through it is $\rho\,dx\,dy$. The magnetic force at the centre of the coil due to this small part is by § 27

$$= \frac{2\pi\rho\,dx\,dy}{a+y}\left(1 - \frac{3}{2}\frac{x^2}{(a+y)^2}\right)$$

$$= \frac{2\pi\rho\,dx\,dy}{a}\left(1 - \frac{y}{a} + \frac{y^2}{a^2}\right)\left(1 - \frac{3x^2}{2a^2}\right)$$

$$= \frac{2\pi\rho\,dx\,dy}{a}\left(1 - \frac{y}{a} + \frac{y^2}{a^2} - \frac{3x^2}{2a^2}\right)$$

where we have expanded the quantity $a+y$ in the denominator and neglected powers and products of x/a or y/a higher than the second. To find the whole magnetic force at the centre, we must integrate this over the section of the coil.

Thus for G, the galvanometer constant, we have

$$G\,i = \frac{2\pi\rho}{a}\int_{-h}^{+h}\int_{-k}^{+k}\left(1 - \frac{y}{a} + \frac{y^2}{a^2} - \frac{3x^2}{2a^2}\right)dx\,dy$$

$$= \frac{2\pi\rho}{a}\left\{4hk + \frac{4h^3k}{3a^2} - \frac{4hk^3}{2a^2}\right\} = \frac{2\pi ni}{a}\left\{1 + \tfrac{1}{3}\frac{h^2}{a^2} - \tfrac{1}{2}\frac{k^2}{a^2}\right\}$$

the term $-y/a$ vanishing on integration;

$$\text{therefore } G = \frac{2\pi n}{a}\left\{1 + \tfrac{1}{3}\frac{h^2}{a^2} - \tfrac{1}{2}\frac{k^2}{a^2}\right\}.$$

If, as is generally the case, h and k are quite small compared with a, an approximate knowledge of h and k is sufficient. The quantity which we require to know accurately is a.

(To be continued.)

THE FRANKFORT EXHIBITION.—XV.

(FROM OUR SPECIAL CORRESPONDENT.)

The Kohlrausch ammeter, as made by Hartmann and Braun, is now tolerably well known to English engineers; and this firm has lately made an instrument of this type for the Lahmeyer Company, of Frankfort, in which the spiral spring is replaced by mercury. Fig. 1 shows the external appearance of the instrument. A thin tube of soft iron with an insulating covering floats in a cylindrical vessel filled to a certain height with mercury. The vessel is of non-magnetic material, and is of small cross section; round it is wound the solenoid. The top of the core carries two projections to keep it from the sides of the containing vessel. When the current is put on, the solenoid is sucked down into the mercury until equilibrium is established. The total distance travelled, about four inches, is graduated in millimetres on the left side of the scale and in amperes on the right, and the scale can, of course, be spread out at any desired position by giving the iron core a corresponding particular shape. The instrument must, of course, be always kept in a vertical position, which is, perhaps, a disadvantage, and the rise and fall of the surface of the mercury with the temperature would also introduce errors.

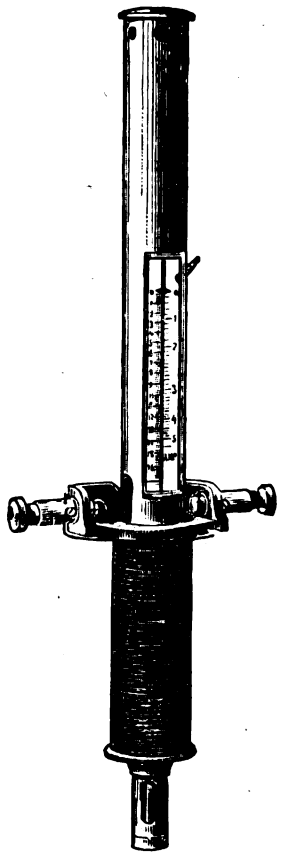

Fig. 1.—Kohlrausch Mercury Ammeter.

In Fig. 2 is illustrated a differential voltmeter made by Hartmann and Braun. Two solenoids act on one core, which dips into each, and is hung on a long spiral steel spring. The movements of this core are transferred to a lever carrying the index, and also two contact arms, which actuate relays ringing different toned bells. The smallest difference in the pressure at the terminals of the coils pulls the core up or down, and brings one of the contact arms up towards its contact piece. The contacts are set so that they are made when the difference of pressure is the maximum allowed. One solenoid is usually kept at the standard pressure, and the other is connected to the circuit where it is desired to maintain the same standard pressure. The voltmeter is useful for running dynamos or batteries in parallel or in the three-wire system. Perhaps one of its most useful applications is in measuring the loss of volts in electric light feeders, one solenoid being connected directly with the dynamo, and the other with the far end of the feeder.

The recording voltmeter (Fig. 3) consists of a Kohlrausch dead-beat spring galvanometer, the index of which carries a pen pressing against a sheet of paper wound on a revolving drum. The pressure of the pen against the drum can be regulated by means of a micrometer screw at the top of the spring. The drum is worked by clockwork, and revolves once in 24 hours. To avoid the necessity of printing different sheets for every instrument the volts are read off by means of a glass scale, the scale being placed over the unrolled sheet of paper after the record has been made. The coil shown on the left is the additional resistance required, and is, of course, wound non-inductively. A similar instrument is also made as a recording ammeter.

Fig. 4 illustrates the motor wattmeter made by the same firm, of which a short notice was given in an early article. The main current enters at the terminal K_1, and traversing the mercury trough R_1, passes on to the copper disc S radially, then

Digitized by Google

out again by the trough r, and thence to the terminal K_2. The electro-magnet E has its exciting coil arranged as a shunt to the main circuit. The retardation is due to the

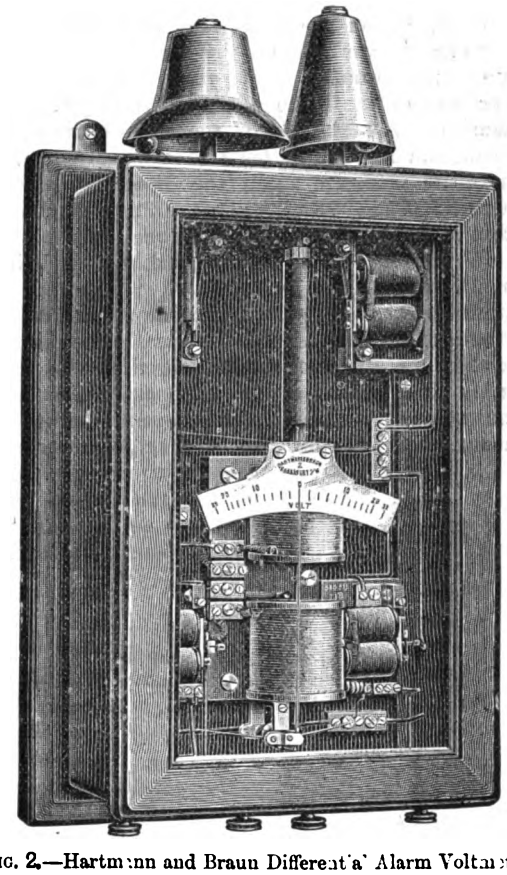

FIG. 2.—Hartmann and Braun Differential Alarm Voltameter.

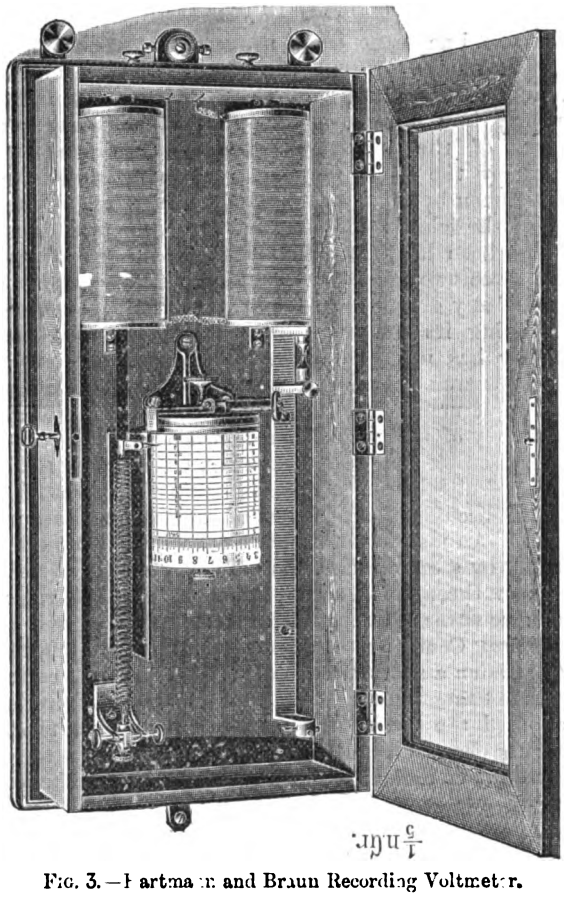

FIG. 3.—Hartmann and Braun Recording Voltmeter.

Foucault currents generated in the rotating disc. The disc works a train of clock-wheels, Z, which actuate recording dials. The meters are made to take currents from 50 amperes up to 1,000 amperes, and are arranged also for use on three wire circuits.

Amongst the apparatus shown by Hartmann and Braun for

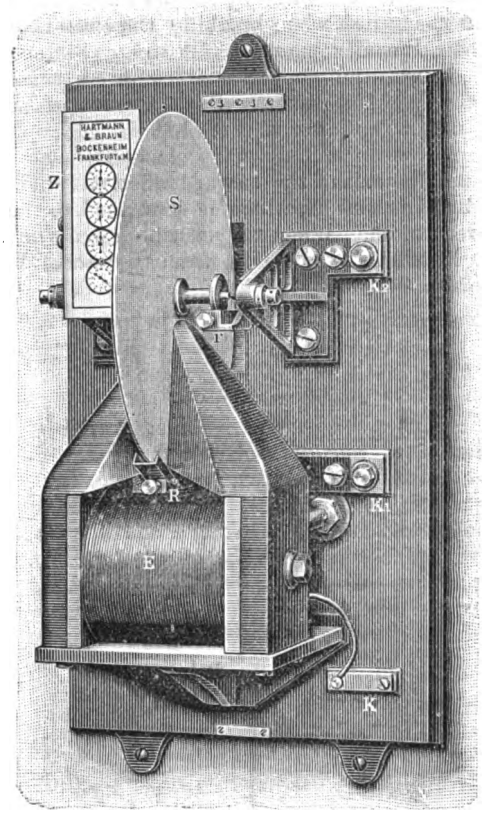

FIG. 4.—Hartmann and Braun Motor Meter.

use with accumulators are several ingenious instruments. One, for instance, is a current index for showing the direction of the current. This consists simply of a magnet, under which runs the wire carrying the current, the magnet turning to the right or left according as the current is coming from or going to the battery. These little instruments were very much used throughout the Exhibition. One of this firm's automatic cut-outs is shown in Fig. 5. The cut-out consists of a copper strip mounted on a vulcanite disc, which is acted on by the spring G. The projecting knob n of the armature of the electro-magnet fits, when the circuit is not broken, into a recess bored in the vulcanite disc, into which is also fitted

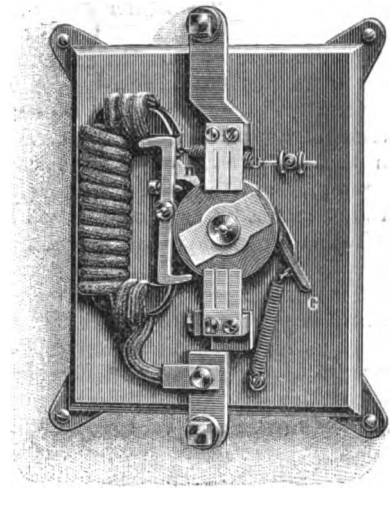

FIG. 5.—Hartmann and Braun Automatic Cut-out.

a small roller to prevent friction between the knob and the vulcanite, and thus allow the knob to slide easily and smoothly. According as the instrument is arranged, when the current

Digitized by Google

increases or decreases by a fixed percentage, the armature is drawn round into the position shown in the illustration, and the knob *n* is drawn out of the hole in the vulcanite, the cut-out being pulled sharply round by the spiral spring G.

The following device used by Siemens and Halske to avoid sparking at the switch when breaking the circuits of the coils exciting their dynamos may present some points of interest. From the substantial copper contact pieces of an ordinary pull over switch S (*see* diagram, Fig. 6), wires are run to two carbon rods, C. The lower of these rods is fixed, but the upper one can be moved up and down by a copper band B, which is wound round the axis of the toothed wheel W. The wheel W is rotated by the screw H, which is connected to the handle of the pull-over switch. When the exciting circuit is made, the screw H is lifted and disengaged from the wheel W, and the

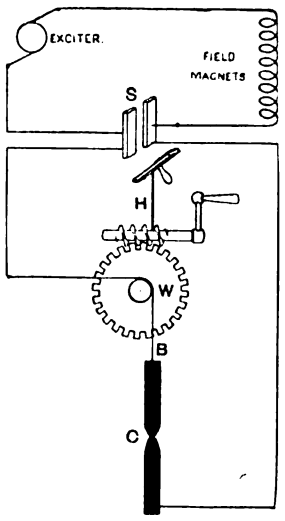

FIG. 6.

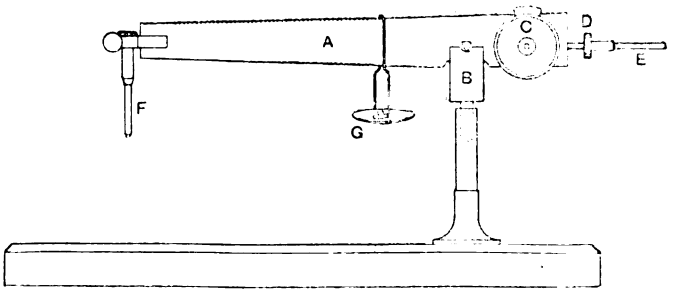
carbons fall into contact. When the switch handle is pulled down, the screw H is lowered on to the wheel W, and the exciting circuit is then finally broken by winding the carbons apart.

THE RELATIVE HARDNESS OF VARIOUS KINDS OF ELECTRO-PLATING.

Few exact experiments have been recorded dealing with the subject to which we now propose to devote a little consideration. The reason for this apparent neglect of what is a matter of some scientific interest, as well as of much technical importance, is to be found in the fact that the accurate determination of the hardness of metals and alloys has only been possible comparatively recently. The fundamental error made by all the earlier devisers of apparatus for the determination of hardness, has been that they have overlooked the fact that the hardness of a material is distinct from its tenacity, and methods of measuring the one must be so planned as to be uninfluenced by the other. The failure to appreciate and comply with this condition has been the cause of much wasted ingenuity and effort, as anyone will admit who cares to refer to the published accounts of former investigations made in this direction.

A few years ago an instrument was designed by Mr. Thomas Turner, of Birmingham, which avoided the errors of its forerunners almost completely. Like all notable improvements it owed its excellence to the fact that regard had been paid by its inventor to first principles. Having studied the various methods that had been from time to time proposed, and in some cases actually used in default of anything better, he perceived their inherent defects, and considering precisely what it was that was required to be measured, he abandoned the lines upon which the largest measure of success had been previously attained, and struck out in an entirely new direction. The instrument which was the outcome of his researches is simple enough, as may be seen from the illustration, in which one form of it is shown. A graduated beam A, with unequal arms like a steelyard, rests upon knife-edges which bear upon suitable steel or agate surfaces carried on the head of the pillar B. A counterweight, C, on the short side of the beam serves to balance the longer arm, and final adjustment of equilibrium is made by the nut D moving along the screw E. At the end of the longer arm of the beam is a brass style, F, shod with a small diamond. A scale pan, G, moves along the longer arm of the beam, and by its position and the weights it contains, determines the pressure which the diamond point exercises upon any surface placed beneath it. The pillar, B, has the upper part bearing the beam pivoted vertically to the lower, so that the beam can be swung bodily round in a horizontal plane, thus moving the diamond point in an arc of any desired length. It will be at once apparent that, when a highly-polished surface is placed beneath the diamond point and a load of suitable magnitude caused to rest upon it by sliding the scalepan along the beam, on drawing the point across the surface by swinging the beam upon its pivot, an abrasion will be made on the surface if the pressure be sufficient. The load that is necessary to produce this effect is a measure of the hardness of the material under examination. When this instrument is first used by one unfamiliar with the indications it gives, a difficulty is experienced in discriminating



between the line made by a pressure on the diamond point, which is insufficient to cut through the surface of the test-piece, and a true abrasion. Even with a very light load, particularly in the case of somewhat soft materials, a sort of smoothing of the portion of the surface which has been traversed by the diamond point will be perceptible, and is easily mistaken by the inexpert for a true scratch. When once the use of the sclerometer—for that is the name of the instrument—has been learnt, no difficulty is found in distinguishing between these two appearances, and the determination of the hardness of any given substance becomes comparatively easy.

Considering its merits it is a little surprising that the sclerometer has not been more widely used for purposes of technical research. A question, such as the relative hardness of the film of metal deposited by electrolysis as a protection to the base body of the article coated, which is acknowledged to be of considerable importance, and has hitherto been subjected to no more fruitful form of investigation than that of vague qualitative discussion, can be settled with ease and accuracy by its means. An instance of what can be done in this direction is afforded by a determination that was recently made of the hardness of three well-known plating materials, silver, nickel, and the zinc-silver alloy now being introduced by the London Metallurgical Company, a description of which appeared in *The Electrician* a short time ago. The tests were carried out by Messrs. Stanger and Blount, of Broadway, Westminster, who adopted the use of the sclerometer in their practice as engineering chemists shortly after its appearance.

The results of their investigations are shown in the following table :—

Sample.	Condition of sample.	Hardness.
Nickel anode	Rolled	11·5
Nickel anode	Rolled, annealed	8·5
Areas anode	Cast	5·5
Silver anode	Rolled	4·5
Silver anode	Rolled, annealed	3·5

Digitized by Google

The numbers represent the weight in grammes to which the pressure of the diamond point upon the test-piece is equivalent. An idea of their value may be obtained from the numbers corresponding to the hardness of a few common metals. Thus, ordinary commercial lead requires a pressure of one gramme on the diamond point to be definitely scratched; tin has a hardness of 2·5; copper about 8; mild steel averages 21; while harder steels and hard cast irons have a hardness of 25·30 or more; and ordinary window glass gives a result of about 60.

The figures are interesting as establishing the claim made for "Arcas" that it is appreciably harder than silver. Of course, both are considerably softer than nickel, the hardness of which is well known, and for many purposes objectionable. The value of the testimony in favour of the new method of plating would be much enhanced by the publication of the results of experiments made on the metals in their deposited form, as it is quite conceivable that an alteration in their molecular condition might occur in the act of deposition, and their hardness, among other properties, might suffer change.

THE NEW YORK RAPID TRANSIT COMMISSION.

For some time past the proceedings of the New York Rapid Transit Commission have been viewed with increasing suspicion by American electrical engineers; and the latest report issued by the Commission, recommending the adoption of a modified "Reno" tunnel, has been met with general disapproval. The complete ignoring of the Greathead system of tunnelling appears to have occasioned surprise, but from all accounts underground New York is not altogether suitable for it. Insinuations of politico-municipal jobbery are, as usual, being freely made; it is hinted that a tunnel burrowing far below pipes and foundations, and disturbing no vested interests, could not for that very reason commend itself to local politicians. Our New York contemporary, the *Electrical Engineer*, calmly gives it as its opinion that a great economy would be effected if the municipal opponents of the deep-tunnel scheme were traced, their worth ascertained, and the sum added to the cost of the tunnel.

The "Reno" tunnel, a description of which appeared in the *Electrical World* of February 14, 1891, comprises two double tracks, one above the other, and the proposed method of construction is somewhat as follows:—One side wall would be constructed at a time, and for this purpose a trench 38ft. deep and 3ft. wide, and lined with planking, would be dug. This trench would be filled in with concrete up to about 11ft. of the surface, and the road relaid. After the other wall has been built up in the same manner, the intervening soil would be excavated, without, so it is asserted, disturbing the street above, by a steel cutting edge, behind which a channel steel roof would be built in by sections. It is proposed to coat the steel roof with asphalte, and to harden the soil in the immediate vicinity of the roof with liquid cement forced in under pressure. This method of building the side walls before the intervening soil is removed is, of course, familiar to all civil engineers, and the forcing in of cement behind a metal roof is one of the leading features of Mr. Greathead's system.

ELECTRIC LIGHTING IN THE ITALIAN NAVY.*

BY LIEUT. A. POUCHAIN.

(Concluded from page 695.)

Projectors and Search-lights.—The projectors settled upon were those of Mangin, with a reflector 40cm. in diameter. The arc lamps used in them were of two types, one being automatically fed by a small motor, whilst the other was a Sautter-Lemonnier hand regulator. The current strength in each was 50 amperes. The hand lamp requires no special description. The Mangin projector was somewhat modified with the view of reducing its weight. This was effected principally by lightening the base and supports. In the form adopted the projector, without lamp, weighed 123·2 kilogrammes, and the base 60·0, giving a total of 183·2, which was 114·6 kilogrammes lighter than the original form.

The Mangin reflector is made of crown glass, spherical in surface at the back, where it is silvered. The front is also spherical, but not concentric with the back surface, and is made to a smaller radius than the latter.

The Pasqualini automatic regulator, which was designed specially for use in the Italian navy, differs from the ordinary types in that the small motor which works it is thrown into and out of action by means of a relay, and allows the arc to be

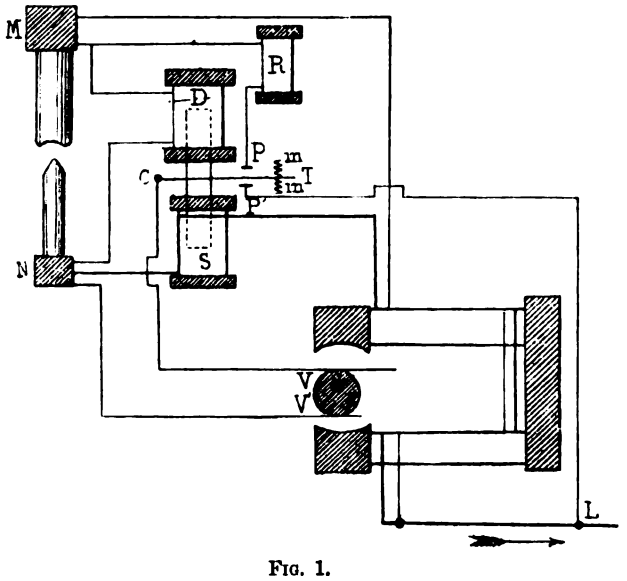


FIG. 1.

formed without the necessity for any special device for the purpose. A diagram showing the connections is given in Fig. 1, which will serve to make clear the operation of the regulator. The relay consists of two coils, one of which, D, is in shunt, and the other, S, in series with the arc. An iron core, Fig. 1 and Fig. 2, co-axial with the two coils, is supported by an arm T pivoted at C, and held in position by two springs *m m*. When the force due to the coil D exceeds that of S, the arm T comes into contact with P, and the armature of the motor is thrown into shunt with the arc, the current entering

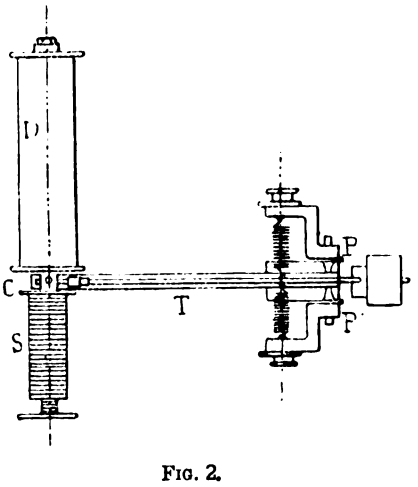

FIG. 2.

it by V and leaving by V_1. The resistance of the armature being very low, a resistance coil R (wound with doubled wire to prevent self-induction) is inserted in the circuit so as to prevent sparking. When, on the other hand, the coil S is more powerful, the arm T makes contact with P, and the armature becomes a shunt to that part of the main circuit which lies between N and L, and the current enters the armature by V_1 and leaves it by V, so that it rotates in a direction opposite to that in which it would move in the preceding case. The field-magnets of the motor have a double winding, one in series and one in shunt with the arc, so that the magnets are always

*Abstracted from the *Rivista Marittima*.

Digitized by Google

excited, whether the arc is extinguished, when the main current is zero, or the carbons are in contact, when the difference of potential between them vanishes.

Supposing now that the lamp is put into circuit when the carbons are separated, the difference of potential between them is then a maximum, and the current is zero. The action of D is a maximum, and that of S zero. T makes contact with P, and the armature commences to rotate. This, by means of screw gearing, Fig. 3, causes the carbons to approach one another until they touch. At this moment the action of S becomes a maximum and that of D vanishes. T goes over into

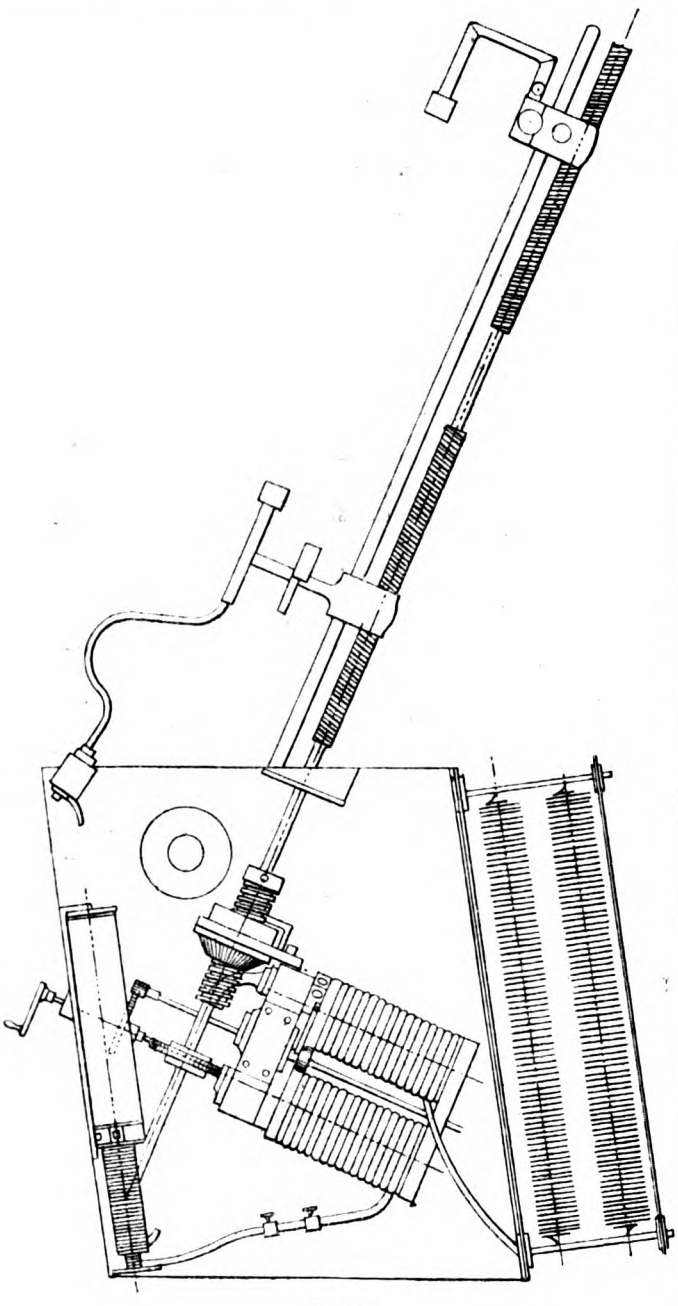

FIG. 3.

contact with P, the motor rotates in the opposite direction, thereby separating the carbons and striking the arc. The separation continues until T is enabled to take up a position of equilibrium between the two contacts.

The variations in current and tension at the arc are found with this regulator to be so small as to be imperceptible with ordinary ammeters and voltmeters.

The whole of the apparatus composing the regulator is enclosed in a case as shown at Fig. 3, and is so arranged that it can easily be applied to a hand lamp. The cost of fitting one of the latter with the Pasqualini regulator was found to be about £10.

The carbons adopted both for the hand and the automatic lamps were 18mm. in diameter. The positives were cored and 260mm. long, whilst the negatives which were plain were 145mm. long. Their durations were 9 and 18 hours respectively. Compensating resistances were supplied for compensation, of two types of 0·18 ohm and 0·30 ohm according to the length of circuit. The mean spherical luminous intensity came out at 4,500 candles, and the maximum useful range of the beam on a dark clear night was about 3,500 metres.

Incandescent Lamps.—The incandescent lamps for interior lighting in the navy were of 12-candle power on the Cruto system, by which the filaments are formed from a solution of sugar. The method of fixing the ends of the filament is as follows: to the platinum wires which pass through the glass are soldered two pieces of copper wire, and to the extremities of these a pair of small platinum tubes. These form sockets for the ends of the filament, and the joint is completed by means of a deposit of carbon obtained from coal gas. A few 25 and 100 candle-power lamps for signalling purposes were also used. All were made for a tension of 63 volts, and to consume 3·5 watts per candle; they were guaranteed for a minimum life of 800 hours, and the increase in resistance of the filaments after 500 hours' use amounted to 6 per cent. The fall in lighting power after this length of service was about 20 per cent. The holders used were of two types, the Edison screw-holder, and a spring holder like the Pieper form for use near the heavy guns.

Cables.—The leads used were of 20 different sizes; 17 of these contained 49, 19 and 7 conductors. Two contained single wires, and one was a twin cable of seven wires in each conductor. The insulation on all of these except the last was as follows:—(*a*) Cotton wound on spirally and treated with a damp-proof insulating varnish; (*b*) another layer of cotton wound spirally, or, for the larger cables, tape instead of thread; (*c*) pure india-rubber; (*d*) vulcanised rubber; (*e*) pure rubber; (*f*) tape.

The whole was vulcanised and varnished, and was either covered with a lead sheath or not, according to the locality in which it was to be placed.

The small twin cable had a special covering consisting of cotton thread and pure rubber, and was finally wound with silk. This was intended for use in the cabins only.

Casing.—The casings are of varnished teak, the covers being secured by screws, and were made in eight different sizes. The distance between the two channels varied in the different sizes from 15 down to six millimetres.

Safety Apparatus.—For the wires of the fuses placed in the leads an alloy of lead and tin was used, which, it was found by experiment, fused at the following values for the various thicknesses.

MM. diameter.	At amperes.
1·8	15
2·0	17
2·2	20
2·5	30
2·9	40
3·3	50
3·7	60
4·2	70
4·6	80
5·0	90
5·3	100

The lengths of the fuse wires were 50mm. for those on the larger cables, and 20mm. for the smaller ones. Every fuse was marked with a characteristic numeral, corresponding to that by which it was distinguished on the plan of the leads supplied.

The automatic cut-outs for the dynamos were operated by means of an electro-magnet and spring, so that when the current going through the machine exceeded a certain value the shunt magnet winding was disconnected, and the dynamo became demagnetised.

Lanterns.—These were separated into five distinct classes. These were:—(*a*) Lanterns for covered bridges, batteries, gangways, turrets, &c.; (*b*) for machine rooms and open bridges; (*c*) for ammunition rooms, &c.; (*d*) for store rooms; (*e*) for the better cabins.

Digitized by Google

The type (*a*) is made either rectangular or round, the framework being of bronze, and a reflector, corrugated in the round form and concave in the rectangular one, being placed behind the lamp.

The type (*b*) is also made in two forms, either portable or fixed; it consists of a cylindrical glass shade, with hemispherical end, on a wooden base if fixed, and with gun metal guard if portable.

The (*c*) lantern was adapted either to be placed in recesses in bulkheads when it had a flat glass face to come flush with the wall, or else it was provided with a hemispheric glass and meant to be fitted to the underside of the deck.

For store rooms the lamps were either made rectangular with double glass face or were placed under pear-shaped globes and mounted on arms.

The (*e*) types were supported by silvered pedestals, or arms, and furnished with frosted glass shades.

Switches and Sockets.—Four types of switches are in use. (*a*) with a removable handle for a large number of lamps on one circuit; (*b*) with fixed handle for 1 to 10 lamps; (*c*) similar to the last, but with movable handle, and (*d*) a pear-shaped switch in wood, for use with flexibles in the cabins. The working parts of all these switches were calculated for a current density of half an ampere per square millimetre. Classified with these were a short circuiting key for ammeters and a two-way switch mounted on porcelain like the rest.

The sockets used are of three types adapted for portable lamps on covered bridges, for auxiliary projectors and for portable lamps in the open and engine rooms respectively.

Ammeters and Voltmeters.—These at present are of the Deprez-Carpentier make, but this selection is only to be considered as provisional. The ammeters register to 100, 150, 200 and 300 amperes, and the voltmeters to 100 volts.

Distributing Board.—The distributing board consists of two sets of brass bars. The bars of one set are placed horizontally and connected to the poles of the machine, the leads being taken from the vertical bars. Connection between the two sets is made by means of plugs in the usual manner. The sections are calculated to give current densities not exceeding one ampere per square millimetre. The main fuses are situated not on the distributing board but in close proximity to it, as are also the proof lamps for each circuit. The board is divided into two halves along a vertical line, one part being assigned to the projectors, and the other working the interior lighting and the signalling apparatus. A diagram, showing the system of distribution on every ship, is mounted on a teak board and fixed to a bulkhead close to the distributing board.

Organisation of the Service.—A choice of the plant to be used in the Royal Italian navy having been arrived at, regulations were drawn up with regard to running the plant and conducting the service with the objects of eliminating any differences between the various ships, and of rendering the whole arrangements easy of control by the authorities. The management of the electric lighting service was put into the hands of the General Direction of Artillery of the Ministry of Marine, and under them of the Local Direction of Artillery and Torpedo Service. The head electro-technical offices were associated with the direction of the artillery and torpedo services of the 1st Department, and had to undertake experiments and tests on plant, the preparation of plans for the whole navy, and the management of repairs for all the ships. Under this head office others were organised to work in conjunction with other departments of the direction of the artillery and torpedo services. A specially qualified staff was selected from the various departmental branches, and workmen in sufficient numbers were allotted for the work in hand. On board the vessels the electrical service was entrusted, under the commander, to the electrical torpedo staff, and the subsidiary boilers to the ship's engineers.

The papers drawn up to serve as a guide in the administration of the service, and to secure uniformity, &c., consisted of the following:—(1) Regulations regarding electrical plant in the Royal Navy; (2) A schedule containing the data of every machine; (3) A journal showing the work of every machine; (4) A detailed account giving full particulars as to the work of every machine, the number of lights running, &c.; (5) A full list of all leads, lamps, and subsidiary apparatus on board; (6) Instructions as to the maintenance of the plant in proper working order.

Electrical Staff.—As soon as the applications of electricity to naval warfare began to make such rapid progress it was considered desirable that every officer in the torpedo service should possess a knowledge of electro-technology. As individuals with these qualifications were not forthcoming in sufficient numbers, a course of study in this branch was included in the curriculum of the Final Naval School at San Bartolomeo, Spezzia. As has been already mentioned, a laboratory in connection with the First Department of the Direction of the Artillery and Torpedo Service was also instituted. Part of the building at San Bartolomeo was set aside for this purpose, and was equipped with all necessary machines and apparatus.

LEEDS ELECTRIC TRAMWAY.

Yesterday afternoon the first overhead-wire tramway in England—or, as it is called in America, trolley line—was inaugurated. The line runs from Burmantofts to Roundhay Park, Leeds. Several trials have been made during the last few days preparatory to opening the line for public traffic early next week. The system adopted is based on the Van Depoele and Thomson-Houston patents, and includes all the latest improvements in details suggested by the experience of the Company in their extensive electric tramway operations in America.

The generating station and car shed is situated about the middle of the line, which is over three miles in length. At present the generating plant consists of a Babcock and Willcox 190 H.P. boiler fitted with mechanical stoker, and a single cylinder 18in. by 18½in. high-pressure engine by McIntosh and Seymour, of Albany, U.S.A., which indicates 200 H.P. at 100lb. steam pressure, and which drives by belts two Thomson-Houston compound-wound dynamos, having each an output of 62,000 watts at 900 revolutions per minute. The current from the dynamos is taken to a special switchboard, designed by Mr. Winslow, of the Thomson-Houston Company, fitted with rheostat regulators and measuring instruments for each dynamo, and an automatic circuit-breaker to prevent overload. This circuit-breaker is an electro-magnetic cut-out arrangement, the circuit being broken when the current in the main reaches a certain strength, and the arc formed on breaking circuit is blown out by Prof. Thomson's well-known device.

The conductor by which the current is conveyed to the car motors is of hard-drawn copper of No. 0 B.W.G. (·34in.), and is suspended about 20ft. above the track level by insulators from galvanised steel suspension wires (No. 5 B.W.G.), which cross the track at right angles, and are fixed to mild steel poles 21ft. 6in. high at either side of the roadway. These are made up of three lengths, 6in. diameter at the bottom and tapering to 4in. at the top. They are set in concrete to a depth of 6ft. The method of fixing the conductor to the suspension wires is rather ingenious. The suspension wires from the poles are fixed to the two ends of a ram's-horn shaped casting, through the conical hole, in the centre of which is passed a bolt having a hard rubber head. A hard rubber conical washer, screwed up tight into the conical hole, fixes the bolt firmly to the suspension. On the end of the bolt is screwed the cap of a copper ear, with a groove underneath, along which the conductor is soldered. The suspension wires, as an extra precaution, are insulated from the poles in the ordinary way. Two feeders of insulated single wire (No. 0000 A.W.G. = ·46in. diameter) carry the current from the generating station to Roundhay-road, and from there one feeder of No. 00 A.W.G. (·365in.) runs along the track. The rails are connected together electrically by the simple device used by Mr. Holroyd Smith at Blackpool. A hole is made at the end of each rail, a piece of No. 7 B.W.G. wire is passed through, connecting two rails together, and the joint is completed by driving in a taper steel pin. The volts at the dynamo terminals are 300, and the maximum working

Digitized by Google

volts of motors about 270, 10 per cent. being allowed for fall on the feeders. The current is carried from the conductor to the motors by an under-running trolley wheel of gun metal, 4½in. diameter, fixed on the end of a long lever, which is hinged at the middle of the car roof. A set of six spiral springs, in extension, pulling on the other end of the lever, maintains contact between the trolley and conductor. There are a number of sidings along the single track, and consequently at these places it is necessary that the current-carrying conductor should branch in order to supply current to motors on the two lines. At each branching the conductor is attached to a right or left hand frog, as the case may be, which guides the trolley to one side or the other, according to the side taken by the car.

Each car is fitted with two single-reduction motors of 15 H.P. each. The makers' designation of the motors is S R.G. 30, type B. They are designed for use with 30in. wheels. The weight of each motor without gear or gear cover is nearly 18½cwt. The armature with pinion weighs 4cwt. 36lb; each field coil, 1cwt. 16lb.; each pole, 2cwt. 46lb.; the casting connecting the armature bearings with the axle, 6cwt. 21lb. The weight of the axle gear is 1cwt. 3qr. 19lb. The motors, which are series-wound machines and are coupled in parallel with each other, are suspended directly on the axle, and geared with cut steel gearing. The reduction ratio is about 4⅔ to 1, the number of teeth in the pinion on the motor shaft being 14, and the number of teeth in wheel on car axle being 67. The gear runs in oil. A flexible suspension, consisting of coach springs and rubber washers in compression under the field magnets of the motor, prevents jarring of the motor on starting. The regulation is effected by means of a rheostat under the control of the driver. The cars, of which there are at present six, were made in New York, and weigh six tons each when unloaded. They are necessarily of the single-deck type, and are constructed to carry 22 passengers. Each car is lighted by five incandescent lamps in series. The fittings and finish of the cars are very handsome. At the terminus there are four tracks, for the accommodation of 12 cars. A pit at one end, 30ft. by 40ft., enables four cars at a time to be examined.

The track on which these cars will run extends over three and a-quarter miles, starting from a thickly populated part of the town, and passing through a suburban district to Roundhay Park, the property of the Corporation. Of this length two miles of the track is double line, and the remaining one and a-quarter miles is single. The double line has been in use for some time, a service of steam tramways having been temporarily placed on it. The single track line is new, and is constructed of 98lb. girder rail laid in concrete. The heaviest gradients are two of 1 in 20, each about 1,000 feet long, and there is another of 1 in 33, about 2,000 feet in length. There seems to be a promise of good traffic, as there is no great competition in the neighbourhood, and there is every reason to suppose that the line will be a mechanical and electrical success. Every care seems to have been taken, in the construction of the line, cars, motors, and generating plant, that the workmanship should be unexceptionable.

THE CHICAGO EXHIBITION.

The following prospectus has been sent us for publication :—

Under date of the 27th August, 1891, Her Majesty was pleased to issue a Commission to the Council of the Society of Arts, authorising them to act as Commissioners for the Universal Exhibition, which, pursuant to an Act of Congress, and in accordance with a proclamation made by the President of the United States of America, will be held at Chicago, from May 1 to October 30, 1893. The Royal Commission are now prepared to receive applications from artists, manufacturers, and others desirous of taking part in the Exhibition, to afford them the necessary information, and to offer them all available facilities which they may desire for this purpose. Such applications must be made upon forms to be obtained from the Secretary of the Commission, at their Offices, Society of Arts, John street, Adelphi, London, W.C. They must be sent in properly filled up, not later than February 29, 1892, and addressed to the Secretary as above.

As the funds granted by H.M. Government will not suffice to defray all the expenses of the Section, it is necessary that they should be supplemented by payments from the exhibitors. A charge will therefore be made to each exhibitor, based on the amount of space occupied, and calculated on the following scale :—

						s.	d.	
For spaces not exceeding 100 sq. ft.						5	0	per sq. ft.
For spaces exceeding 100 sq. ft. and not exceeding 200 sq. ft.						4	6	„
„	„	200	„	„	300 „	4	0	„
„	„	300	„	„	500 „	3	6	„
„	„	500	„	„	750 „	3	0	„
„	„	750	„	and upwards		2	6	„

The minimum charge will be £5.

It is not expected that the total receipts from all sources will more than suffice to defray the cost of an adequate representation of British industry; but should there be a sufficient surplus after the payment of all the costs of the Section, the Royal Commission will refund the balance *pro ratâ* with the amounts contributed by the several exhibitors. The amount produced by the payments of exhibitors will, therefore, be treated as a guarantee fund, to be expended if necessary, but if not to be refunded to the contributors.

The Exhibition is situated in Jackson Park, within the southern limits of the city of Chicago. The principal buildings are devoted to the following main divisions :—(1) Fine Arts; (2) Manufactures and Liberal Arts; (3) Agriculture; (4) Machinery; (5) Electricity; (6) Mines; (7) Transportation; (8) Horticulture. In all these space has been allotted to Great Britain, though it is expected that the principal British Court will be that in the building of Manufactures and Liberal Arts, since the privilege has been conceded to this country of massing all, or most, of its exhibits together, should such a course prove desirable.

Exhibitors' goods will be transmitted direct in bond to Chicago, where the usual Customs examination will be made. Goods for exhibition only will not be liable to duty, but on goods sold the usual rates will have to be paid. Goods can be sold in bond, at prices independent of the tariff, the duties being payable by the purchaser.

The American Railroad Companies propose to carry goods back from the Exhibition free, charging the usual rates for the outgoing journey. These rates, it may be noted, are low in comparison with those usual in European countries. It is hoped that special terms for Exhibition goods traffic may be obtained from the Atlantic Steamship Companies. Full information as to routes, traffic rates, &c., will be provided in due course.

A general Official Catalogue will be published in English, French, German, and Spanish. A special catalogue will also be published for the British section. Exhibitions of live stock will be held, and prizes will be offered in connection with them. A special circular has been issued, giving information about these.

A limited quantity of steam and water power will be supplied gratuitously. Further supplies will be provided at a fixed rate. Countershafts, pulleys, belts, &c., must be provided by the exhibitor. Application for motive power must be made on special forms, which will be supplied on demand.

The general reception of articles at the Exhibition buildings will commence on November 1, 1892, and no articles will be admitted after April 10, 1893. Foundations for heavy machinery may be put in, and special constructive work commenced, as soon as the state of the ground and the buildings permits.

Special regulations will be hereafter issued for the organisation of the international juries.

The Royal Commission are informed that the contract labour laws of the United States will not prevent exhibitors from importing foreign labour, or from entering into binding contracts with their *employés*. Further information on this head will be supplied on application.

Every person who becomes an exhibitor in the British section thereby agrees to be governed by the rules and regulations laid down by the Exhibition Executive, or by the Royal Commission through its executive officer.

The following classification has been adopted :—

Department A.—*Agriculture, Forest Products, and Forestry—Machinery and Appliances.*

Department B.—*Viticulture, Horticulture, Floriculture.*

Department C.—*Live Stock—Domestic and Wild Animals.*

Department D.—*Fish, Fisheries, Fish Products, and Apparatus of Fishing.*

Department E.—*Mines, Mining, and Metallurgy.*—Group 55: Boring and drilling tools and machinery, and apparatus for breaking out ore and coal. Group 56: Pumps, engines, and apparatus used in mining for pumping, draining, and hoisting.

Department F.—*Machinery.*—Group 78: Electric welding, forging, riveting, shaping, tempering, and brazing metals. (See also Department J.)

Department G.—*Transportation—Railways, Vessels, Vehicles.* Group 31: Electric Railways.

Department H.—*Manufactures*—Group 108: Rubber goods, caoutchouc, gutta-percha, celluloid, and zylonite.

Department J.—*Electricity.*—Group 119: Apparatus to illustrate the phenomena and laws of electricity and magnetism. Group 120: Thermo-electric batteries. Group 121: Electrical batteries, secondary or "storage" batteries. Group 122: Machines and appliances for producing electrical currents by mechanical power—dynamos. Group 123: Transmission and regulation of the electrical current. Group 124: Electric motors and their applications. Group 125: Lighting by electricity. Group 126: Heating by electricity. Group 127: Electro-metallurgy and electro-chemistry. Group 128: Electric forging, welding, shaping, tempering,

Digitized by Google

brazing, &c. Group 129: Electric telegraph and electric signals. Group 130: The telephone and its appliances. Group 131: The phonograph. Group 132: Electricity in surgery and therapeutics. Group 133: Applications of electricity in various ways not before specified. Group 134: History and statistics of electrical invention.

DEPARTMENT K.—*Fine Arts—Pictorial, Plastic, and Decorative.*

DEPARTMENT L.—*Liberal Arts — Education, Literature, Engineering, Public Works, Music, and the Drama.*

DEPARTMENT M.—*Ethnology, Archæology, Progress of Labour and Invention.*

The Royal Commission is composed as follows:—The Prince of Wales (President of the Society of Arts); the Attorney-General (Vice-President and Chairman of the Council of the Society); Sir Frederick Bramwell (Vice-President and Deputy-Chairman of the Society); the Duke of Edinburgh, the Duke of Clarence and Avondale, Sir Frederick Abel, the Duke of Abercorn, Mr. William Anderson, Sir Francis Dillon Bell, Sir George Birdwood, Sir Edward, Birkbeck, Major-Gen. Sir Owen Tudor Burne (Vice-Presidents); Mr. Michael Carteighe; Dr. R. Brudenell Carter, Lord Alfred S. Churchill (Vice-Presidents); Mr. B. Francis Cobb (Treasurer); Sir Philip Cunliffe-Owen, Prof. James Dewar, Major-Gen. J. F. D. Donnelly (Vice-Presidents); Sir James N. Douglass; Sir Henry Doulton (Vice-President); Mr. James Dredge, Mr. Francis Elgar; Mr. James Staats Forbes, Sir Douglas Galton, Mr. Thomas Hawksley (Vice-Presidents); Mr. Alexander B. W. Kennedy, Mr. Charles Malcolm Kennedy, Mr. John Biddulph Martin, Mr. George Matthey, Mr. John Fletcher Moulton; Sir Henry F. Ponsonby, Mr. Wyndham S. Portal (Vice-Presidents); Mr. William Henry Preece; Sir Robert Rawlinson (Vice-President); Prof. William Chandler Roberts-Austen; Sir Owen Roberts (Treasurer); Sir Saul Samuel; Sir Henry Trueman Wood (Secretary); Messrs. Henry B. Wheatley and E. H. Lloyd (Assistant Secretaries).

THE LINK SWITCH.

The necessity for a really reliable electric light switch has been fully recognised by electrical engineers and by that section of the public which is keenly interested in trustworthy appliances that never get out of order. Notwithstanding the constant demand for such a perfect switch, and despite the fact that patents and specialities are numberless, improvements are continually being introduced. One of the best examples, and one which has deservedly met with the approval of the users, is generally known as the "tumbler switch," and is actuated by a rocking lever which depresses an insulated contact bar, pivoted at one end, against the force of a spring. The contact pieces, or brushes, are electrically connected by the metallic end of the contact bar when it is depressed. When the rocking lever is turned in the opposite direction the elasticity of the spring raises the contact bar and breaks the circuit. It is obvious that if the spring becomes weakened or the contact bar should stick, the circuit cannot be broken by any movement of the rocking lever. This is a serious disadvantage, and attempts are sometimes made to avoid it, by the use of light spring contacts. A new switch of this particular type, but constituting a distinct improvement upon the "tumbler switch," has been brought out recently by "The General Electric Company (Limited)," and patented by Mr. G. Binswanger, and which we will briefly describe.

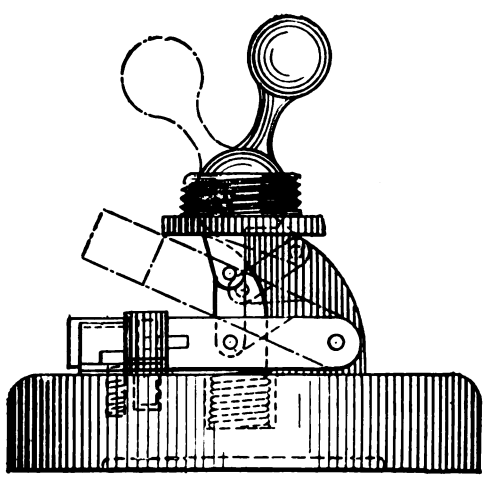

FIG. 1.

Fig. 1 is an elevation of a small "link switch," with the protecting cover removed. The handle is pivoted to a bracket attached to the base, and the contact bar pivoted at one end engages with stout contact pieces when the switch is in the "on" position. The handle is connected to the contact-bar by a toggle joint, consisting of a link jointed to both. The spiral spring is placed under the contact-bar, so that when this is depressed it is locked, owing to the joints of the toggle being in line. The dotted outline shows the "off" position, and it is obvious that the connection of the contact-bar with the rocking lever by means of the link enables the movement of the rocking lever to mechanically pull the contact bar out of contact, *independently* of the action of the spring and *in spite of* any sticking of the contacts. Fig. 2 is an elevation of a double pole, or multiple contact "link switch," in which the contact-bars are connected to the link by a transverse bar rigidly attached to all the bars. A modification is shown by the sectional elevation (Fig. 3), in which the cam or handle presses down the contact bar, and the link is *not* jointed to it, but is jointed to the contact-bar, and works freely within a slot in the lever-handle, a stop preventing it from becoming disengaged. Ordinarily this link is inoperative, since the spring alone raises the contact-bar when the rocking lever is thrown over. Should the spring fail to act properly, or the contacts adhere beyond its lifting power, the stop engages with the edges of the slot in the lever-handle, and the contact-bar is raised mechanically, as in the instances already cited. This pattern of switch will therefore snap off, and prevent any attempt to turn the lamp half down, a common cause of damage to switches.

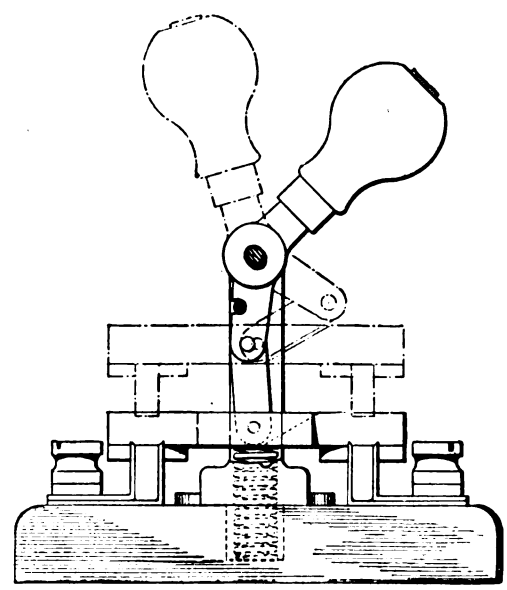

FIG. 2.

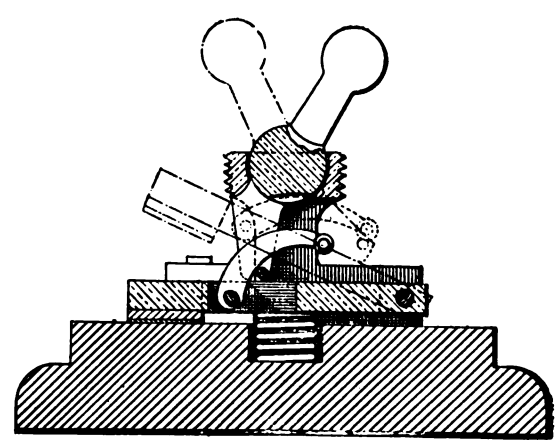

FIG. 3.

It will be seen that the mechanism is extremely simple, and not liable to derangement, while the mechanical action ensures the proper and effective working of the switch. The end of the contact bar is made of solid brass, and wedged in firmly between the two contact brushes, thus ensuring a much better contact than in those switches which rely on the action of a spring to open the circuit.

THE GOVERNMENT AND THE TELEPHONES.

The following letter, which appeared in *The Times* of Monday, will be of interest. We are glad to see that the writer is emphatically of opinion that the matter is too important a one to be left to drift:—

TO THE EDITOR OF THE TIMES.

SIR: Since my return to London I have read the correspondence that took place a few weeks ago in *The Times*, and the comments of the electrical journals on the proposed new departure as to telephones.

I am not a shareholder in, and have no direct or indirect financial interest in, any telephone company; but I have used the telephone for several years, and, in common with all who use it, I am interested in the discussion which took place in your columns during the vacation. The service in London is not perfect, yet it is most useful, and has been much improved since the amalgamation of the Companies, and doubtless every improvement that can be made, under existing conditions, will be effected by the able men who direct the National Telephone Company.

Mr. Bennett's wish is to establish an ideal telephone service at very low rates of subscription, and naturally we all wish to have such a service. Many practical men say, and the electrical papers seem to agree, that Mr. Bennett's plan, so far as he has made it known, cannot be made commercially successful. It is certainly strange that the National Telephone Company should have allowed Mr. Bennett to leave their employment, if they believed he could render their service many times more efficient than it now is, while reducing the cost to subscribers, and at the same time enabling the Company to earn larger dividends than they are now doing.

I have no wish to enter into the merits of the existing system as compared with that suggested by Mr. Bennett and others; for it seems to me that a very important public question is involved in this matter of telephones—one which concerns the good faith of the Government.

Shortly after the Telephone Company started, the Post Office brought an action against that company, claiming a monopoly of telephonic, as well as of telegraphic, communication. It is well known that the decision of the Court of first instance was in favour of the Government; but it was felt at the time, and is felt by lawyers and others still, that if the Company had appealed the decision of the Court of first instance would almost certainly have been upset. The Post Office, however, offered the Telephone Company a licence for 30 years, on their paying a royalty of 10 per cent.; the company not having much money, and shrinking from a costly legal fight against the Government, accepted those terms; and on the strength of this long licence, far more than on their patents, a capital of more than two and a-half millions of pounds has actually been paid by the shareholders and expended in the development of the system from the crude state in which it was when they commenced business.

It seems now that the National Telephone Company is threatened with the active opposition of other companies licensed by the Post Office, and even by the Post Office itself. There is to be free trade in telephones in England, in face of the partnership in profits which exists between the Post Office and the National Telephone Company.

As the Telephone Company has not taken any part in the correspondence in *The Times*, I presume we are right in thinking that they are not seriously afraid of this competition. Perhaps they are right, inasmuch as at enormous expense they have got trunk lines all over England and Scotland, and it does not seem probable that any other company will be able to get trunk lines throughout the kingdom at much less cost than has already been paid by the National Telephone Company, and that therefore it is hardly probable that there will be any second trunk line through the kingdom. If the Government establish or favour another trunk system it can hardly be expected to pay.

But, Sir, cannot we take, and ought we not to take, this discussion as to the future of the telephone in England out of the domain of rival companies, and ought we not to look fairly in the face the question of the Government buying up the existing telephone companies, or, if they refuse to buy, then standing aside and allowing their responsible licensee to carry out the business for which they are licensed by the company, on the good faith of which compromise the very large capital has been raised and spent?

Mr. Preece, the Post Office adviser in such matters, said in his address before the International Electrical Congress at Frankfort in September last, "In a commercial country like England an invention to attract attention and to prosper must be patented. It must have the prospect of great gains to attract capital. It must, therefore, be developed by private enterprise. When a new industry has thus been developed, and when it affects the public weal, Government is forced to step in and take the control of it." I have never seen the licence which the Government granted; it is, however, common knowledge that the Government reserved to itself the right to purchase the telephone companies at certain periods, one of which expired on June 30th last. Ought not the Government to have exercised this right in June last? I judge from what Mr. Preece said at Frankfort that the Post Office, wisely realising the importance of acquiring the telephones, and knowing they would never again buy them up so cheaply, were in favour of exercising their right of purchasing on June 30th last; but, as the purchase was not made, I suppose this wise policy was overruled by the Treasury. I presume that, the period having elapsed, the Government have lost their absolute right to purchase the telephones in the present year. Surely, however, it will be better that they should approach the Telephone Company, and arrange to purchase all their interests under the conditions of the licence, rather than that we should have an unseemly quarrel, and a number of rival companies starting, very few, if any of them, ever paying a dividend. Moreover, is it right that a Government department, having granted a licence, under which they benefit largely, and in consequence of which two and a-half million sovereigns have been raised, should throw obstacles in the way of or even trade against their licensees?

We all want a perfect telephonic system. The Government could establish such a system better than any one else; and, best of all, the telephone department of the Post Office would pay well, for the National Telephone Company is paying well. The rental for the year ending April 30, 1890, was given in *The Electrician* as £364,704. 17s. 5d., and for the year ending April 30, 1891, at £422,378. 6s. 2d.; the balance to the credit of net revenue this year is given as £194,821. 8s. 1d.

The Government could do, at any rate, as well, perhaps better, as they can raise the necessary stock at a cheaper rate than any company. If the Government do not buy now, it will cost them very much more to acquire all the telephone companies at some future date, and this will be a great mistake. I do not know whether the Telephone Company wishes to sell; I feel sure that it will be for the public advantage that the Government should purchase.—I remain your obedient servant, S.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *October* 16, 1891.

The Street Railway Convention at Pittsburgh.—Everything indicates that the Street Railway Convention, to be held in Pittsburgh next week, will be a thorough success. The exhibits at the last Convention in Buffalo were remarkably fine, and even more is promised for the present Convention. Not only the great electrical companies, but the electric supply dealers and the manufacturers of trucks and other general street-car machinery, will be out in full force with exhibits. One of the interesting things promised is the new Thomson-Houston iron-clad single-reduction gear motor, of which I wrote you several weeks ago. It is known to the trade as the "W.P." (water-proof), from the remarkably complete manner in which it is cased in by its own magnetic circuit. Originally designed for a narrow-gauge machine, it has now taken its place as one of the standard motors, and is likely in a considerable measure to take the place of the Thomson-Houston regular "S.R.G." machine. The armature, a powerful toothed ring, gives plenty of torque, and is very efficient, even at its low rotative speed; and the only objectionable feature of the machine is the one-sidedness of the magnetic circuit, which, however, appears to produce no serious results, and has one advantage, that is a tendency to lessen wear on the bearings by the magnetic pull relieving part of the weight of the armature.

The New Edison System of Electric Traction.—Meanwhile the papers have been full of vague talk concerning the marvellous new system of electric traction about to be devised by the "Wizard of Menlo Park," who, by the way, has not lived there for some years. Simmered down, this marvellous invention appears to be, as I hinted in my last letter, a modification of Edison's old scheme of supplying the current from the rails at a very low pressure, feeding sections of rail by continuous-current transformers. Several years ago when he was working along the same line the inventor stated that by the use of a very low voltage he had been able to reduce the leakage current to 5 H.P. per mile of track, even in bad weather. Altogether it appears to be a case of "much cry and little wool" up to date, although it has undoubtedly caused some street railway men to hesitate about taking up any of the present systems.

The Stanley Alternating Motor.—It is reported that the next 30 days will see the Stanley alternating-current motor, of which I wrote you some months ago, on the market in working form and in sizes as high, perhaps, as 5 H.P. You will remember that this machine does not differ from the ordinary direct-current motor with the laminated field, except that a condenser in the field circuit annuls the self-induction and allows the magnetism to be properly developed. The machines run well, and start apparently as freely as their direct-current counterparts, but their efficiency must necessarily be somewhat lower. In a 1 H.P. motor, for example, running with currents at the frequencies generally employed, it would be a difficult matter to bring the hysteresis much, if anything, below 100 watts, particularly as the property of constant self-induction required for the proper action

Digitized by Google

of the condenser compels the use of a powerful field magnet. He employs a motor and dynamo directly and intimately connected, both machines are shunt wound, the fields are in series with each other, so that the strength of the two fields varies together, while the armature circuits which are independent of the fields are also in series with each other. A rheostat placed in the joint field circuit controls the current passing through it. As a result, the speed of the motor armature can be very nicely regulated and will remain constant at any given speed under varying load. Dropping off the electromotive force of supply enables the motor to work with a fair efficiency, even at low speed, while the current through the armatures necessarily varies according to the load. The fundamental idea is by changing the electromotive force of supply to vary the current in proportion to the work.

PARIS NOTES.

(FROM OUR SPECIAL CORRESPONDENT.)

PARIS, *October* 26, 1891.

Accumulator cars will shortly be given a trial on a large scale in Paris. The line chosen for the experiment is one belonging to the Compagnie des Tramways Nord, and running from the Opera House to St. Denis, a distance of about six kilometres. Between the Rue du Faubourg Montmartre and the Rue Rochechouart there is a 5·5 per cent. gradient some 400 metres long. The Compagnie des Tramways are to pay the Société Électrique 16 centimes per car-kilometre (say, 2½d. per car-mile). Laurent-Cély accumulators, made by the Société pour le Travail Électrique des Métaux, will be employed. Accumulator cars are also to be employed by the Lyons Tramway Company. These cars are fitted with 112 Faure-Sellon-Volckmar cells, Gall steel chain gearing and Alioth motors being used.

Messrs. Rothschild have placed the sum of 175,000 francs at the service of MM. Hutin and Leblanc, to enable them to carry out experiments on a commercial scale on their rotating field motor. Let me remind your readers that the Hutin-Leblanc motor has the advantage of only requiring two wires, and that the rotating field is produced by two groups of coils connected in parallel across the alternate-current mains, a condenser being interposed in one of the groups. The revolving armature consists of two inter-crossed polygonal windings, each comprising eight coils. The ends of these windings are connected to three rings, one of which is common to the two circuits. Three brushes bear upon these rings. These brushes are connected to two rheostats, which enable one to switch more or less resistance into either of the armature circuits. On starting, it is advisable to make the resistance very high, in order to increase the torque.

The Boulevard Barbès, in the vicinity of the Gare du Nord, has just been lit up by arc lamps, arranged two in series across a 110-volt circuit. The same style of post as is used on the Boulevard Sébastopol has been adopted. This particular pattern, I may add, is being everywhere substituted for the various experimental types erected in the different sectors.

The accounts of the Compagnie Parisienne de l'Air Comprimé (Système V. Popp) published on the 27th ult., show a deficit of 307,709fr. The Directors explain this state of things by saying that the Company has been obliged to greatly modify its organisation, owing to the failure of various arrangements; and they further state that the plant has fallen into bad repair, owing to the fact that the staff has been entirely occupied in laying mains in the district allotted to the Company within the time allowed by its concession. In some of the Popp Company's stations continuous-current transformers are being installed, and it is intended to run these in parallel with the accumulators.

The system of telephonic messages received a great impetus last month by its extension to the whole of Paris. In August the number of messages telephoned amounted to 5,400, while in September 9,017 were sent. For a sum of 50 centimes one may telephone to the exchange nearest the addressee, where the message is reduced to writing and delivered by a messenger boy.

Interurban telephony continues to grow in favour. The latest additions to our trunk wire system are the lines connecting Bordeaux with Arcachon (60 kilometres), and Vienne with Lyons (30 kilometres). The Toulouse exchange has also come into operation.

Esslingen.—At a meeting on the 13th inst., the municipality of Esslingen granted a concession for the supply of electric light and power in that town for twenty years to the Maschinenfabrik, Esslingen.

CORRESPONDENCE.

MULTIPHASE CURRENTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: If Mr. Kapp expects by his letter of the 17th to draw me into a hostile controversy, he must remember that it takes two to make a quarrel, and I esteem him far too highly to care to be one of the two. Mr. Kapp has, I fear, misread my British Association Paper; he has certainly mistaken the object of that part which referred to the Lauffen experiment, which was in the interests of those pioneers, to preserve their well-wishers from the disappointment prepared by the well-meaning but sensational penny-a-liner.

I was also anxious to support the claims of Tesla secured by his twenty-five American patents on this subject, and the practical results of whose work I have examined and tested in America, though they are little known here. I had a remarkable proof of the necessity in all fairness of doing so, for one of the greatest electrical authorities confessed to me yesterday his ignorance of the fact that the dynamo used with Tesla's motors generated separate currents of distinct phases.

I also desired to make it known that the pioneers at Lauffen did not claim any new invention in the plan of using a rotating magnetic field, and that the experiments were chiefly interesting in that they tested the possibility of maintaining high tension over a long distance of bare wire.

The sensational writers had proclaimed that these motors were a great advance in principle on Tesla's, that there was less lag and greater starting torque, and that for transmission of power by alternating currents they offered the only practical solution. This was unfair on the pioneers, who will always be given the highest possible credit for the good work they really have done. They are the Allgemeine Elektricitäts Gesellschaft and their staff, the Oerlikon works, and last but by no means least Mr. C. E. L. Brown, a man whose rare constructive ability is coupled with the utmost fairness to other inventors, and whose letter in your last isssue is like a summary of my British Association remarks.

Neither Brown, Tesla, nor myself are likely to be found among the scoffers; and when Mr. Kapp calmly reviews the situation, I am pretty sure he will find that his sentiments do not differ from those of the rest of us.—I am, &c.,

34, Great George-street, Westminster. GEORGE FORBES.

THE BROWN ROTARY ENGINE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I noticed with much pleasure the critical tone of the article, in your issue of the 9th inst., on the Brown Rotary Engine, which has recently been receiving more attention of a certain kind than its merits deserve. The report upon it by Prof. Jamieson has been well distributed, and doubtless has proved a fairly successful advertisement for the purpose intended; but it is not at all what we ought to expect from its author. At least it does not seem to me that this report, judiciously omitting any critical references to the mechanism, and amplifying and appropriating advantages common to rotary engines in general, although it may be admirable from the one point of view, is conceived in a proper spirit of fairness to the mechanical world which esteems the Professor among its leading lights. Surely he forgot his well-earned repute when giving his unqualified approval—indirectly only be it observed, yet approval practically—to the absurd mechanism of this engine. For in face of the records of past experience in this connection, it were but silly temporising to apply a less vigorous term. By anyone who has devoted any study at all to the science of mechanism the contrivance can only be regarded as another example of misguided ingenuity; and the most lenient criticism that can conscientiously be vouchsafed it is to admit it to be evidently of most careful and excellent workmanship, but of a radically bad design.

However, the very best of modern workshop practice could not effect an actual cure of the manifold hereditary diseases with which the device is afflicted. Based upon a mechanically

Digitized by Google

faulty principle, and of very near resemblance indeed to some of the most primitive of inventions in this line, such an engine may likely enough be machined to a sufficient perfection to show fair results at the commencement of its career; but it is impossible to entertain the least hope of its maintaining this efficiency for any duration of time under the ordinary conditions of use.

It is not necessary here to go fully into the reasons for this adverse opinion, for these become sufficiently apparent on consideration of the design. But in the *English Mechanic* two or three years ago I discussed this subject with more detail, and I then pointed out some very potent reasons for the long unbroken series of failures with rotary engines of this class. I should explain that I adopted a method of classification, not a mathematical classification as Reauleaux's, but one based more on mechanical lines easily recognisable without analytical investigation of the mechanism. On this system I grouped engines of the type in question under what I designated the cam class; and I showed that, although the most honoured of inventions, this class of engine has actually about the least practical utility of any for the purpose of fluid pressure engines, for the obvious reason that a cam surface cannot be effectively packed. The only obstacle offered to leakage consists of a mathematical line of contact between the non-coincident, or, as Reauleaux puts it, higher paired surfaces of the cam and packing. This alone is a fatal condemnation of the class, and the defect is emphasised by wear; whereas coincident or lower paired surfaces, which are the only true packing agents worthy of recognition of the engineer, generally tend to make a more perfect and steamtight contact.

Enough of the mechanical ineptitude of this engine; but let me remark of the figures obtained in the test, that although very fair they are not extraordinary, and are discounted by several considerations besides the important fact that the engine tested was a new one. Thus rotary engines in general have an advantage in efficiency due to higher speeds; and generally the heat, friction, and steam losses may be slightly less on account of their greater compactness or weight efficiency, their lighter mechanism, easier steam distribution, and lesser clearance. Data of other engines indicate this; but these apparent virtues are mostly gained at a heavy expense of durability, which after all is the crucial test that prime movers have to pass. Will their spick and span efficiency endure under the tender care of the ordinary engine driver? Too often in the case of rotary engines the result has answered no; and I doubt greatly that the Brown engine will prove an exception.

I forbear commenting at length upon the irreversability of this engine, or upon the superfluous exhaust valves and the very questionable use of gear wheels and rotary steam valves in a high-speed motor; as these are merely details emphasising the general faultiness of design, what I want particularly to enforce is the absolute impracticability of any pressure engine containing higher paired packing surfaces, showing either a good average efficiency or an average life.

I have argued this matter with emphasis, not in jealousy of the inventor, or antagonism to any of the parties concerned, but because I fear the seeming laudation that has been widely bestowed on this engine may do real harm to the truer interests of mechanical science and progress by encouraging inventors in their too ready notion that any mechanism will suit a purpose, whether of rotary engines or anything else whatever, so long as it is a mechanism. For these there appears to be no *science* of mechanism, no fixed mechanical laws; and their innocent, yet energetic, anarchism is responsible for much confusion of ideas, even upon issues which really are clear as day.—I am, &c., J. Whitcher.

16, Brighton-road, Stoke Newington, N.
October 26th, 1891.

MR. EDISON AND ELECTRIC TRACTION.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I observe that, in a recent issue of the *Standard*, Messrs. Merryweather and Sons, on behalf of Mr. John Gordon, are contesting the originality of Mr. Edison's reported invention of a new method of electric traction, in which the current is conveyed to the motor through an insulated rail, divided into sections, of which only one or two sections are in circuit at a time; the said sections being put in and out of circuit by automatic switches placed at intervals along the line.

In a letter of mine which you kindly inserted in your issue of June 30, 1883—eight years ago—an exactly similar system is described and roughly illustrated. I published the invention in the hope that someone possessing greater facilities for its development might profit by the suggestion, and am glad to learn that Mr. Gordon has put it to a successful test. I trust the results will prove so profitable that he may, without compunction, accord the comparatively barren honour of priority to another British inventor.—I am, &c.,

John Tourtel.

Mansion House-chambers, 11, Queen Victoria-street, E.C.,
October 27, 1891.

[We have taken no notice of Mr. Edison's invention, except by the publication of the brief accounts given in the American Notes of our New York correspondent, because, so far, there does not seem to be anything original in it. Mr. Tourtel suggested the use of sectional conductors in the letter to which he refers; but the patent of Profs. Ayrton and Perry, No. 2,895 of May 11th in the same year, had already covered the ground very fully.—Ed. *E.*]

THE DETERMINATION OF CURRENTS IN ABSOLUTE ELECTRO-MAGNETIC MEASURE.

TO THE EDITOR OF THE ELECTRICIAN.

Sir,—In § 19 of Mr. Searle's interesting Papers on the "Determination of Currents &c.," it is stated that "the strength of a magnetic shell is the magnetic moment of a square cm. of the shell." In common perhaps with others of your readers I shall be thankful to Mr. Searle if he will explain how the magnetic moment of a square cm. is obtained, since in this case the length $2l$ is indefinitely small, and at first sight one cannot see how the reasoning of § 18 applies; in fact, Mr. Searle has apparently omitted a connecting link which is absolutely necessary for the proper understanding of all that has since followed.—I am, &c.,

Oct. 23, 1891. "ia"

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I think that I can meet the difficulty felt by "ia" in the following way:—Consider a "magnetic shell," not indefinitely thin, but 1mm. in thickness. Draw upon its surface a set of lines, dividing it into small squares, each 1/10th mm. on a side. Suppose the "shell" divided into small prisms by planes passing through this network of lines at right angles to the surface. The "shell" will be divided into a large number of small magnets, whose length is 10 times their thickness. Apparently "ia" will find no difficulty in applying the reasoning of § 18 to each of these. Now, each of these small magnets has a definite magnetic moment, and the "magnetic moment of a square cm. of the shell," or its "strength," is 10,000 times the magnetic moment of each small magnet. However thin we suppose the shell to become, we can still suppose it divided into small magnets whose lengths are great compared with their diameters. Of course when the shell is very thin the strength of the poles of the small magnets must be very great, so as to keep the sum of the magnetic moments of all the small magnets, which can be packed together into a square cm. of the shell, a constant quantity i.—I am, &c., G. F. C. Searle.

Cambridge, Oct. 27, 1891.

THE INTERNATIONAL OKONITE COMPANY.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Our attention has been called to your report of the meeting of the International Okonite Company, and to Mr. Shaw's correction of the same. As the statement which appeared in your columns, although subsequently corrected,

Digitized by Google

might convey the impression that there had been a general falling-off in the volume of electrical business during the period under review, it may be of interest for us to state that during this time the business of our electrical department had more than doubled in comparison with the previous twelve months,—an experience which we believe has been shared by many firms engaged in constructing electrical plant.—We are, &c., MATHER AND PLATT.

Salford Iron Works, Manchester,
October 27, 1891.

THE BREWERS' EXHIBITION AT THE AGRICULTURAL HALL.

During this week this Exhibition has been opened, and for the first time for some years we are able to note that a considerable amount of electric lighting is to be seen at quite a number of the exhibits. Further, we are glad to learn that the Directors of the Agricultural Hall Company have under their consideration the question of making a large permanent installation of the electric light for the general lighting of the Hall. Some years ago we believe the Directors accepted an offer from an electric lighting firm (now defunct) to light the hall; but from various causes the installation was a failure, and since then the Agricultural Hall Company have looked with scant favour upon the various proposals made to them for lighting the hall by electricity. Should the Directors decide to instal the electric light the order will amount to some thousands of pounds.

At the Exhibition under review, which will be closed to-morrow (Saturday), Messrs. Easton and Anderson have a large exhibit, showing their "Whitehall" dynamos at work. Amongst the exhibits being driven by this firm's machines are those of the Blackman Ventilating Company, Mr. Robert Boby, and Messrs. Crees and Company.

At the stall of the Trent Gas Engine Company there is on view a complete installation of the electric light, including a Trent gas engine coupled to one of Messrs. Laurence, Scott and Company's small motors, driving 20 16 c.p. lamps, which the Trent Gas Engine Company are guaranteeing do not cost more than 2d. per hour for gas; the installation is a very neat one, and is the only installation shown at a fixed price complete at the Exhibition. The Trent Company also show their patent "Trent" anti-fluctuators for preventing the jumping of the light when the pipes are also supplying a gas engine.

Mr. E. S. Hindley shows a number of his small portable engines; the Blackman Ventilating Company show an "Electric Blackman," being a Blackman fan and electric motor combined, similar to those employed by the committee of the recent Electrical Exhibition at Frankfort. As mentioned above, one of the 36in. Blackman fans is coupled direct to a "Whitehall" motor supplied by Messrs. Easton and Anderson; Messrs. H. Greene and Sons exhibit a number of fittings for the electric light; Mr. J. J. Hicks and Mr. Joseph Long have on view a large number of their well-known scientific instruments; and the Loft's Patent Check Till Company show what they describe as "an auto-telegraphic machine, a new invention of great interest, especially to scientific men."

Altogether, the thirteenth Annual Brewers' Exhibition is a very good show, and the managers (Messrs. Dale and Reynolds) are to be congratulated upon its success.

TRADE NOTES AND NOTICES.

ELECTRIC LIGHTING COMPANY, LIMITED (IN LIQUIDATION).—A meeting of this Company will be held at Mr. R. A. McLean's office, 1, Queen Victoria-street, E.C., on Nov. 26th, at 11, to receive the liquidator's report.

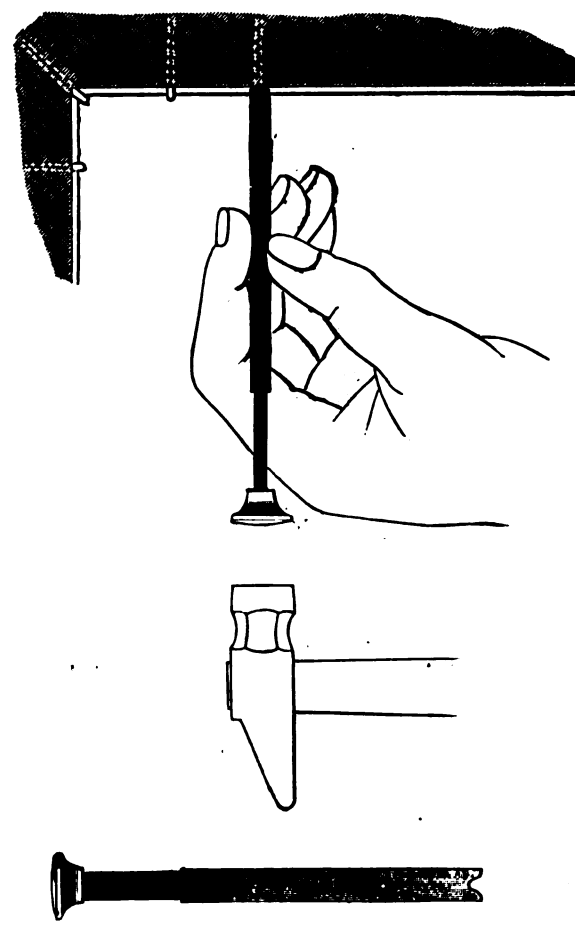
INTERNATIONAL ELECTRIC COMPANY.—We have to acknowledge the receipt of a well-printed and exhaustive catalogue of the above Company, which has just been issued. It is full of illustrations, setting out the various manufactures of the Company, including bells, relays, indicators and indicator movements, pushes, front and side door pulls (many of these are of very artistic design), switches, measuring instruments, portable batteries, insulators, wires and cables, telephones, microphones, and combination micro-telephones, as well as a great variety of other electrical accessories, including electro-medical apparatus. The list is a very complete one; but we would advise that the pink errata sheet, instead of being attached to the end of the book, should be placed in the front.

MESSRS. BENHAM AND FROUD (LIMITED).—This firm report that business is very brisk in their electrical fittings department, and that amongst the numerous orders recently received is one for an extremely recherché suite of ballroom brackets in heavy silver gilt, for one of the Indian princes. The design selected is of the choicest description. They further notify that a considerable trade is now springing up for their wrought-iron work fittings for the electric light.

MESSRS. JULIUS SAX.—This firm have fitted up 4,500 incandescent lamps, 1,500 electric bells, and 4,000 feet of speaking tube at the newly-erected Buckingham Palace-mansions, Buckingham Palace-road, S.W.

BANKRUPT.—Edwin Moorhouse, electrician, of 203, Hyde Park-road, and 40, New Briggate, Leeds, has been adjudicated a bankrupt.

A STAPLE DRIVER.—The well-known driver for paper fasteners has been adapted by Messrs. Woodhouse and Rawson for stapling electric bell and telephone wires. The arrangement should be very useful in running wires overhead and in difficult places. It appears that it is intended only for holding the staple in place until it has been driven far enough to hold, when the tube is removed,



Staple Driver.

and the staple is to be driven home. This is just what should not be done; and all the mischief arises from the use of staples because they are driven against the wire. If the driver were strong enough to take all the blows, and had an efficient stop, the hammer might be freely used, without any need of careful watching to see that the wire was not being cut.

REMOVAL NOTICE.—Mr. Sidney a'Court, A.M.I.C.E., A.M.I.E.E., Consulting Electrical Engineer, has removed from 6, Queen Anne's-gate, to 11, Little Queen-street, Westminster, S.W.

NEW FIRM.—Messrs. D. Young and J. T. Knowles inform us that they have commenced business as Patent Agents, under the style of D. Young and Co., at 11 and 12, Southampton-buildings, Chancery-lane, W.C.

WATERHOUSE ARC LIGHTING SYSTEM.—Messrs. Shippey Bros. notify that considerable improvements have been made in the Waterhouse arc lamp; and that this system, in combination with the Waterhouse dynamos for 3-brush regulation, will shortly be placed upon the European markets.

A PATENT ELECTRIC COMMUNICATOR FOR CARRIAGES, CABS, &c.—Messrs. Julius Sax are making a very useful communicator for vehicles, consisting of an indicator, which is placed on the splash-board in front of the driver, or let inside the roof of a hansom cab, and button-boards, which are fixed inside either cab or carriage for use of the occupant. The apparatus has been devised to enable the occupants of a vehicle to communicate their wishes to the driver. It is claimed that its action is certain and extremely simple. So

Digitized by Google

soon as one of the buttons is touched the signal at once appears before the driver, a small bell ringing at the same time to call his attention. The order or signal remains on the indicator until cancelled by touching the button marked "clear." A bell and a patent dry battery is placed under the driver's seat. The accumulators used last for about 15 hours. Messrs. Julius Sax have already supplied these communicators to a number of well-known persons and firms, including the Prince of Wales, the Duke of Westminster, Messrs. de Rothschild, Col. North, and to the firms of carriage builders, Messrs. Slatter and Sons, Laurie and Marner, Shanks, McNaught and Co., Whitlock, Brainsby and Sons, Morel, and Mühlbacker; and they have also supplied communicators for the

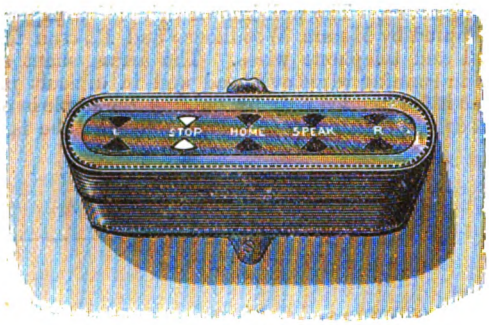


FIG. 1.

FIG. 2

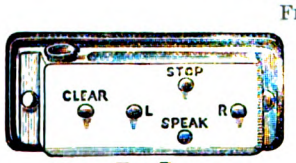

FIG. 3.

FIG. 4.

state coach of the Lord Mayor and Sheriff Harris's processional chariot. The illustrations (Fig. 1, 2, 3 and 4) given herewith are sufficiently explanatory of the apparatus.

COMPANIES' MEETINGS & REPORTS.

The Crompton Electric Supply Company of Australia (Limited).

The second annual ordinary general meeting of the shareholders of this Company was held at the registered offices of the Company, Mansion House-buildings, Queen Victoria-street, E.C., on Tuesday, the 27th inst.; J. F. Albright, Esq., in the chair.

We have been favoured with the following brief summary of the proceedings:—

The SECRETARY (Mr. F. R. Reeves) having read the notice convening the meeting,

The CHAIRMAN congratulated the shareholders upon the improved position of the Company, as shown by the accounts before the meeting, which accounts he regretted, however, the Directors were not able to ask the shareholders to pass as final, because of some small matters of detail required by the London auditors which had not yet been received from Sydney. He (the Chairman) had, however, no doubt as to the accuracy of the accounts, which were signed by the whole of the Sydney Directors, and certified by an independent firm of public accountants in Sydney. Adverting to the promotion by the Company of a Bill in the New South Wales Parliament for powers to supply electricity in the City of Sydney, the Chairman stated that the Bill had already passed the Committee. It was hoped that they would be able to carry the Bill through, as if this were accomplished the financial results to the Australian Company were expected to be very good indeed, to say nothing of the important additional influence which the carrying out of such a scheme would bring to the Company. He concluded by moving that the Directors' report and statement of accounts be received, and that the report of the Directors be adopted.

Mr. T. R. TUFNELL seconded the Chairman's resolution, but spoke at some length expressing his regret at the Sydney Committee not having supplied the whole of the information required by the London Board of Directors.

The resolution was put to the meeting and carried unanimously, as was also a resolution declaring additional dividends of 2 per cent. for 1890, making 8 per cent. in all for that year, and an interim dividend of 7 per cent. for 1891.

The retiring Director, Mr. W. G. Whiffen, was unanimously re-elected; and a resolution, voting 50 guineas per annum each to the Directors for their services, the maximum sum which the Directors would agree to accept, notwithstanding a proposal to vote a larger figure, was also passed.

The auditors, Messrs. Payne and Bankes, were re-elected; and the meeting closed with a vote of thanks to the Chairman and secretary.

The following is the report of the Directors referred to:—

The Directors having now received from Sydney the certified statements of account made up to May 31, 1891, two years from the date of commencement of the Company's business, have pleasure in submitting the same to the shareholders, together with a balance-sheet and profit and loss account, made up to the same date. The Directors, however, regret to state that the auditors report certain items in the Sydney accounts as being insufficiently detailed, and therefore they are unable to ask the shareholders to pass the accounts herewith as final.

Since the last meeting of the shareholders, Mr. J. F. Albright has visited Sydney and other parts of Australia, where he examined thoroughly into the business, and made an exhaustive and satisfactory report thereon, expressing himself hopeful as to future increase.

The Sydney Committee have, with the accounts, sent home a report, which is couched throughout in a sanguine and confident tone as to the position and prospects of the Company. Both of these reports can be seen upon application to the secretary.

A powerful syndicate has been formed in Sydney for the purpose of promoting a Bill in Parliament for the electric lighting of the city of Sydney. This Company hold shares in the syndicate, and by the latest advices there is considerable hope of the Bill being carried. Should the Bill pass this Company will materially benefit, both as engineers and contractors, besides adding greatly to its credit and influence.

Messrs. Crompton and Co. (Limited) have recently granted to this Company, without payment for goodwill, the exclusive right to carry out electric works in New Zealand under their patents. Business has already resulted therefrom, and the prospects of future work are good.

The net profits available for division, according to the accounts, after making full provision for bad and doubtful debts, and deducting the dividend paid in October last year, amount to £1,558. 3s. 6d. The Directors propose to distribute a further dividend of 2 per cent. for the year ending May 31, 1890, making, with the interim dividend already paid, a total of 8 per cent. for that year, and an interim dividend of 7 per cent. per annum for the second year to May 31st last, carrying the balance forward, pending the receipt of the details from Sydney required by the auditors.

In accordance with the Articles of Association, Mr. W. G. Whiffen retires from the Board by rotation, but being eligible, offers himself for re-election. The auditors, Messrs. Payne and Bankes, also offer themselves for re-election.

Messrs. Crompton and Company (Limited).

The following circular has been issued by the Directors of this Company, dated the 26th October inst.:—

"To the Shareholders,—The continued growth of this Company's business has forced upon the Directors the necessity of proposing some method of obtaining additional working capital, and the course which, after careful consideration, commends itself to the Board, is to ask the shareholders for power to increase the number of preference shares by the issue of 10,000 additional shares of £5 each. It is proposed that these shares shall rank in all respects *pari passu* with the existing preference shares, both as to cumulative dividend and distribution of assets, and that 5,000 shares shall be offered first to the present members of the Company at par. With regard to the second 5,000 shares, the Directors have it in contemplation to reserve these for a later issue, at a premium. The Directors request that the form of proxy enclosed with the circular may be signed and returned to the Company as an indication of the approval by the members of the course proposed."

Accompanying this circular is a formal notice of an extraordinary meeting to be held on Tuesday next, the 3rd prox., at the offices, Mansion House-buildings, E.C., at 3 o'clock, for the purpose of considering, and if approved, of passing the following resolution:—

"*That the capital of the Company be increased by the issue of 10,000 additional preference shares of £5 each, such shares to be numbered 20,001 to 30,000, inclusive, and to rank for preference or priority as regards dividends, and in the distribution of assets, and in all respects pari passu with the already existing preference shares of the Company, and the Directors are hereby authorised to issue these new shares at such times and on such terms as they may think fit.*"

Monte Video Telephone Company (Limited).

The following is the report of the Directors, to be presented to the shareholders at the annual general meeting to be held at the offices of the Company, No. 25, Abchurch lane, London, E.C., to-day (Friday), at 2.30 p.m.

Your Directors present herewith the audited statement of accounts for the year ending 31st July last, which, including the balance of £184 1s. 6d. brought forward from last year, shows a profit of £4,970 6s. 11d., after providing for all working expenses in Monte Video and London, and after writing off £114 14s. 8d. for proportion of preliminary expenses, and £20 for depreciation of furniture at head office and in Monte Video.

Digitized by Google

Taking into consideration the present position of business in Monte Video, consequent upon the severe commercial and financial depression that has existed there since July, 1890, and having in view the difficulty of collecting the amounts due by subscribers, and also regarding the amount which has been expended on capital account through the necessity for new lines and connections, your Directors, being influenced by a desire to strengthen the position of the Company, feel that the only course open to them is to recommend that the sum of £4,500, as advised by the auditors, be added to the depreciation fund, and the balance of £470 6s. 11d. be carried forward to next year.

In view of the almost complete collapse of commerce in the River Plate during the year now completed, your Directors feel that there is cause for congratulation in the present position of the Company, the Manager of which has had several difficulties to contend with during the period now referred to. Through the stoppage of the National Bank at Monte Video, at a time when this Company held a large amount of its notes, a considerable loss was entailed. As might be expected, the loss in bad debts through failures consequent upon the position of business generally, has been considerable, and the sum of £1,512 8s. 7d. has been written off to meet this. A further loss was occasioned by the defalcation of one of the Company's collectors. Some unexpected expense has also been incurred by reason of new regulations issued by the Municipality of Monte Video enforcing the removal of supports and posts from the streets.

The number of subscribers has, naturally, fallen off to some extent, but there are still about 1,400 paying subscribers on the list, which is a position the Directors have every confidence in maintaining, and eventually strengthening on any improvement in the general condition of affairs at Monte Video.

Arrangements for the reduction of the expenses, both in Monte Video and in London, have been made.

As provided for by the Articles of Association, Mr. Holland retires from the Board, but, being eligible, offers himself for re-election. The Auditors, Messrs. Gérard van de Linde and Son, also retire, but offer themselves for re-election.

NEW COMPANIES, STATUTORY RETURNS, &c.

ECONOMIC BRICK COMPANY (LIMITED).—This Company was registered on October 20, 1891, with a capital of £20,000, in £1 shares. Among the objects is included that of producing and using electricity, magnetism, or other power.

WILLIAM MELBURN AND SONS (LIMITED).—Registered by Jordan and Sons, 120, Chancery-lane, W.C., with a capital of £20,000, in £5 shares. Objects: To acquire the engineering works known as the Britannia Iron-works, Stalybridge, and generally to carry on business as iron, steel and brass founders and engineers.

WADDINGTON, RATH, AND COMPANY (LIMITED).—This Company was registered on October 20, 1891, with a capital of £25,000, in £5 shares, by Messrs. Rooke and Sons, 45, Lincoln's Inn-fields, W.C. The objects are to acquire, and take over as a going concern, the business of india-rubber manufacturers, waterproof manufacturers, mechanical and electrical engineers, tube makers, &c., carried on by Messrs. H. H. Waddington and A. J. Rath, under the name of "Waddington, Rath, and Co." at Spring Bank Mills, Spring Bank-street, Hyde, Cheshire.

CITY OF LONDON ELECTRIC LIGHTING (PIONEER) COMPANY (LIMITED).—In our last issue we gave particulars of the voluntary winding-up of this Company, and the resolutions passed at the confirmatory meeting have been duly filed. The Company, as our readers are aware, was registered on February 5th last, with a capital of £100,000 in £50 shares, to amalgamate the three contracts of the Brush Electrical Engineering Company, Limited (West and Central), and the Laing, Wharton, and Down Construction Syndicate, Limited (East), preparatory to the formation of the larger company, the City of London Electric Lighting Company (Limited). At the time of the statutory return 1,000 shares had been taken up, and £25 had been called and paid on each of these shares.

ELECTRIC ARMS AND AMMUNITION SYNDICATE (LIMITED).—The annual return of this Company, made up to October 23, 1891, was filed on the following day. The Company was registered on October 9, 1889, with a capital of £40,000 in £100 shares. 290 shares have been taken up, upon 80 of which £70 per share has been called. 210 shares have been considered as fully paid. The calls paid amount to £4,860, leaving £740 unpaid. The principal holders are the American Arms and Ammunition Company, of 42, Broadway, New York (with 160 shares), and George B. Satterlee, of the same address (with 56 shares). Office: 35, Queen Victoria-street, E.C.

ELECTRIC TRACTION COMPANY (LIMITED).—The following was filed on Oct. 24, 1891:—"To the Registrar of Joint Stock Companies. I beg to inform you that a meeting of the above-named Company was duly held on September 30, 1891, for the purpose of having an account laid before them, showing the manner in which the winding-up of the Company had been conducted, and the property of the Company disposed of; and the same was done accordingly. Dated, London, Oct. 24, 1891. Fred. M. H. Jones, liquidator." This Company was registered on February 6, 1888, with a capital of £30,000 in £10 shares. At the time of the last return 1,000 fully paid, and 832 other shares were taken up, the principal holders being Lord Egerton of Tatton, Sir Robert Abercrombie, and F. W. J. Hubel. At a meeting held at New Broad-street House on July 1, 1891, a resolution for the winding up of the Company was passed, and subsequently confirmed; and the liquidator (Mr. G. A. Redford) was authorised to carry out the sale of the Company's property in cash or shares in the General Electric Power and Traction Company (Limited), agreed to by a contract, dated May 23, 1890, and made between this Company of the first part, Moritz Immisch and Co. of the second part, and the General Electric Power and Traction Company (Limited) of the third part. Offices: New Broad-street House, 35, New Broad-street, E.C.

ELECTRIC WELDING COMPANY (LIMITED).—An agreement made October 14, 1891 (and filed on the 21st) between the above Company (called the English Company) of the first part, the City of London Contract Corporation, Limited (called the Contract Corporation), of the second part, and the Thomson European Electric Welding Company, a Corporation established under the laws of the State of Maine in the U.S.A., and located at Portland in the said State (called the Thomson European Company) of the third part, states that whereas by an agreement dated August 20, 1891, between the Contract Corporation of the one part and the English Company of the other part, the Contract Corporation agreed to sell to the English Company, among other things, certain letters patent and patent rights, agreed to purchase by the Contract Corporation from the Thomson European Company in consideration of (among other things) the allotment to the Contract Corporation or their nominees of 8,333 ordinary fully paid £10 shares of the English Company and numbered 1,001 to 9,333 inclusive. The direction of the Contract Corporation nominate the Thomson European Company as the allottees of the said 8,333 fully paid £10 shares, and that as soon as the agreement had been filed with the Registrar of Joint-Stock Companies, the English Company will allot and issue to the Thomson European Company the said shares. Office: 2, Tokenhouse-buildings, E.C.

LAWS' ELECTRICAL APPLIANCES COMPANY (LIMITED).—An agreement made on October 16, 1891 (and filed on the 20th), between Major E. F. Law, of the first part, Messrs. C. T. D. Crews, Sinclair Macleay, J. T. F Otway, W. H. James, and E. F. Law of the second part, and the above-named Company of the third part, states that certain patents, No. 16,485, of 1886, granted to E. F. Law (for "improved means for facilitating the rapid publication of news"); 12,025, of 1887, granted to E. F. Law (for "improvements in apparatus for controlling typewriters, type-setting machines, and the like, by the aid of electricity"); 3,359, of 1888, granted to F. F. Law (for improvements similar to the above); 506, of 1889, granted to H. H. Lake as a communication from E. F. Law (for "improvements in and relating to electrical switches, chiefly designed for use in connection with apparatus for obtaining synchronous movements"; 185,824 (France), granted to E. F. Law; and 8,306, of 1890, granted to H. H. Lake, as a communication from E. F. Law, are to be sold to and purchased by the Company; and in full consideration thereof £3,600, in £5 shares, shall be allotted to Major Law and the parties of the second part. An agreement, dated October 17, 1891 (filed on the 20th), between William Clowes and Sons (Limited) and the above Company states that Messrs. Clowes are to erect a type-setting or composing machine, on which the patents of the Company can be advantageously worked, to allow one of their *employés* to superintend the direction thereof, and to assist in the proposed experiments for one month, to pay £100 to Laws' Company towards the costs of the said experiments, and to pay £25 to Laws' Company towards the preliminary expenses in the registration of the Company, and in full consideration thereof 66 fully-paid shares are to be allotted to William Clowes and Sons (Limited) or their nominees. The machine which is to be erected will remain the property of Messrs. Clowes, and Laws' Company are not authorised to construct machines of the kind of which Messrs. Clowes are the makers, or to allow the apparatus covered by Major Laws' invention to be used in combination with any other machine without the consent of Clowes and Sons. Our readers will doubtless remember that the above Company was registered on September 23, 1891, with a capital of £4,000, in £5 shares.

NORWICH ELECTRICITY COMPANY (LIMITED).—The first annual return of this Company, made up to the 10th October, 1891, was filed on the 22nd following. The Company was registered on the 25th January, 1890, and had a capital of £50,000 in £10 shares, 7 shares are taken up but nothing has been called thereon. The present shareholders are the original subscribers. Office: The Old Bank of England Chambers, Queen-street, Norwich.

CITY NOTES, &c.

BABCOCK AND WILLCOX (LIMITED).—The statutory meeting of the above Company was held on Tuesday, at the Cannon-street Hotel. The Chairman, Mr. Andrew Stewart, said that the allotment of the shares had been of a very satisfactory nature, and he hoped that a quotation of the shares would soon be obtained on the Stock Exchange. What the Directors had seen of the Company's business had exceeded their most sanguine expectations, and they were very full of work.

CITY AND SOUTH LONDON RAILWAY COMPANY.—The traffic receipts of this Company for the week ended October 25th amounted to £756; aggregate receipts for half-year to date, £11,961.

CONSOLIDATED TELEPHONE CONSTRUCTION AND MAINTENANCE COMPANY (LIMITED).—The Directors have declared the usual interim dividends for the half-year of £6 per cent. on the preferred and £5 per cent. on the ordinary shares, both less income-tax, and payable on and after November 16, 1891. The transfer books will be closed from the 23rd to 26th October.

ELECTRIC AND GENERAL INVESTMENT COMPANY (LIMITED).—It will be seen by our advertisement columns that the Directors have declared an interim dividend on the capital paid up on the ordinary shares at the rate of 20 per cent. per annum for the six months ended November 30, 1891, payable on and after that date.

Digitized by Google

INDO-EUROPEAN TELEGRAPH COMPANY (LIMITED).—The Board of Directors of this Company have declared an interim dividend for the half-year ended June 30th last at the rate of 5 per cent. per annum, free of income-tax, payable on and after November 1st next.

JOHANNESBURG GAS COMPANY (LIMITED).—We understand that at the adjourned meeting of this Company, held on Wednesday, the resolutions were carried dissolving the Company and forming a new company under the title of the Johannesburg Lighting Company (see *The Electrician*, July 17th), and that the Transvaal Government has given the Company the monopoly of lighting Johannesburg by electricity or otherwise, giving further time in which to do the work on condition that 15 arc lights are installed immediately.

WEST INDIA AND PANAMA TELEGRAPH COMPANY (LIMITED).—For the half-year ended June 30th last, the Directors propose dividends of 6s. per share each on the first and second preference shares, with a distribution of 1s. per share on the Ordinary shares. The sum of £2,000 is to be placed to reserve, leaving £5,255 to be carried forward.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY (LIMITED).—After placing £25,000 to the reserve fund and £6,233. 10s. to the debenture redemption fund, the Directors recommend a dividend of 6s. per share, free of income-tax, or at the rate of £4 per cent. per annum, for the six months ended June 30th last, being the same as for the corresponding period. The traffic receipts of this Company for the week ended October 23rd, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brasilian Telegraph Company, were £3,708.

WESTMINSTER ELECTRIC SUPPLY CORPORATION (LIMITED).—The Stock Exchange have ordered the 17,047 additional shares (Nos. 42,954 to 60,000) to be quoted in the Official List.
